CONTENTS

PREFACE: A User's Guide to Organic Chemistry:
Structure and Function xxiii

1  STRUCTURE AND BONDING IN ORGANIC MOLECULES  1
  1-1 The Scope of Organic Chemistry: An Overview  2
  Chemical Highlight 1-1 Urea: From Urine to Wöhler’s Synthesis to Industrial Fertilizer  4
  1-2 Coulomb Forces: A Simplified View of Bonding  5
  1-3 Ionic and Covalent Bonds: The Octet Rule  7
  1-4 Electron-Dot Model of Bonding: Lewis Structures  13
  1-5 Resonance Forms  18
  1-6 Atomic Orbitals: A Quantum Mechanical Description of Electrons Around the Nucleus  23
  1-7 Molecular Orbitals and Covalent Bonding  28
  1-8 Hybrid Orbitals: Bonding in Complex Molecules  31
  1-9 Structures and Formulas of Organic Molecules  37

Chapter Integration Problems  40
Important Concepts  43
Problems  44

2  STRUCTURE AND REACTIVITY  49
  2-1 Kinetics and Thermodynamics of Simple Chemical Processes  50
  2-2 Acids and Bases; Electrophiles and Nucleophiles; Using Curved “Electron-Pushing” Arrows  56
  Chemical Highlight 2-1 Stomach Acid and Food Digestion  59
  2-3 Functional Groups: Centers of Reactivity  67
  2-4 Straight-Chain and Branched Alkanes  70
  2-5 Naming the Alkanes  71
  2-6 Structural and Physical Properties of Alkanes  76
  Chemical Highlight 2-2 “Sexual Swindle” by Means of Chemical Mimicry  79
  2-7 Rotation about Single Bonds: Conformations  79
2-8 Rotation in Substituted Ethanes

Chapter Integration Problems

Important Concepts

Problems

3 REACTIONS OF ALKANES

3-1 Strength of Alkane Bonds: Radicals

3-2 Structure of Alkyl Radicals: Hyperconjugation

3-3 Conversion of Petroleum: Pyrolysis

Chemical Highlight 3-1 Sustainability and the Needs of the 21st Century: “Green” Chemistry

3-4 Chlorination of Methane: The Radical Chain Mechanism

3-5 Other Radical Halogenations of Methane

3-6 Chlorination of Higher Alkanes: Relative Reactivity and Selectivity

3-7 Selectivity in Radical Halogenation with Fluorine and Bromine

3-8 Synthetic Radical Halogenation

Chemical Highlight 3-2 Chlorination, Chlormal, and DDT

3-9 Synthetic Chlorine Compounds and the Stratospheric Ozone Layer

3-10 Combustion and the Relative Stabilities of Alkanes

Chapter Integration Problems

Important Concepts

Problems

4 CYCLOALKANES

4-1 Names and Physical Properties of Cycloalkanes

4-2 Ring Strain and the Structure of Cycloalkanes

4-3 Cyclohexane: A Strain-Free Cycloalkane

4-4 Substituted Cyclohexanes

4-5 Larger Cycloalkanes

4-6 Polycyclic Alkanes

Chemical Highlight 4-1 Cyclohexane, Adamantane, and Diamandoids: Diamond “Molecules”

4-7 Carbocyclic Products in Nature

Chemical Highlight 4-2 Cholesterol: How Is It Bad and How Bad Is It?

Chemical Highlight 4-3 Controlling Fertility: From “the Pill” to RU-486

Chapter Integration Problems

Important Concepts

Problems

7 FURTHER REACTIONS OF HALOALKANES
7-1 Solvolysis of Tertiary and Secondary Haloalkanes 251
7-2 Unimolecular Nucleophilic Substitution 252
7-3 Stereochemical Consequences of \( S_N1 \) Reactions 256
7-4 Effects of Solvent, Leaving Group, and Nucleophile on Unimolecular Substitution 258
7-5 Effect of the Alkyl Group on the \( S_N1 \) Reaction: Carbocation Stability 260
Chemical Highlight 7-1 Unusually Stereoselective \( S_N1 \) Displacement in Anticancer Drug Synthesis 263
7-6 Unimolecular Elimination: E1 264
7-7 Bimolecular Elimination: E2 267
7-8 Competition Between Substitution and Elimination: Structure Determines Function 270
7-9 Summary of Reactivity of Haloalkanes 273
Chapter Integration Problems 275
New Reactions 277
Important Concepts 277
Problems 278

8 HYDROXY FUNCTIONAL GROUP: Alcohols
8-1 Naming the Alcohols 288
8-2 Structural and Physical Properties of Alcohols 289
8-3 Alcohols as Acids and Bases 292
8-4 Industrial Sources of Alcohols: Carbon Monoxide and Ethene 295
8-5 Synthesis of Alcohols by Nucleophilic Substitution 295
8-6 Synthesis of Alcohols: Oxidation-Reduction Relation Between Alcohols and Carbonyl Compounds 297
Chemical Highlight 8-1 Biological Oxidation and Reduction 298
Chemical Highlight 8-2 The Breath Analyzer Test 302
8-7 Organometallic Reagents: Sources of Nucleophilic Carbon for Alcohol Synthesis 304
8-8 Organometallic Reagents in the Synthesis of Alcohols 307
8-9 Complex Alcohols: An Introduction to Synthetic Strategy 309
Chemical Highlight 8-3 Transition Metal-Catalyzed Cross-Coupling Reactions 310
Chapter Integration Problems 319
New Reactions 322
Important Concepts 326
Problems 326
# Further Reactions of Alcohols and the Chemistry of Ethers

## 9-1
Reactions of Alcohols with Base: Preparation of Alkoxides 334

## 9-2
Reactions of Alcohols with Strong Acids: Alkyloxonium Ions in Substitution and Elimination Reactions of Alcohols 335

## 9-3
Carbocation Rearrangements 338

## 9-4
Esters from Alcohols and Haloalkane Synthesis 344

## 9-5
Names and Physical Properties of Ethers 347

## 9-6
Williamson Ether Synthesis 350

## Chemical Highlight 9-1
Chemiluminescence of 1,2-Dioxacyclobutanes 351

## 9-7
Synthesis of Ethers: Alcohols and Mineral Acids 355

## 9-8
Reactions of Ethers 357

## Chemical Highlight 9-2
Protecting Groups in Synthesis 359

## 9-9
Reactions of Oxacyclopropanes 360

## Chemical Highlight 9-3
Hydrolytic Kinetic Resolution of Oxacyclopropanes 362

## 9-10
Sulfur Analogs of Alcohols and Ethers 365

## 9-11
Physiological Properties and Uses of Alcohols and Ethers 367

## Chemical Highlight 9-4
Garlic and Sulfur 371

## Chapter Integration Problems

## New Reactions

## Important Concepts

## Problems

# Using Nuclear Magnetic Resonance Spectroscopy to Deduce Structure

## 10-1
Physical and Chemical Tests 388

## 10-2
Defining Spectroscopy 388

## 10-3
Hydrogen Nuclear Magnetic Resonance 390

## Chemical Highlight 10-1
Recording an NMR Spectrum 393

## 10-4
Using NMR Spectra to Analyze Molecular Structure: The Proton Chemical Shift 395

## 10-5
Tests for Chemical Equivalence 400

## Chemical Highlight 10-2
Magnetic Resonance Imaging in Medicine 404

## 10-6
Integration 405

## 10-7
Spin–Spin Splitting: The Effect of Nonequivalent Neighboring Hydrogens 407

## 10-8
Spin–Spin Splitting: Some Complications 414

## Chemical Highlight 10-3
The Nonequivalence of Diastereotropic Hydrogens 418
### 10-9 Carbon-13 Nuclear Magnetic Resonance

**Chemical Highlight 10-4** Correlated NMR Spectra: COSY and HETCOR

**Chemical Highlight 10-5** Structural Characterization of Natural Products: Antioxidants from Grape Seeds

*Chapter Integration Problems*

*Important Concepts*

*Problems*

### 11 ALKENES; INFRARED SPECTROSCOPY AND MASS SPECTROMETRY

**11-1** Naming the Alkenes

**11-2** Structure and Bonding in Ethene: The Pi Bond

**11-3** Physical Properties of Alkenes

**11-4** Nuclear Magnetic Resonance of Alkenes

**Chemical Highlight 11-1** Prostaglandins

**11-5** Catalytic Hydrogenation of Alkenes: Relative Stability of Double Bonds

**11-6** Preparation of Alkenes from Haloalkanes and Alkyl Sulfonates: Bimolecular Elimination Revisited

**11-7** Preparation of Alkenes by Dehydration of Alcohols

**11-8** Infrared Spectroscopy

**11-9** Measuring the Molecular Mass of Organic Compounds: Mass Spectrometry

**Chemical Highlight 11-2** Security in the 21st Century: Applications of IR and MS

**Chemical Highlight 11-3** Detecting Performance-Enhancing Drugs Using Mass Spectrometry

**11-10** Fragmentation Patterns of Organic Molecules

**11-11** Degree of Unsaturation: Another Aid to Identifying Molecular Structure

*Chapter Integration Problems*

*New Reactions*

*Important Concepts*

*Problems*

**INTERLUDE:** Solving Problems in Organic Chemistry

### 12 REACTIONS OF ALKENES

**12-1** Why Addition Reactions Proceed: Thermodynamic Feasibility

**12-2** Catalytic Hydrogenation

**12-3** Nucleophilic Character of the Pi Bond: Electrophilic Addition of Hydrogen Halides

A User's Guide to ORGANIC CHEMISTRY: Structure and Function

In this edition of Organic Chemistry: Structure and Function, we maintain our goal of helping students organize all the information presented in the course and fit it into a logical framework for understanding contemporary organic chemistry. This framework emphasizes that the structure of an organic molecule determines how that molecule functions in a chemical reaction. In the sixth edition, we have strengthened the themes of understanding reactivity, mechanisms, and synthetic analysis to apply chemical concepts to realistic situations. We have incorporated new applications of organic chemistry in the life sciences, industrial practices, green chemistry, and environmental monitoring and clean-up. This edition includes more than 100 new or substantially revised problems, including new problems on synthesis and green chemistry, and new “challenging” problems. Organic Chemistry: Structure and Function is offered in an online version to give students cost-effective access to all content from the text plus all student media resources. For more information, please visit our Web site at http://ebooks.bfwpub.com.

CONNECTING STRUCTURE AND FUNCTION

This textbook emphasizes that the structure of an organic molecule determines how that molecule functions in a chemical reaction. By understanding the connection between structure and function, we can learn to solve practical problems in organic chemistry.

Chapters 1 through 5 lay the foundation for making this connection. In particular, Chapter 1 shows how electronegativity is the basis for polar bond formation, setting the stage for an understanding of polar reactivity. Chapter 2 makes an early connection between acidity and electrophilicity, as well as their respective counterparts, basicity-nucleophilicity. Chapter 3 relates the structure of radicals to their relative stability and reactivity. Chapter 4 illustrates how ring size affects the properties of cyclic systems, and Chapter 5 provides an early introduction to stereochemistry. The structures of haloalkanes and how they determine haloalkane behavior in nucleophilic substitution and elimination reactions are the main topics of Chapters 6 and 7. Subsequent chapters present material on functional-group compounds according to the same scheme introduced for haloalkanes: nomenclature, structure, spectroscopy, preparations, reactions, and biological and other applications. The emphasis on structure and function allows us to discuss the mechanisms of all new important reactions concurrently, rather than scattered throughout the text. We believe this unified presentation of mechanisms benefits students by teaching them how to approach understanding reactions rather than memorizing them.
UNDERSTANDING AND VISUALIZING REACTION MECHANISMS

The emphasis on structure and function in the early chapters primes the students for building a true understanding of reaction mechanisms, encouraging understanding over memorization.

Because visualizing chemical reactivity can be challenging for many students, we use many different visual cues and models to help students visualize reactions and how they proceed mechanistically.

- **NEW.** Improved and expanded coverage of **electron-pushing arrows** in Section 2-2. The use of electron-pushing arrows, introduced in Section 2-2, is reinforced in Section 6-3 and applied extensively in all subsequent chapters.

- **Interlude: A Summary of Organic Reaction Mechanisms,** following Chapter 14, summarizes the relatively few types of reaction mechanisms that drive the majority of organic reactions, thereby encouraging understanding over memorization.

- **Computer-generated ball-and-stick and space-filling models** help students visualize steric factors in many kinds of reactions. Icons in the page margins indicate where model building by students will be especially helpful for visualizing three-dimensional structures and dynamics.

- **Electrostatic potential maps** of many species help students see how electron distributions affect the behavior of species in various interactions.

- **Mechanism icons** in the page margins highlight the locations of important mechanisms.

- **Model-building icons** in the page margins indicate all of the structures that are found on the book’s Web site as 3-D and rotatable structures.

- **Reaction Summary Road Maps,** found at the ends of some chapters, summarize the principal reactions for preparation and applications of each major functional group. The **Preparation maps** indicate the possible origins of a functionality—that is, the precursor functional groups. The **Reaction maps** show what each functional group does. In both maps, reaction arrows are labeled with particular reagents and start from or end at specific reactants or products. The reaction arrows are also labeled with new section numbers indicating where the transformation is discussed in the new edition.

- Approximately **50 animated mechanisms** are offered on the W. H. Freeman Web site. All mechanisms are indicated by Media Link icons in the page margins.
STRONGER PEDAGOGY FOR SOLVING PROBLEMS

Exercise 7-4

Working with the Concepts: Stereochemical Consequences of S\textsubscript{N}1 Displacement

Gentle warming of (2R,4R)-2-ido-4-methylhexane in methanol gives two stereoisomeric methyl ethers. How are they related to each other? Explain mechanistically.

Strategy

The substrate is secondary; therefore, substitution can proceed by either the S\textsubscript{N}1 or the S\textsubscript{N}2 mechanism. Let’s consider the reaction conditions to see which is more likely and what its consequences will be.

Solution

• The reaction takes place in methanol, CH\textsubscript{3}OH, a poor nucleophile (disfavoring S\textsubscript{N}2) but a very polar, protic solvent, well suited for dissociation of secondary and tertiary haloalkanes into ions (favoring S\textsubscript{N}1).

• Dissociation of the excellent leaving group I\textsubscript{2} from C2 gives a trigonal planar carbocation. Methanol may attack from either face (compare mechanism steps 1 and 2 in Section 7-2), giving two stereoisomeric oxonium ions. The positively charged oxygen makes the attached hydrogen very acidic; after proton loss, two stereoisomeric ethers result (mechanism step 3 in Section 7-2; see also Figure 7-3). We have here another example of solvolyis (specifically, methanolation), because the nucleophile is the solvent (methanol).

(Caution! When describing the S\textsubscript{N}1 mechanism, avoid the following two very common errors: (1) Do not dissociate CH\textsubscript{3}OH to give methoxide (CH\textsubscript{3}O\textsuperscript{-}) and a proton before bonding with the cationic carbon. Methanol is a weak acid whose dissociation is thermodynamically not favored. (2) Do not dissociate CH\textsubscript{3}OH to give a methyl cation and hydroxide ion. Although the presence of the OH functional group in alcohols may remind you of the formulas of inorganic hydroxides, alcohols are not sources of hydroxide ion.)

• The two stereoisomeric ether products are diastereomers; 2S,3R and 2R,3R. At the reaction site, C2, both R and S configurations result from the two possible pathways of methanol attack, a and b. At C3 a stereocenter where no reaction occurs, the original R configuration remains unchanged.

Exercise 7-5

Try It Yourself

Hydrolysis of molecule A (shown in the margin) gives two alcohols. Explain.

NEW. Interlude: Solving Problems in Organic Chemistry, following Chapter 11, examines the different types of problems common in organic chemistry and teaches students how to approach and proceed through each type of problem.

Improved Problem-Solving Approaches

• NEW. In this edition we have revised all of the in-chapter exercises, called Working with the Concepts. Each exercise now begins with a Strategy section that emphasizes the reasoning students need to apply in attacking problems. The Solution arranges the steps logically and carefully, modeling good problem-solving skills.

• NEW. Try It Yourself Exercises. Each in-chapter worked exercise is paired with a Try It Yourself problem that follows up on the concept being taught.

• NEW. Caution statements appear in many of the exercises, alerting students to potential pitfalls and how to avoid them. The exercises chosen for solution are typical homework or test questions, enabling students to acquire a feel for solving complex problems, rather than artificially simplified ones. In response to strong positive feedback on this feature, we have increased substantially the number of these solutions.
Many more exercises. We have increased the number of end-of-chapter problems to give students more practice solving problems.

A Wide Variety of Problem Types

Users and reviewers of past editions have often cited the end-of-chapter problems as a major strength of the book, both for the range of difficulty levels and the variety of practical applications. We highlight those end-of-chapter problems that are more difficult with a special icon.

- The Chapter Integration Problems include worked-out, step-by-step solutions to problems involving several concepts from within chapters and from among several chapters. These solutions place particular emphasis on problem analysis, deductive reasoning, and logical conclusions.

- Team Problems encourage discussion and collaborative learning among students. They can be assigned as regular homework or as projects for groups of students to work on.

- For students planning careers in medicine or related fields, Preprofessional Problems offer a multiple-choice format typical of problems on the MCAT®, GRE, and DAT. In addition, a selection of actual test passages and questions from past MCAT® exams appears in an appendix.

REAL CHEMISTRY BY PRACTICING CHEMISTS:
An Emphasis on Practical Applications

Every chapter of this text features discussions of biological, medical, and industrial applications of organic chemistry, many of them new to this edition. Some of these applications are found in the text discussion, others in the exercises and problems, and still others in the Chemical Highlight boxes. Topics range from the chemistry behind the effects on human health of “compounds in the news” (cholesterol, trans fatty acids, grape seed extracts, green tea), to advances in the development of “green,” environmentally friendly methods in the chemical industry, new chemically based methods of disease diagnosis and treatment, and uses of transition metals and enzymes to catalyze reactions in pharmaceutical and medicinal chemistry. A major application of organic chemistry, stressed throughout the text, is the synthesis of new products and materials. We emphasize the development of good synthetic strategies and the avoidance of pitfalls, illustrating these ideas with many Working with the Concepts and Integration Problems. Many chapters contain specific syntheses of biological and medicinal importance.

NEW. “WHIP” strategy. Beginning in Chapter 3 we introduce a novel and powerful approach to problem solving, the “WHIP” approach. We teach students how to recognize the fundamental types of questions they are likely to encounter, and explain the solution strategy in full detail in a new Interlude section that follows Chapter 11. The “WHIP” strategy encourages students to ask the following questions: WHAT does the problem ask? HOW to begin? INFORMATION needed? PROCEED logically; do not skip steps! Solutions of several problem types illustrate the strategy.
New Applications Include:

Detecting Performance Enhancing Drugs Using Mass Spectrometry (Ch. 11, p. 476),

Synthesis of Immunosuppressants (Ch. 14, p. 644),

A Green Approach to Ibuprofen (Ch. 16, p. 736),

Synthetic Differentiation of Carboxyl Groups (Ch. 17, p. 796),

Plastics Fibers and Energy from Biomass-Derived Hydroxyesters (Ch. 19, p. 905),

Synthesis of the Natural Product Buflavine (Ch. 21, p. 991),

Industrial Production of Phenol from Cumene (Ch. 22, p. 1041),

Synthesis of the Antihypertensive Phenolamine (Ch. 22, p. 1047),

Synthesis of the Natural Product Resveratrol (Ch. 22, p. 1047),

Drug Design and “Bird Flu” (Ch. 24, p. 1152),

Synthesis of the Drug Varenicline (Chantix) (Ch. 25, p. 1171),

Organocatalytic Reductions (Ch. 25, p. 1186),

Synthesis of the Natural Product Buflavine (Ch. 26, p. 1222).

NEW AND UPDATED TOPICS

As with all new editions, each chapter has been carefully reviewed and revised. Updates and improvements, many of which involve “green” chemistry, include:

New section: Curved arrows show how starting materials convert to products (Ch. 2, p. 57)

New section: Sustainability and Green Chemistry (Ch 3, p. 103)

New section: Applications and Hazards of Haloalkanes: “Greener” Alternatives (Ch. 6, p. 217)

Expanded coverage of solvation effects in $S_N2$ reactions (Ch. 6, p. 235)

New section: Which is “Greener”: $S_N1$ or $S_N2$? (Ch. 7, p. 263)

Expanded coverage of green uses of ethanol (Ch. 9, p. 368)

Expanded coverage of resonance in NMR (Ch. 10, p. 390)

New section: Sharpless Oxidations and the Synthesis of Antitumor Drugs (Ch. 12, p. 536)

Expanded coverage of the Diels-Alder reaction (Ch.14, p. 628) and Electroyclic Reactions (Ch.14, p. 641)

Expanded coverage of annulenes and aromaticity (Ch. 15, p. 697)

Expanded coverage of the stereochemistry of the Wittig reaction (Ch. 17, p. 806)

Expanded coverage of intramolecular aldol condensations (Ch. 18, p. 843)
New section: Substitution at the Carboxy Carbon Occurs by Addition–Elimination (Ch. 19, p. 886)
Expanded coverage of relative reactivity of carboxylic acid derivatives (Ch. 20, p. 926)
Expanded coverage of the mechanism of the base-mediated ester hydrolysis (Ch. 20, p. 938)
Expanded coverage of IR spectroscopy of amines (Ch. 21, p. 977)
Expanded coverage of phenol syntheses from haloarenes, including a new section on Pd catalysis (Ch. 22, p. 1038)
Expanded coverage of cell-surface carbohydrate recognition (Ch. 24, p. 1150)

SUPPLEMENTAL MATERIAL FOR STUDENTS AND INSTRUCTORS

We believe a student needs to interact with a concept several times in a variety of scenarios to obtain a practical understanding. With that in mind, W. H. Freeman has developed the most comprehensive student learning package available.

FOR INSTRUCTORS

Instructors Resource CD-ROM
ISBN: 1-4292-3149-1
To help instructors create lecture presentations, Web sites, and other resources, this CD-ROM allows instructors to export resources directly to their computers. Some of these resources include:
- All textbook images, in both JPEG and PPT format
- Animated Mechanisms
- Full solutions to all problems within the text
- Lecture PowerPoints
- Clicker Questions
- Text Test Bank, which includes hundreds of multiple-choice questions

Electronic Resources
Instructors can access valuable teaching tools at www.whfreeman.com/organic6e. These password-protected resources are designed to enhance lecture presentations, and include Textbook Images (available in JPEG and PowerPoint format), the Online Quiz Gradebook, Clicker Questions, Video Lectures, MCAT Solutions, and more.

WebAssign Premium
For instructors interested in online homework management, W. H. Freeman and WebAssign have partnered to deliver WebAssign Premium—a comprehensive and flexible suite of resources for your course. Combining the most widely used online homework platform with a wealth of visualization and tutorial resources, WebAssign Premium extends and enhances the classroom experience for instructors and students by combining algorithmically generated versions of selected end-of-chapter questions with a fully interactive eBook at an affordable price. See page xxx for more details, or visit www.webassign.net to sign up for a faculty demo account.

• NEW. Molecular Modeling Problems
With this edition we now offer new molecular modeling problems for almost every chapter, which can be found on the text’s companion Web site. The problems were written to be performed using the popular Spartan Student Edition™ software from Wavefunction, Inc. With purchase of this text, students can buy Spartan Student Edition software at a significant discount from www.wavefun.com/cart/spartaned.html using the code WHFOCHEM.
While the problems are written to be performed using Spartan Student Edition software, they can be completed using any electronic structure program that allows Hartree-Fock, density functional, and MP2 calculations.

FOR STUDENTS

Study Guide and Solutions Manual
by Neil Schore, University of California, Davis
Written by Organic Chemistry coauthor Neil Schore, this invaluable manual includes chapter introductions that highlight new materials, chapter outlines, detailed comments for each chapter section, a glossary, and solutions to the end-of-chapter problems, presented in a way that shows students how to reason their way to the answer.

Workbook for Organic Chemistry: Supplemental Problems and Solutions
by Jerry Jenkins, Otterbein College
ISBN: 1-4292-4758-4
Jerry Jenkins’ extensive workbook provides approximately 80 problems per topic with full worked-out solutions. The perfect aid for students in need of more problem-solving, the Workbook for Organic Chemistry can be paired with any organic chemistry text on the market. For instructors interested in online homework, W.H. Freeman has also placed these problems in WebAssign.

Molecular Model Set
ISBN: 0-7167-4822-3
A modeling set offers a simple, practical way to see, manipulate, and investigate molecular behavior. Polyhedra mimic atoms, pegs serve as bonds, oval discs become orbitals. Freeman is proud to offer this inexpensive, best-of-its-kind kit containing everything you need to represent double and triple bonds, radicals, and long pairs of electrons—including more carbon pieces than are offered in other sets.

Spartan Student Discount
With purchase of this text, student can buy Spartan Student at a significant discount at www.wavefun.com/cart/spartaned.html using the code WHFOCHEM.

PREMIUM MULTIMEDIA RESOURCES
The Organic Chemistry Book Companion Web site, which can be accessed at www.whfreeman.com/organic6e, contains a wealth of Premium Student Resources. Students can unlock these resources with the click of a button, putting extensive concept and problem-solving support right at their fingertips. Some of the resources available are listed below.

NEW. ChemCasts replicate the face-to-face experience of watching an instructor work a problem. Using a virtual whiteboard, the Organic ChemCast tutors show students the steps involved in solving key worked examples, while explaining the concepts along the way. The worked examples featured in the ChemCasts were chosen with the input of organic chemistry students.

NEW. Organic Flashcards contain over 200 terms and images designed to test students’ organic chemistry knowledge and reinforce
key concepts along the way. Selected from the key terms and concepts in the text, the Organic Flashcards also include nomenclature exercise information and reaction summary road map content. These dynamic Web-based cards also allow students to create their own cards, start review quizzes, and print for on-the-go studying.

**NEW.** ChemNews from *Scientific American* provides an up-to-the-minute streaming feed of organic chemistry-related new stories direct from *Scientific American* magazine. Stay on top of the latest happenings in chemistry, all in one, easy place.

**NEW.** The multimedia-enhanced eBook contains the complete text with a wealth of helpful functions. All student multimedia, including the ChemCasts, Organic Flashcards, and ChemNews from *Scientific American*, are linked directly to the eBook pages. Students are thus able to access supporting resources when they need them—taking advantage of the “teachable moment” as students read. Customization functions include instructor and student notes, document linking, and editing capabilities. The eBook also includes 3D molecule images for all model-building exercises, courtesy of ChemSpider (www.chemspider.com).

**Online Learning Environments**
The above resources are available in two platforms. WebAssign Premium offers the most effective and widely used online homework system in the sciences, and is designed specifically for those instructors seeking graded homework management. The Student Companion Web site provides the student-oriented support materials independent of any homework system.

**WebAssign Premium**
For instructors interested in online homework management, WebAssign Premium features a time-tested, secure online environment used by millions of students worldwide. Featuring algorithmic problem generation and supported by a wealth of chemistry-specific learning tools, WebAssign Premium for *Organic Chemistry* presents instructors with a powerful assignment manager and study environment. WebAssign Premium provides the following resources:

- Algorithmically generated problems, where applicable: Students receive homework problems containing unique values for computation, encouraging them to work out the problems on their own.
- Complete access to the interactive eBook, from a live table of contents, as well as from relevant problem statements.
- Links to ChemCasts, Organic Flashcards, ChemNews from *Scientific American*, and other interactive tools are provided as hints and feedback to ensure a clearer understanding of the problems and the concepts they reinforce.
- Graded molecular drawing problems using the popular MarvinSketch application allow instructors to evaluate student understanding of molecular structure. The system evaluates virtually “drawn” molecular structures, returning a grade as well as helpful feedback for common errors.

**Student Companion Web site**
The *Organic Chemistry* Book Companion Web site, (www.whfreeman.com/organic6e), provides a range of tools for problem solving and chemical explorations. They include, among others:

- Student self-quizzes
- An interactive periodic table of the elements
- Author Lecture Videos
- Reaction and nomenclature exercises, which are drag-and-drop exercises designed for memorization and rote memorization
• Animated Mechanisms for reference and quizzing
• To access additional support, including the ChemCasts, Organic Flashcards, and ChemNews from Scientific American, students can upgrade their access through a direct subscription to the Premium component of the Web site.

Peter Vollhardt thanks his synthetic and physical colleagues at UC Berkeley, in particular Professors Bob Bergman, Carolyn Bertozzi, Ron Cohen, Jean Frechet, Steve Pedersen, Rich Saykally, Andrew Streitwieser, Dirk Trauner, Dave Wernher, and Evan Williams, for general and very specific suggestions. He would also like to thank his administrative assistant, Bonnie Kirk, for helping with the logistics of producing and handling manuscript and galleys, and his graduate student Robin Padilla for general help. Neil Schore thanks his organic colleagues, especially Dr. Melekeh Nasiri, who was constantly on the lookout for inconsistencies and errors in the textbook problems and study guide solutions.
Our thanks go to the many people who helped with this edition. Jessica Fiorillo, acquisitions editor, and Randi Rossignol, development editor, at W. H. Freeman and Company, guided this edition from concept to completion. David Chelton used persistence and humor to help us stick with our plan. Dave Quinn, media editor, managed the media and supplements with great skill, and Brittany Murphy, editorial assistant, coordinated our efforts. Also many thanks to Blake Logan, our designer; and Susan Wein, production coordinator, for their fine work and attention to the smallest detail. Thanks also to Dennis Free at Aptara, for his unlimited patience.
How do chemicals regulate your body? Why did your muscles ache this morning after last night’s long jog? What is in the pill you took to get rid of that headache you got after studying all night? What happens to the gasoline you pour into the gas tank of your car? What is the molecular composition of the things you wear? What is the difference between a cotton shirt and one made of silk? What is the origin of the odor of garlic? You will find the answers to these questions, and many others that you may have asked yourself, in this book on organic chemistry.

Chemistry is the study of the structure of molecules and the rules that govern their interactions. As such, it interfaces closely with the fields of biology, physics, and mathematics. What, then, is organic chemistry? What distinguishes it from other chemical disciplines, such as physical, inorganic, or nuclear chemistry? A common definition provides a partial answer: *Organic chemistry is the chemistry of carbon and its compounds.* These compounds are called *organic molecules.*

Organic molecules constitute the chemical building blocks of life. Fats, sugars, proteins, and the nucleic acids are compounds in which the principal component is carbon. So are countless substances that we take for granted in everyday use. Virtually all the clothes that we wear are made of organic molecules—some of natural fibers, such as cotton and silk; others artificial, such as polyester. Toothbrushes, toothpaste, soaps, shampoos, deodorants, perfumes—all contain organic compounds, as do furniture, carpets, the plastic in light fixtures and cooking utensils, paintings, food, and countless other items. Consequently, organic chemical industries are among the largest in the world, including petroleum refining and processing, agrochemicals, plastics, pharmaceuticals, paints and coatings, and the food conglomerates.

Organic substances such as gasoline, medicines, pesticides, and polymers have improved the quality of our lives. Yet the uncontrolled disposal of organic chemicals has polluted the environment, causing deterioration of animal and plant life as well as injury and disease to humans. If we are to create useful molecules—and learn to control their effects—we need a knowledge of their properties and an understanding of their behavior. We must be able to apply the principles of organic chemistry.
This chapter explains how the basic ideas of chemical structure and bonding apply to organic molecules. Most of it is a review of topics that you covered in your general chemistry courses, including molecular bonds, Lewis structures and resonance, atomic and molecular orbitals, and the geometry around bonded atoms.

1-1 The Scope of Organic Chemistry: An Overview

A goal of organic chemistry is to relate the structure of a molecule to the reactions that it can undergo. We can then study the steps by which each type of reaction takes place, and we can learn to create new molecules by applying those processes.

Thus, it makes sense to classify organic molecules according to the subunits and bonds that determine their chemical reactivity: These determinants are groups of atoms called functional groups. The study of the various functional groups and their respective reactions provides the structure of this book.

Functional groups determine the reactivity of organic molecules

We begin with the alkanes, composed of only carbon and hydrogen atoms (“hydrocarbons”) connected by single bonds. They lack any functional groups and as such constitute the basic scaffold of organic molecules. As with each class of compounds, we present the systematic rules for naming alkanes, describe their structures, and examine their physical properties (Chapter 2). An example of an alkane is ethane. Its structural mobility is the starting point for a review of thermodynamics and kinetics. This review is then followed by a discussion of the strength of alkane bonds, which can be broken by heat, light, or chemical reagents. We illustrate these processes with the chlorination of alkanes (Chapter 3).

A Chlorination Reaction

\[
\text{CH}_4 + \text{Cl}_2 \xrightarrow{\text{Energy}} \text{CH}_3\text{Cl} + \text{HCl}
\]

Next we look at cyclic alkanes (Chapter 4), which contain carbon atoms in a ring. This arrangement can lead to new properties and changes in reactivity. The recognition of a new type of isomerism in cycloalkanes bearing two or more substituents—either on the same side or on opposite sides of the ring plane—sets the stage for a general discussion of stereoisomerism. Stereoisomerism is exhibited by compounds with the same connectivity but differing in the relative positioning of their component atoms in space (Chapter 5).

We shall then study the haloalkanes, our first example of compounds containing a functional group—the carbon–halogen bond. The haloalkanes participate in two types of organic reactions: substitution and elimination (Chapters 6 and 7). In a substitution reaction, one halogen atom may be replaced by another; in an elimination process, adjacent atoms may be removed from a molecule to generate a double bond.

A Substitution Reaction

\[
\text{CH}_3\text{Cl} + \text{K}^+\text{I}^- \rightarrow \text{CH}_3\text{I} + \text{K}^+\text{Cl}^-
\]

An Elimination Reaction

\[
\text{CH}_2\text{CH}_2 + \text{K}^+\text{OH}^- \rightarrow \text{H}_2\text{C}═\text{CH}_2 + \text{HOH} + \text{K}^+\text{I}^-
\]

Like the haloalkanes, each of the major classes of organic compounds is characterized by a particular functional group. For example, the carbon–carbon triple bond is the functional group of alkynes (Chapter 13); the smallest alkyne, acetylene, is the chemical burned in a welder’s torch. A carbon–oxygen double bond is characteristic of aldehydes and ketones (Chapter 17); formaldehyde and acetone are major industrial commodities. The amines (Chapter 21), which include drugs such as nasal decongestants and amphetamines, contain...
nitrogen in their functional group; methyl amine is a starting material in many syntheses of medicinal compounds. We shall study the tools for identifying these molecular subunits, especially the various forms of spectroscopy (Chapters 10, 11, and 14). Organic chemists rely on an array of spectroscopic methods to elucidate the structures of unknown compounds. All of these methods depend on the absorption of electromagnetic radiation at specific wavelengths and the correlation of this information with structural features.

Subsequently, we shall encounter organic molecules that are especially crucial in biology and industry. Many of these, such as the carbohydrates (Chapter 24) and amino acids (Chapter 26), contain multiple functional groups. However, in every class of organic compounds, the principle remains the same: The structure of the molecule determines the reactions that it can undergo.

**Synthesis is the making of new molecules**

Carbon compounds are called “organic” because it was originally thought that they could be produced only from living organisms. In 1828, Friedrich Wöhler* proved this idea to be false when he converted the inorganic salt lead cyanate into urea, an organic product of protein metabolism in mammals (Chemical Highlight 1-1).

**Wöhler’s Synthesis of Urea**

\[
\text{Pb(OCN)}_2 + 2 \text{H}_2\text{O} + 2 \text{NH}_3 \rightarrow 2 \text{H}_2\text{NCONH}_2 + \text{Pb(OH)}_2\]

**Synthesis**, or the making of molecules, is a very important part of organic chemistry (Chapter 8). Since Wöhler’s time, many millions of organic substances have been synthesized from simpler materials, both organic and inorganic.† These substances include many that also occur in nature, such as the penicillin antibiotics, as well as entirely new compounds. Some, such as cubane, have given chemists the opportunity to study special kinds of bonding and reactivity. Others, such as the artificial sweetener saccharin, have become a part of everyday life.

Typically, the goal of synthesis is to construct complex organic chemicals from simpler, more readily available ones. To be able to convert one molecule into another, chemists must know organic reactions. They must also know the physical factors that govern such processes, such as temperature, pressure, solvent, and molecular structure. This knowledge is equally valuable in analyzing reactions in living systems.

As we study the chemistry of each functional group, we shall develop the tools both for planning effective syntheses and for predicting the processes that take place in nature. But how? The answer lies in looking at reactions step by step.

---

*Professor Friedrich Wöhler (1800–1882), University of Göttingen, Germany. In this and subsequent biographical notes, only the scientist’s last known location of activity will be mentioned, even though much of his or her career may have been spent elsewhere.

†As of September 2009, the Chemical Abstracts Service had registered over 50 million chemical substances and more than 61 million genetic sequences.
Urination is the main process by which we excrete nitrogen from our bodies. Urine is produced by the kidneys and then stored in the bladder, which begins to contract when its volume exceeds about 200 mL. The average human excretes about 1.5 L of urine daily, and a major component is urea, about 20 g per liter. In an attempt to probe the origins of kidney stones, early (al)chemists, in the 18th century, attempted to isolate the components of urine by crystallization, but they were stymied by the cocrystallization with the also present sodium chloride. William Prout,* an English chemist and physician, is credited with the preparation of pure urea in 1817 and the determination of its accurate elemental analysis as CH₄N₂O. Prout was an avid proponent of the then revolutionary thinking that disease has a molecular basis and could be understood as such. This view clashed with that of the so-called vitalists, who believed that the functions of a living organism are controlled by a “vital principle” and cannot be explained by chemistry (or physics).

Into this argument entered Wöhler, an inorganic chemist, who attempted to make ammonium cyanate, NH₄OCN (also CH₄N₂O), from lead cyanate and ammonia in 1828, but who obtained the same compound that Prout had characterized as urea. To one of his mentors, Wöhler wrote, “I can make urea without a kidney, or even a living creature.” In his landmark paper, “On the Artificial Formation of Urea,” he commented on his synthesis as a “remarkable fact, as it is an example of the artificial generation of an organic material from inorganic materials.” He also alluded to the significance of the finding that a compound with an identical elemental composition as ammonium cyanate can have such completely different chemical properties, a forerunner to the recognition of isomeric compounds. Wöhler’s synthesis of urea forced his contemporary vitalists to accept the notion that simple organic compounds could be made in the laboratory. As you shall see in this book, over the ensuing decades, synthesis has yielded much more complex molecules than urea, some of them endowed with self-replicating and other “lifelike” properties, such that the boundaries between what is lifeless and what is alive are dwindling.

Apart from its function in the body, urea’s high nitrogen content makes it an ideal fertilizer. It is also a raw material in the manufacture of plastics and glues, an ingredient of some toiletry products and fire extinguishers, and an alternative to rock salt for deicing roads. It is produced industrially from ammonia and carbon dioxide to the tune of 100 million tons per year.

*Dr. William Prout (1785–1850), Royal College of Physicians, London.
How can we determine reaction mechanisms? The strict answer to this question is, we cannot. All we can do is amass circumstantial evidence that is consistent with (or points to) a certain sequence of molecular events that connect starting materials and products (“the postulated mechanism”). To do so, we exploit the fact that organic molecules are no more than collections of bonded atoms. We can, therefore, study how, when, and how fast bonds break and form, in which way they do so in three dimensions, and how changes in substrate structure affect the outcome of reactions. Thus, although we cannot strictly prove a mechanism, we can certainly rule out many (or even all) reasonable alternatives and propose a most likely pathway.

In a way, the “learning” and “using” of organic chemistry is much like learning and using a language. You need the vocabulary (i.e., the reactions) to be able to use the right words, but you also need the grammar (i.e., the mechanisms) to be able to converse intelligently. Neither one on its own gives complete knowledge and understanding, but together they form a powerful means of communication, rationalization, and predictive analysis. To highlight the interplay between reaction and mechanism, icons are displayed in the margin at appropriate places throughout the text.

Before we begin our study of the principles of organic chemistry, let us review some of the elementary principles of bonding. We shall find these concepts useful in understanding and predicting the chemical reactivity and the physical properties of organic molecules.

1-2 Coulomb Forces: A Simplified View of Bonding

The bonds between atoms hold a molecule together. But what causes bonding? Two atoms form a bond only if their interaction is energetically favorable, that is, if energy—heat, for example—is released when the bond is formed. Conversely, breaking that bond requires the input of the same amount of energy.

The two main causes of the energy release associated with bonding are based on Coulomb’s law of electric charge:

1. Opposite charges attract each other (electrons are attracted to protons).
2. Like charges repel each other (electrons spread out in space).

Bonds are made by simultaneous coulombic attraction and electron exchange

Each atom consists of a nucleus, containing electrically neutral particles, or neutrons, and positively charged protons. Surrounding the nucleus are negatively charged electrons, equal in number to the protons so that the net charge is zero. As two atoms approach each other, the positively charged nucleus of the first atom attracts the electrons of the second atom; similarly, the nucleus of the second atom attracts the electrons of the first atom. As a result, the nuclei are held together by the electrons located between them. This sort of bonding is described by Coulomb’s law: Opposite charges attract each other with a force inversely proportional to the square of the distance between the centers of the charges.

Coulomb’s Law

\[
\text{Attracting force} = \text{constant} \times \frac{(+) \text{ charge} \times (-) \text{ charge}}{\text{distance}^2}
\]

This attractive force causes energy to be released as the neutral atoms are brought together. This energy is called the bond strength.

*Lieutenant-Colonel Charles Augustin de Coulomb (1736–1806), Inspecteur Général of the University of Paris, France.
When the atoms reach a certain closeness, no more energy is released. The distance between the two nuclei at this point is called the bond length (Figure 1-1). Bringing the atoms closer together than this distance results in a sharp increase in energy. Why? As stated above, just as opposite charges attract, like charges repel. If the atoms are too close, the electron–electron and nuclear–nuclear repulsions become stronger than the attractive forces. When the nuclei are the appropriate bond length apart, the electrons are spread out around both nuclei, and attractive and repulsive forces balance for maximum bonding. The energy content of the two-atom system is then at a minimum, the most stable situation (Figure 1-2).

An alternative to this type of bonding results from the complete transfer of an electron from one atom to the other. The result is two charged ions: one positively charged, a cation, and one negatively charged, an anion (Figure 1-3). Again, the bonding is based on coulombic attraction, this time between two ions.

The coulombic bonding models of attracting and repelling charges shown in Figures 1-2 and 1-3 are highly simplified views of the interactions that take place in the bonding of atoms. Nevertheless, even these simple models explain many of the properties of organic molecules. In the sections to come, we shall examine increasingly more sophisticated views of bonding.
1-3 Ionic and Covalent Bonds: The Octet Rule

We have seen that attraction between negatively and positively charged particles is a basis for bonding. How does this concept work in real molecules? Two extreme types of bonding explain the interactions between atoms in organic molecules:

1. A **covalent bond** is formed by the sharing of electrons (as shown in Figure 1-2).
2. An **ionic bond** is based on the electrostatic attraction of two ions with opposite charges (as shown in Figure 1-3).

We shall see that many atoms bind to carbon in a way that is intermediate between these extremes: Some ionic bonds have covalent character and some covalent bonds are partly ionic (polarized).

What are the factors that account for the two types of bonds? To answer this question, let us return to the atoms and their compositions. We start by looking at the periodic table and at how the electronic makeup of the elements changes as the atomic number increases.

**The periodic table underlies the octet rule**

The partial periodic table depicted in Table 1-1 includes those elements most widely found in organic molecules: carbon (C), hydrogen (H), oxygen (O), nitrogen (N), sulfur (S), chlorine (Cl), bromine (Br), and iodine (I). Certain reagents, indispensable for synthesis and commonly used, contain elements such as lithium (Li), magnesium (Mg), boron (B), and phosphorus (P). (If you are not familiar with these elements, refer to Table 1-1 or the periodic table on the inside cover.)

The elements in the periodic table are listed according to nuclear charge (number of protons), which equals the number of electrons. The nuclear charge increases by one with each element listed. The electrons occupy energy levels, or “shells,” each with a fixed capacity. For example, the first shell has room for two electrons; the second, eight; and the third, 18. Helium, with two electrons in its shell, and the other noble gases, with eight electrons (called **octets**) in their outermost shells, are especially stable. These elements show very little chemical reactivity. All other elements (including carbon, see margin) lack octets in their outermost electron shells. **Atoms tend to form molecules in such a way as to reach an octet in the outer electron shell and attain a noble-gas configuration.** In the next two sections, we describe two extreme ways in which this goal may be accomplished: by the formation of pure ionic or pure covalent bonds.

---

**Exercise 1-1**

(a) Redraw Figure 1-1 for a weaker bond than the one depicted. (b) Write the elements in Table 1-1 from memory.

---

**Note:** The superscripts indicate the number of electrons in each principal shell of the atom.
In pure ionic bonds, electron octets are formed by transfer of electrons

Sodium (Na), a reactive metal, interacts with chlorine, a reactive gas, in a violent manner to produce a stable substance: sodium chloride. Similarly, sodium reacts with fluorine (F), bromine, or iodine to give the respective salts. Other alkali metals, such as lithium and potassium (K), undergo the same reactions. These transformations succeed because both reaction partners attain noble-gas character by the transfer of outer-shell electrons, called valence electrons, from the alkali metals on the left side of the periodic table to the halogens on the right.

Let us see how this works for the ionic bond in sodium chloride. Why is the interaction energetically favorable? First, it takes energy to remove an electron from an atom. This energy is the ionization potential (IP) of the atom. For sodium gas, the ionization energy amounts to 119 kcal mol\(^{-1}\).* Conversely, energy may be released when an electron attaches itself to an atom. For chlorine, this energy, called its electron affinity (EA), is \(-83\) kcal mol\(^{-1}\). These two processes result in the transfer of an electron from sodium to chlorine. Together, they require a net energy input of \(119 - 83 = 36\) kcal mol\(^{-1}\).

\[
\begin{array}{c}
\text{Na}^{2,8,1} & \xrightarrow{\text{1}\text{e}} & [\text{Na}^{2,8}]^+ \\
\text{Sodium cation} & \text{(Neon configuration)}
\end{array}
\]

\[
\begin{array}{c}
\text{Cl}^{2,8,7} & \xrightarrow{\text{1}\text{e}} & [\text{Cl}^{2,8,8}]^- \\
\text{Chloride anion} & \text{(Argon configuration)}
\end{array}
\]

\[
\text{Na} + \text{Cl} \longrightarrow \text{Na}^+ + \text{Cl}^- \\
\text{Total} = 119 - 83 = 36\text{ kcal mol}^{-1} (151\text{ kJ mol}^{-1})
\]

Why, then, do the atoms readily form NaCl? The reason is their electrostatic attraction, which pulls them together in an ionic bond. At the most favorable interatomic distance [about 2.8 Å (angstroms) in the gas phase], this attraction releases (see Figure 1-1) about 120 kcal mol\(^{-1}\) (502 kJ mol\(^{-1}\)). This energy release is enough to make the reaction of sodium with chlorine energetically highly favorable \([+36 - 120 = -84\text{ kcal mol}^{-1} (-351\text{ kJ mol}^{-1})]\).

**Formation of Ionic Bonds by Electron Transfer**

\[
\text{Na}^{2,8,1} + \text{Cl}^{2,8,7} \longrightarrow [\text{Na}^{2,8}]^+ [\text{Cl}^{2,8,8}]^- , \text{ or NaCl} (\sim 84\text{ kcal mol}^{-1})
\]

More than one electron may be donated (or accepted) to achieve noble-gas electronic configurations. Magnesium, for example, has two valence electrons. Donation to an appropriate acceptor produces the corresponding doubly charged cation with the electronic structure of neon. In this way, the ionic bonds of typical salts are formed.

A representation of how charge (re)distributes itself in molecules is given by electrostatic potential maps. These computer-generated maps not only show a form of the molecule’s “electron cloud” but also use color to depict deviations from charge neutrality. Excess electron density—for example, a negative charge—is shown in colors shaded toward red; conversely, diminishing electron density—ultimately, a positive charge—is shown in colors shaded toward blue. Charge-neutral regions are indicated by green. The reaction of a sodium atom with a chlorine atom to produce Na\(^+\)Cl\(^-\) is pictured this way in the margin. In the product, Na\(^+\) is blue, Cl\(^-\) is red.

---

\*This book will cite energy values in the traditional units of kcal mol\(^{-1}\), in which mol is the abbreviation for mole and a kilocalorie (kcal) is the energy required to raise the temperature of 1 kg (kilogram) of water by 1°C. In SI units, energy is expressed in joules (kg m\(^2\) s\(^{-2}\)), or kilogram-meter\(^2\) per second\(^2\)). The conversion factor is 1 kcal = 4184 J = 4.184 kJ (kilojoule), and we will list these values in parentheses in key places.
A more convenient way of depicting valence electrons is by means of dots around the symbol for the element. In this case, the letters represent the nucleus including all the electrons in the inner shells, together called the **core configuration**.

\]

The hydrogen atom is unique because it may either lose an electron to become a bare nucleus, the **proton**, or accept an electron to form the **hydride ion**, \([\text{H}]^-\), which possesses the helium configuration. Indeed, the hydrides of lithium, sodium, and potassium (\(\text{Li}^-\text{H}^+, \text{Na}^-\text{H}^+, \text{and K}^-\text{H}^+\)) are commonly used reagents.

**Exercise 1-2**

Draw electron-dot pictures for ionic LiBr, Na\(_2\)O, BeF\(_2\), AlCl\(_3\), and MgS.

**In covalent bonds, electrons are shared to achieve octet configurations**

Formation of ionic bonds between two identical elements is difficult because the electron transfer is usually very unfavorable. For example, in \(\text{H}_2\), formation of \(\text{H}^+\text{H}^-\) would require an energy input of nearly 300 kcal mol\(^{-1}\) (1255 kJ mol\(^{-1}\)). For the same reason, none of the halogens, \(\text{F}_2\), \(\text{Cl}_2\), \(\text{Br}_2\), and \(\text{I}_2\), has an ionic bond. The high IP of hydrogen also prevents the bonds in the hydrogen halides from being ionic. For elements nearer the center of the periodic table, the formation of ionic bonds is unfeasible, because it becomes more and more difficult to donate or accept enough electrons to attain the noble-gas configuration. Such is the case for carbon, which would have to shed four electrons to reach the helium electronic structure or add four electrons for a neonlike arrangement. The large amount of charge that would develop makes these processes very energetically unfavorable.

Instead, **covalent bonding** takes place: The elements *share* electrons so that each atom attains a noble-gas configuration. Typical products of such sharing are \(\text{H}_2\) and \(\text{HCl}\). In \(\text{HCl}\), the chlorine atom assumes an octet structure by sharing one of its valence electrons with that of hydrogen. Similarly, the chlorine molecule, \(\text{Cl}_2\), is diatomic because both component atoms gain octets by sharing two electrons. Such bonds are called **covalent single bonds**.
**Chapter 1**

### Structure and Bonding in Organic Molecules

**Electron-Dot Picture of Covalent Single Bonds**

\[
\begin{align*}
\text{H} & \cdot + \text{H} \rightarrow \text{H} \cdot \text{H} \\
\text{H} & \cdot + \text{Cl} \rightarrow \text{H} \cdot \text{Cl} \\
\text{Cl} & \cdot + \text{Cl} \rightarrow \text{Cl} \cdot \text{Cl}
\end{align*}
\]

Because carbon has four valence electrons, it must acquire a share of four electrons to gain the neon configuration, as in methane. Nitrogen has five valence electrons and needs three to share, as in ammonia; and oxygen, with six valence electrons, requires only two to share, as in water.

\[
\begin{align*}
\text{H} & \cdot \text{C} \cdot \text{H} \quad \text{H} & \cdot \text{N} \cdot \text{H} \quad \text{H} & \cdot \text{O} \cdot \text{H} \\
\text{H} & \quad \text{H} & \quad \text{H}
\end{align*}
\]

Methane Ammonia Water

It is possible for one atom to supply both of the electrons required for covalent bonding. This occurs upon addition of a proton to ammonia, thereby forming NH\(_4^+\), or to water, thereby forming H\(_3O^+\).

\[
\begin{align*}
\text{H} & \cdot \text{N} \cdot + \text{H}^+ \rightarrow \left[ \text{H} \cdot \text{N} \cdot \text{H} \right]^+ \\
\text{H} & \cdot \text{O} \cdot + \text{H}^+ \rightarrow \left[ \text{H} \cdot \text{O} \cdot \text{H} \right]^+
\end{align*}
\]

Ammonium ion Hydronium ion

Besides two-electron (single) bonds, atoms may form four-electron (double) and six-electron (triple) bonds to gain noble-gas configurations. Atoms that share more than one electron pair are found in ethene and ethyne.

\[
\begin{align*}
\text{H} & \cdot \text{C} \cdot \cdot \cdot \text{H} \quad \text{H} & \cdot \text{C} \cdot \cdot \cdot \text{C} \cdot \text{H} \\
\text{H} & \cdot \quad \text{H} & \cdot
\end{align*}
\]

Ethene (Ethylene)* Ethyne (Acetylene)*

The drawings above, with pairs of electron dots representing bonds, are also called **Lewis**\(^\dagger\) structures. We shall develop the general rules for formulating such structures in Section 1–4.

---

**Exercise 1-3**

Draw electron-dot structures for F\(_2\), CF\(_4\), CH\(_2\)Cl\(_2\), PH\(_3\), BrI, HO\(^-\), H\(_2\)N\(^-\), and H\(_3\)C\(^-\). (Where applicable, the first element is at the center of the molecule.) Make sure that all atoms have noble-gas electron configurations.

---

**In most organic bonds, the electrons are not shared equally:**

**polar covalent bonds**

The preceding two sections presented two extreme ways in which atoms attain noble-gas configurations by entering into bonding: pure ionic and pure covalent. In reality, most bonds are of a nature that lies between these two extremes: **polar covalent**. Thus, the ionic bonds in most salts have some covalent character; conversely, the covalent bonds to carbon have some ionic or polar character. Recall (Section 1–2) that both sharing of electrons and

\(^\dagger\)Professor Gilbert N. Lewis (1875–1946), University of California, Berkeley.

\(^*\)In labels of molecules, systematic names (introduced in Section 2–5) will be given first, followed in parentheses by so-called common names that are still in frequent usage.
coulombic attraction contribute to the stability of a bond. How polar are polar covalent bonds and what is the direction of the polarity?

We can answer these questions by considering the periodic table and keeping in mind that the positive nuclear charge of the elements increases from left to right. Thus, the elements on the left of the periodic table are often called electropositive, electron donating, or “electron pushing,” because their electrons are held by the nucleus less tightly than are those of elements to the right. These elements at the right of the periodic table are described as electronegative, electron accepting, or “electron pulling.” Table 1-2 lists the relative electronegativities of some elements. On this scale, fluorine, the most electronegative of them all, is assigned the value 4.

Consideration of Table 1-2 readily explains why the most ionic (least covalent) bonds occur between elements at the two extremes (e.g., the alkali metal salts, such as sodium chloride). On the other hand, the purest covalent bonds are formed between atoms of equal electronegativity (i.e., identical elements, as in H2, N2, O2, F2, and so on) or in carbon–carbon bonds. However, most covalent bonds are between atoms of differing electronegativity, resulting in their polarization. The polarization of a bond is the consequence of a shift of the center of electron density in the bond toward the more electronegative atom. It is indicated in a very qualitative manner (using the Greek letter delta $\delta$) by designating a partial positive charge, $\delta^+$, and partial negative charge, $\delta^-$, to the respective less or more electronegative atom. The larger the difference in electronegativity, the bigger is the charge separation. As a rule of thumb, electronegativity differences of 0.3 to 2.0 units indicate polar covalent bonds; lesser values are typical of essentially “pure” covalent bonds, larger values of “pure” ionic ones.

The separation of opposite charges is called an electric dipole, symbolized by an arrow crossed at its tail and pointing from positive to negative. A polarized bond can impart polarity to a molecule as a whole, as in HF, ICl, and CH3F.

In symmetrical structures, the polarizations of the individual bonds may cancel, thus leading to molecules with no net polarization, such as CO2 and CCl4 (margin). To know whether a molecule is polar, we have to know its shape, because the net polarity is the vector sum of the bond dipoles. The electrostatic potential maps in the margin clearly
illustrate the polarization in CO₂ and CCl₄, showing the respective carbon atoms shaded relatively blue, the attached, more electronegative atoms relatively red. Moreover, you can recognize how the shape of each molecule renders it nonpolar as a whole. There are two cautions in viewing electrostatic potential maps: (1) The scale on which the color differentials are rendered may vary. For example, a much more sensitive scale is used for the molecules in the margin, in which the charges are only partial, than for NaCl on p. 8, in which the atoms assume full charges. Thus, it may be misleading to compare the electrostatic potential maps of one set of molecules with those of another, electronically very different group. Most organic structures shown in this book will be on a comparative scale, unless mentioned otherwise. (2) Because of the way in which the potential at each point is calculated, it will contain contributions from all nuclei and electrons in the vicinity. As a consequence, the color of the spatial regions around individual nuclei is not uniform.

### Valence electron repulsion controls the shapes of molecules

Molecules adopt shapes in which electron repulsion (including both bonding and nonbonding electrons) is minimized. In diatomic species such as H₂ or LiH, there is only one bonding electron pair and one possible arrangement of the two atoms. However, beryllium fluoride, BeF₂, is a triatomic species. Will it be bent or linear? Electron repulsion is at a minimum in a linear structure, because the bonding and nonbonding electrons are placed as far from each other as possible, at 180°.* Linearity is also expected for other derivatives of beryllium, as well as of other elements in the same column of the periodic table.

In boron trichloride, the three valence electrons of boron allow it to form covalent bonds with three chlorine atoms. Electron repulsion enforces a regular trigonal arrangement—that is, the three halogens are at the corners of an equilateral triangle, the center of which is occupied by boron, and the bonding (and nonbonding) electron pairs of the respective chlorine atoms are at maximum distance from each other, that is, 120°. Other derivatives of boron, and the analogous compounds with other elements in the same column of the periodic table, are again expected to adopt trigonal structures.

Applying this principle to carbon, we can see that methane, CH₄, has to be tetrahedral. Placing the four hydrogens at the vertices of a tetrahedron minimizes the electron repulsion of the corresponding bonding electron pairs.

---

*Math is true only in the gas phase. At room temperature, BeF₂ is a solid (it is used in nuclear reactors) that exists as a complex network of linked Be and F atoms, not as a distinct linear triatomic structure.
ease of drawing only. Do not confuse such two-dimensional drawings with the true three-dimensional molecular shapes (trigonal for BCl₃ and tetrahedral for CH₄).

**Exercise 1-4**

Show the bond polarization in H₂O, SCl₂, SO₂, IBr, CH₄, CHCl₃, CH₂Cl₂, and CH₃Cl by using dipole arrows to indicate separation of charge. (In the last four examples, place the carbon in the center of the molecule.)

**Exercise 1-5**

Ammonia, \( \text{NH}_3 \), is not trigonal but pyramidal, with bond angles of 107.3°. Water, \( \text{H}_2\text{O} \), is not linear but bent (104.5°). Why? (Hint: Consider the effect of the nonbonding electron pairs.)

**In Summary** There are two extreme types of bonding, ionic and covalent. Both derive favorable energetics from Coulomb forces and the attainment of noble-gas electronic structures. Most bonds are better described as something between the two types: the polar covalent (or covalent ionic) bonds. Polarity in bonds may give rise to polar molecules. The outcome depends on the shape of the molecule, which is determined in a simple manner by arrangement of its bonds and nonbonding electrons to minimize electron repulsion.

**1-4 Electron-Dot Model of Bonding: Lewis Structures**

Lewis structures are important for predicting geometry and polarity (hence reactivity) of organic compounds, and we shall use them for that purpose throughout this book. In this section, we provide rules for writing such structures correctly and for keeping track of valence electrons.

**Lewis structures are drawn by following simple rules**

The procedure for drawing correct electron-dot structures is straightforward, as long as the following rules are observed.

**Rule 1.** *Draw the (given or desired) molecular skeleton.* As an example, consider methane. The molecule has four hydrogen atoms bonded to one central carbon atom.

\[
\begin{array}{c}
\text{H} \\
\text{H C H} \\
\text{H} \\
\text{H} \\
\text{H} \\
\text{H}
\end{array}
\]

Correct Incorrect

**Rule 2. Count the number of available valence electrons.** Add up all the valence electrons of the component atoms. Special care has to be taken with charged structures (anions or cations), in which case the appropriate number of electrons has to be added or subtracted to account for extra charges.

<table>
<thead>
<tr>
<th>Compound</th>
<th>Cations</th>
<th>Anions</th>
</tr>
</thead>
<tbody>
<tr>
<td>CH₄⁺</td>
<td>( \text{CH}_4 + )</td>
<td>( \text{CH}_4^- )</td>
</tr>
<tr>
<td>H₂O⁺</td>
<td>( \text{H}_2\text{O} + )</td>
<td>( \text{H}_2\text{O}^- )</td>
</tr>
</tbody>
</table>

**CH₄**

\[
\begin{array}{c}
\text{H} \\
\text{H C H} \\
\text{H} \\
\text{H} \\
\text{H} \\
\text{H}
\end{array}
\]

\( \text{Total} = 8 \text{ electrons} \)

**HBr**

\[
\begin{array}{c}
\text{H} \\
\text{H C H} \\
\text{H} \\
\text{Br}
\end{array}
\]

\( \text{Total} = 8 \text{ electrons} \)

**NH₃**

\[

\text{H} \\
\text{H} \\
\text{H}
\end{array}
\]

\( \text{Total} = 8 \text{ electrons} \)

\( +1 \)

\( -1 \)

\( \text{Charge} \)

\( \text{Charge} \)

---

**Exercise 1-5**

Ammonia, \( \text{NH}_3 \), is not trigonal but pyramidal, with bond angles of 107.3°. Water, \( \text{H}_2\text{O} \), is not linear but bent (104.5°). Why? (Hint: Consider the effect of the nonbonding electron pairs.)
Rule 3. (The octet rule) Depict all covalent bonds by two shared electrons, giving as many atoms as possible a surrounding electron octet, except for H, which requires a duet. Make sure that the number of electrons used is exactly the number counted according to rule 2. Elements at the right in the periodic table may contain pairs of valence electrons not used for bonding, called lone electron pairs or just lone pairs.

Consider, for example, hydrogen bromide. The shared electron pair supplies the hydrogen atom with a duet, the bromine with an octet, because the bromine carries three lone electron pairs. Conversely, in methane, the four C–H bonds satisfy the requirement of the hydrogens and, at the same time, furnish the octet for carbon. Examples of correct and incorrect Lewis structures for HBr are shown below.

Correct Lewis Structure       Incorrect Lewis Structures
\[
\begin{align*}
\text{Correct} & : H : Br : \\
\text{Incorrect 1} & : H : Br : \\
\text{Incorrect 2} & : H : Br :
\end{align*}
\]

Frequently, the number of valence electrons is not sufficient to satisfy the octet rule only with single bonds. In this event, double bonds (two shared electron pairs) and even triple bonds (three shared pairs) are necessary to obtain octets. An example is the nitrogen molecule, \( N_2 \), which has ten valence electrons. An N–N single bond would leave both atoms with electron sextets, and a double bond provides only one nitrogen atom with an octet. It is the molecule with a triple bond that satisfies both atoms. You may find a simple procedure useful that gives you the total number of bonds needed in a molecule to give every atom an octet (or duet). Thus, after you have counted the supply of available electrons (rule 2), add up the total “electron demand,” that is, two electrons for each hydrogen atom and eight for each other element atom. Then subtract “demand” from supply and divide by 2. For \( N_2 \), demand is 16 electrons, supply is 10, and hence the number of bonds is 3.

Further examples of molecules with double and triple bonds are shown below.

Correct Lewis Structures
\[
\begin{align*}
\text{Correct} & : H : C : H \\
\text{Correct} & : H : C : H \\
\end{align*}
\]

In practice, another simple sequence may help. First, connect all mutually bonded atoms in your structure by single bonds (i.e., shared electron pairs); second, if there are any electrons left, distribute them as lone electron pairs to maximize the number of octets; and finally, if some of the atoms lack octet structures, change as many lone electron pairs into shared electron pairs as required to complete the octet shells (see also the Chapter Integration Problems 1-23 and 1-24).
Exercise 1-6

Draw Lewis structures for the following molecules: HI, CH₃CH₂CH₃, CH₃OH, HSSH, SiO₂ (OSiO), O₂, CS₂ (SCS).

**Rule 4.** Assign (formal) charges to atoms in the molecule. Each lone pair contributes two electrons to the valence electron count of an atom in a molecule, and each bonding (shared) pair contributes one. An atom is charged if this total is different from the outer-shell electron count in the free, nonbonded atom. Thus we have the formula

\[
\text{Formal charge} = \left( \text{number of outer-shell electrons on the free, neutral atom} \right) - \left( \text{number of unshared electrons on the atom in the molecule} \right) - \frac{1}{2} \left( \text{number of bonding electrons surrounding the atom in the molecule} \right)
\]

or simply

\[
\text{Formal charge} = \text{number of valence electrons} - \text{number of lone pair electrons} - \frac{1}{2} \text{number of bonding electrons}
\]

The reason for the term *formal* is that, in molecules, charge is not localized on one atom but is distributed to varying degrees over its surroundings.

As an example, which atom bears the positive charge in the hydronium ion? Each hydrogen has a valence electron count of 1 from the shared pair in its bond to oxygen. Because this value is the same as the electron count in the free atom, the (formal) charge on each hydrogen is zero. The electron count on the oxygen in the hydronium ion is 2 (the lone pair) + 3 (half of 6 bonding electrons) = 5. This value is one short of the number of outer-shell electrons in the free atom, thus giving the oxygen a charge of +1. Hence the positive charge is assigned to oxygen.

Another example is the nitrosyl cation, NO⁺. The molecule bears a lone pair on nitrogen, in addition to the triple bond connecting the nitrogen to the oxygen atom. This gives nitrogen five valence electrons, a value that matches the count in the free atom; therefore the nitrogen atom has no charge. The same number of valence electrons (5) is found on oxygen. Because the free oxygen atom requires six valence electrons to be neutral, the oxygen in NO⁺ possesses the +1 charge. Other examples are shown below.

```
\begin{align*}
\text{Hydronium ion} & \quad \text{H}^+ : \text{O} : \text{H} \\
\text{Nitrosyl cation} & \quad : \text{N} : \ddot{\text{O}} : \\
\text{Ethynyl (vinyl) cation} & \quad \text{H}^+ \text{:C} \dddot{\text{C}} \dddot{\text{H}} \\
\text{Methyl cation} & \quad \text{H}^+ \dddot{\text{C}} : \text{H} \\
\text{Ammonium ion} & \quad \text{H}^+ \dddot{\text{N}} : \text{H} \\
\text{Methanethiolate ion} & \quad \text{H}^+ \dddot{\text{C}} : \text{S}^- \\
\text{Protonated formaldehyde} & \quad \dddot{\text{O}}^+ \dddot{\text{H}} \\
\text{Charge-separated Lewis structures} & \quad -\dddot{\text{C}} \equiv \dddot{\text{O}}^+ : \\
\text{Carbon monoxide} & \quad \dddot{\text{H}}^+: \text{O} : \\
\text{Nitric acid} & \quad : \dddot{\text{N}}: \dddot{\text{O}}^- : \\
\end{align*}
```

Sometimes the octet rule leads to charges on atoms even in neutral molecules. The Lewis structure is then said to be *charge separated*. An example is carbon monoxide, CO. Some compounds containing nitrogen–oxygen bonds, such as nitric acid, HNO₃, also exhibit this property.

**The octet rule does not always hold**

The octet rule strictly holds only for the elements of the second row and then only if there is a sufficient number of valence electrons to satisfy it. Thus, there are three exceptions to be considered.
Chapter 1
Structure and Bonding in Organic Molecules

Exception 1. You will have noticed that all our examples of “correct” Lewis structures contain an even number of electrons; that is, all are distributed as bonding or lone pairs. This distribution is not possible in species having an odd number of electrons, such as nitrogen oxide (NO) and neutral methyl (methyl radical, \(-\text{CH}_3\); see Section 3-1).

\[
\begin{align*}
\text{Nitrogen oxide} & :N\cdot\cdot\cdot:O \\
\text{Methyl radical} & :H\cdot\cdot\cdot:CH_3 \\
\text{Beryllium hydride} & :H\cdot\cdot\cdot:Be: \cdot \cdot \cdot:H \\
\text{Borane} & :H\cdot\cdot\cdot:B\cdot\cdot\cdot: \cdot \cdot \cdot:H
\end{align*}
\]

Exception 2. Some compounds of the early second-row elements, such as \(\text{BeH}_2\) and \(\text{BH}_3\), have a deficiency of valence electrons.

Because compounds falling under exceptions 1 and 2 do not have octet configurations, they are unusually reactive and transform readily in reactions that lead to octet structures. For example, two molecules of \(-\text{CH}_3\) react with each other spontaneously to give ethane, \(\text{CH}_3\text{–CH}_3\), and \(\text{BH}_3\) reacts with hydride, \(\text{H}^-\), to give borohydride, \(\text{BH}_4^-\).

\[
\begin{align*}
\text{Ethane} & \quad \text{H} \cdot \cdot \cdot: \text{CH}_3 + \cdot \cdot \cdot: \text{CH}_3 \rightarrow \text{H} \cdot \cdot \cdot: \cdot \cdot \cdot: \text{CH}_3 \\
\text{Borohydride} & \quad \text{H} \cdot \cdot \cdot: \text{B} + \cdot \cdot \cdot: \text{H}^- \rightarrow \text{H} \cdot \cdot \cdot: \cdot \cdot \cdot: \text{H}
\end{align*}
\]

Exception 3. Beyond the second row, the simple Lewis model is not strictly applied, and elements may be surrounded by more than eight valence electrons, a feature referred to as valence-shell expansion. For example, phosphorus and sulfur (as relatives of nitrogen and oxygen) are trivalent and divalent, respectively, and we can readily formulate Lewis octet structures for their derivatives. But they also form stable compounds of higher valency, among them the familiar phosphoric and sulfuric acids. Some examples of octet and expanded-octet molecules containing these elements are shown below.

\[
\begin{align*}
\text{Phosphorous trichloride} & \quad \text{Cl} \cdot \cdot \cdot: \cdot \cdot \cdot: \cdot \cdot \cdot: \text{Cl} \\
\text{Phosphoric acid} & \quad \text{H} \cdot \cdot \cdot: \text{O} \cdot\cdot\cdot: \cdot \cdot \cdot: \text{H} \\
\text{Hydrogen sulfide} & \quad \text{H} \cdot \cdot \cdot: \cdot \cdot \cdot: \cdot \cdot \cdot: \text{S} \\
\text{Sulfuric acid} & \quad \text{H} \cdot \cdot \cdot: \cdot \cdot \cdot: \cdot \cdot \cdot: \text{O} \cdot\cdot\cdot: \cdot \cdot \cdot: \text{H}
\end{align*}
\]

An explanation for this apparent violation of the octet rule is found in a more sophisticated description of atomic structure by quantum mechanics (Section 1-6). However, you will notice that, even in these cases, you can construct dipolar forms in which the Lewis octet rule is preserved (see Section 1-5).

Covalent bonds can be depicted as straight lines

Electron-dot structures can be cumbersome, particularly for larger molecules. It is simpler to represent covalent single bonds by single straight lines; double bonds are represented by
two lines and triple bonds by three. Lone electron pairs can either be shown as dots or simply omitted. The use of such notation was first suggested by the German chemist August Kekulé,* long before electrons were discovered; structures of this type are often called Kekulé structures.

**Straight-Line Notation for the Covalent Bond**

- **Methane**
  - H\(\equiv\)C\(\equiv\)H
  - N\(\equiv\)N:
  - Ethene
  - H\(\equiv\)C\(\equiv\)H
  - Hydronium ion
  - Protonated formaldehyde

---

**Exercise 1-7**

**Working with the Concepts: Drawing Lewis Structures**

**Draw** the Lewis structure of HClO\(_2\) (HOCIO), including the assignment of any charges to atoms.

**Strategy**
To solve such a problem, it is best to follow one by one the rules given in this section for drawing Lewis structures.

**Solution**
- **Rule 1:** The molecular skeleton is given as unbranched, as shown.
- **Rule 2:** Count the number of valence electrons:
  \[ \text{H} = 1, \quad 2 \text{O} = 12, \quad \text{Cl} = 7, \quad \text{total} = 20 \]
- **Rule 3:** How many bonds (shared electron pairs) do we need? The supply of electrons is 20; the electron requirement is 2 for H and 3\(\times\)8 = 24 electrons for the other three atoms, for a total of 26 electrons. Thus we need \((26 - 20)/2 = 3\) bonds.

To distribute all valence electrons according to the octet rule, we first connect all atoms by two-electron bonds, H\(\equiv\)O\(\equiv\)Cl\(\equiv\)O, using up 6 electrons. Second, we distribute the remaining 14 electrons to provide octets for all nonhydrogen atoms, (arbitrarily) starting at the left oxygen. This process requires in turn 4, 4, and 6 electrons, resulting in octet structures without needing additional electron sharing:

\[ \begin{align*}
\text{H:} & \quad \text{O:} \quad \text{Cl:} \quad \text{O:} \\
\text{4 electrons} & \quad \text{4 electrons} & \quad \text{6 electrons} \\
\end{align*} \]

- **Rule 4:** We determine any formal charges by noting any discrepancies between the “effective” valence electron count around each atom in the molecule we have found and its outer-shell count when isolated. For H in HOCIO, the valence electron count is 1, which is the same as in the H atom, so it is neutral in the molecule. For the neighboring oxygen, the two values are again the same, 6. For Cl, the effective electron count is 6, but the neutral atom requires 7. Therefore, Cl bears a positive charge. For the terminal O, the electron counts are 7 (in the molecule) and 6 (neutral atom), giving it a negative charge. The final result is

\[ \begin{align*}
\text{H:} & \quad \text{O:} \quad \text{Cl:} \quad \text{O:} \\
\text{4 electrons} & \quad \text{4 electrons} & \quad \text{6 electrons} & \quad \text{6 electrons} \\
\end{align*} \]

---

**Exercise 1-8**

**Try It Yourself**

Draw Lewis structures of the following molecules, including the assignment of any charges to atoms (the order in which the atoms are attached is given in parentheses, when it may not be obvious from the formula as it is commonly written): SO, F\(_2\)O (FOF), BF\(_3\)NH\(_3\) (F\(_3\)BNH\(_3\)), CH\(_3\)OH\(_2\)\(^+\) (H\(_3\)COH\(_2\)\(^+\)), Cl\(_2\)C\(\equiv\)O, CN\(^-\), C\(_2\)\(^2-\).

---

*Professor F. August Kekulé von Stradonitz (1829–1896), University of Bonn, Germany.
In Summary Lewis structures describe bonding by the use of electron dots or straight lines. Whenever possible, they are drawn so as to give hydrogen an electron duet and other atoms an electron octet. Charges are assigned to each atom by evaluating its electron count.

1-5 Resonance Forms

In organic chemistry, we also encounter molecules for which there are several correct Lewis structures.

The carbonate ion has several correct Lewis structures

Let us consider the carbonate ion, \( \text{CO}_3^{2-} \). Following our rules, we can easily draw a Lewis structure (A) in which every atom is surrounded by an octet. The two negative charges are located on the bottom two oxygen atoms; the third oxygen is neutral, connected to the central carbon by a double bond and bearing two lone pairs. But why choose the bottom two oxygen atoms as the charge carriers? There is no reason at all—it is a completely arbitrary choice. We could equally well have drawn structure B or C to describe the carbonate ion. The three correct Lewis pictures are called resonance forms.

Resonance Forms of the Carbonate Ion

The individual resonance forms are connected by double-headed arrows and are placed within one set of square brackets. They have the characteristic property of being interconvertible by electron-pair movement only, indicated by red arrows, the nuclear positions in the molecule remaining unchanged. Note that, to turn A into B and then into C, we have to shift two electron pairs in each case. Such movement of electrons can be depicted by curved arrows, a procedure informally called “electron pushing.”

The use of curved arrows to depict electron-pair movement is a useful technique that will prevent us from making the common mistake of changing the total number of electrons when we draw resonance forms. It is also advantageous in keeping track of electrons when formulating mechanisms (Sections 2-2 and 6-3).

But what is its true structure?

Does the carbonate ion have one uncharged oxygen atom bound to carbon through a double bond and two other oxygen atoms bound through a single bond each, both bearing a negative charge, as suggested by the Lewis structures? Or, to put it differently, are A, B, and C equilibrating isomers? The answer is no. If that were true, the carbon–oxygen bonds would be of different lengths, because double bonds are normally shorter than single bonds. But the carbonate ion is perfectly symmetrical and contains a trigonal central carbon, all C–O bonds being of equal length—between the length of a double and that of a single bond. The negative charge is evenly distributed over all three oxygens: It is said to be delocalized, in accord with the tendency of electrons to “spread out in space” (Section 1-2). In other words, none of the individual Lewis representations of this
molecule is correct on its own. Rather, the true structure is a composite of A, B, and C. The resulting picture is called a resonance hybrid. Because A, B, and C are equivalent (i.e., each is composed of the same number of atoms, bonds, and electron pairs), they contribute equally to the true structure of the molecule, but none of them by itself accurately represents it.

Because it minimizes coulombic repulsion, delocalization by resonance has a stabilizing effect: The carbonate ion is considerably more stable than would be expected for a doubly negatively charged organic molecule.

The word resonance may imply to you that the molecule vibrates or equilibrates from one form to another. This inference is incorrect. The molecule never looks like any of the individual resonance forms; it has only one structure, the resonance hybrid. Unlike substances in ordinary chemical equilibria, resonance forms are not real, although each makes a partial contribution to reality. The trigonal symmetry of carbonate is clearly evident in its electrostatic potential map shown on page 18.

An alternative convention used to describe resonance hybrids such as carbonate is to represent the bonds as a combination of solid and dotted lines. The \( \frac{2}{3} \) sign here indicates that a partial charge (\( \frac{2}{3} \) of a negative charge) resides on each oxygen atom (see margin). The equivalence of all three carbon–oxygen bonds and all three oxygens is clearly indicated by this convention. Other examples of resonance hybrids of octet Lewis structures are the acetate ion and the 2-propenyl (allyl) anion.

Resonance is also possible for nonoctet molecules. For example, the 2-propenyl (allyl) cation is stabilized by resonance.

When drawing resonance forms, keep in mind that (1) pushing one electron pair toward one atom and away from another results in a movement of charge; (2) the relative positions of all the atoms stay unchanged—only electrons are moved; (3) equivalent resonance forms contribute equally to the resonance hybrid; and (4) the arrows connecting resonance forms are double headed (\( \leftrightarrow \)).

The recognition and formulation of resonance forms is important in predicting reactivity. For example, reaction of carbonate with acid can occur at any two of the three oxygens to give carbonic acid, \( \text{H}_2\text{CO}_3 \) (which is actually in equilibrium with \( \text{CO}_2 \) and \( \text{H}_2\text{O} \)). Similarly, acetate ion is protonated at either oxygen to form acetic acid (see margin). Analogously, the 2-propenyl anion is protonated at either terminus to furnish propene, and
the corresponding cation reacts with hydroxide at either end to give the corresponding alcohol (see below).

\[
\begin{align*}
\text{Propene} & \quad + \text{H}^+ \longrightarrow \text{C} = \text{C} - \text{H} \quad \text{is the same as} \quad \text{H} - \text{C} = \text{C} - \text{H} \\
\text{2-Propen-1-ol} & \quad + \text{HO}^- \longrightarrow \text{C} = \text{C} - \text{H} \quad \text{is the same as} \quad \text{H} - \text{C} = \text{C} - \text{H}
\end{align*}
\]

**Exercise 1-9**

(a) Draw two resonance forms for nitrite ion, \( \text{NO}_2^- \). What can you say about the geometry of this molecule (linear or bent)? (Hint: Consider the effect of electron repulsion exerted by the lone pair on nitrogen.)

(b) The possibility of valence-shell expansion increases the number of feasible resonance forms, and it is often difficult to decide on one that is “best.” One criterion that is used is whether the Lewis structure predicts bond lengths and bond angles with reasonable accuracy. Draw Lewis octet and valence-shell-expanded resonance forms for \( \text{SO}_2 \) (OSO). Considering the Lewis structure for \( \text{SO} \) (Exercise 1-8), its experimental bond length of 1.48 Å, and the measured S–O distance in \( \text{SO}_2 \) of 1.43 Å, which one of the various structures would you consider “best”?

**Not all resonance forms are equivalent**

The molecules described above all have equivalent resonance forms. However, many molecules are described by resonance forms that are not equivalent. An example is the enolate ion. The two resonance forms differ in the locations of both the double bond and the charge.

**The Two Nonequivalent Resonance Forms of the Enolate Ion**

\[
\begin{align*}
\text{Enolate ion} & \quad \left[ \text{H} - \text{C} = \text{C} - \text{H} \right] \\
& \quad \text{is the same as} \quad \left[ \text{H} - \text{C} = \text{C} - \text{H} \right]
\end{align*}
\]

Although both forms are contributors to the true structure of the ion, we shall see that one contributes more than the other. The question is, which one? If we extend our consideration of nonequivalent resonance forms to include those containing atoms without electron octets, the question becomes more general.

**[Octet ↔ Nonoctet] Resonance Forms**

\[
\begin{align*}
\text{Formaldehyde} & \quad \left[ \text{H} - \text{C} = \text{H} \right] \\
\text{Sulfuric acid} & \quad \left[ \text{H} - \text{O} - \text{S} - \text{O} - \text{H} \right]
\end{align*}
\]
Such an extension requires that we relax our definitions of “correct” and “incorrect” Lewis structures and broadly regard all resonance forms as potential contributors to the true picture of a molecule. The task is then to recognize which resonance form is the most important one. In other words, which one is the major resonance contributor? Here are some guidelines.

**Guideline 1.** *Structures with a maximum of octets are most important.* In the enolate ion, all component atoms in either structure are surrounded by octets. Consider, however, the nitrosyl cation, NO⁺: One resonance form has a positive charge on oxygen with electron octets around both atoms; the other form places the positive charge on nitrogen, thereby resulting in an electron sextet on this atom. Because of the octet rule, the second structure contributes less to the hybrid. Thus, the N–O linkage is closer to being a triple than a double bond, and more of the positive charge is on oxygen than on nitrogen. Similarly, the dipolar resonance form for formaldehyde (p. 20) generates an electron sextet around carbon, rendering it a minor contributor. The possibility of valence shell expansion for third-row elements (Section 1-4) makes the non-charge-separated picture of sulfuric acid with 12 electrons around sulfur a feasible resonance form, but the dipolar octet structure is better.

**Guideline 2.** *Charges should be preferentially located on atoms with compatible electronegativity.* Consider again the enolate ion. Which is the major contributing resonance form? Guideline 2 requires it to be the first, in which the negative charge resides on the more electronegative oxygen atom. Indeed, the electrostatic potential map shown in the margin on p. 20 confirms this expectation.

Looking again at NO⁺, you might find guideline 2 confusing. The major resonance contributor to NO⁺ has the positive charge on the more electronegative oxygen. In cases such as this, the octet rule overrides the electronegativity criterion; that is, guideline 1 takes precedence over guideline 2.

**Guideline 3.** *Structures with less separation of opposite charges are more important resonance contributors than those with more charge separation.* This rule is a simple consequence of Coulomb’s law: Separating opposite charges requires energy; hence neutral structures are better than dipolar ones. An example is formic acid, shown below. However, the influence of the minor dipolar resonance form is evident in the electrostatic potential map in the margin: The electron density at the carbonyl oxygen is greater than that at its hydroxy counterpart.

In some cases, to draw octet Lewis structures, charge separation is necessary; that is, guideline 1 takes precedence over guideline 3. An example is carbon monoxide. Other examples are phosphoric and sulfuric acids, although valence-shell expansion allows the formulation of expanded octet structures (see also Section 1-4 and guideline 1).

When there are several charge-separated resonance forms that comply with the octet rule, the most favorable is the one in which the charge distribution best accommodates the relative electronegativities of the component atoms (guideline 2). In diazomethane, for example, nitrogen is more electronegative than carbon, thus allowing a clear choice between the two resonance contributors (see also the electrostatic potential map in the margin).
Chapter 1
Structure and Bonding in Organic Molecules

Exercise 1-10

Working with the Concepts: Drawing Resonance Forms

Draw two all-octet resonance forms for nitrosyl chloride, ONCl. Which one is better?

**Strategy**
To formulate any octet structure, we follow the rules given in Section 1-4 for drawing Lewis structures. Once this task is completed, we can apply the procedures and guidelines from the present section to derive resonance forms and evaluate their relative contributions.

**Solution**
* Rule 1: The molecular skeleton is given as shown.
* Rule 2: Count the number of valence electrons:

\[
N = 5, \ O = 6, \ Cl = 7, \ total = 18
\]

* Rule 3: How many bonds (shared electron pairs) do we need? The supply of electrons is 18; and the electron requirement is \(3 \times 8 = 24\) electrons for the three atoms. Thus we need \((24 - 18)/2 = 3\) bonds. Because there are only three atoms, there has to be a double bond.

To distribute all valence electrons according to the octet rule, we first connect all atoms by two-electron bonds, \(O:N:Cl\), using up 4 electrons. Second, we use 2 electrons for a double bond, arbitrarily added to the left portion to render \(O::N:Cl\). Third, we distribute the remaining 12 electrons to provide octets for all atoms, (again arbitrarily) starting at the left with oxygen. This process requires in turn 4, 2, and 6 electrons, resulting in the octet structure \(O::N::Cl\); which we shall label A.

* Rule 4: We determine any formal charges by noting any discrepancies between the “effective” valence electron count around each atom in A and its outer-shell count when it is isolated. For O, the two lone pairs and the double bond give a valence electron count of 6, as in the O atom; for N it is 5 and for Cl it is 7, again as found in the respective neutrals. Thus, there is no formal charge in A.

* We are now ready to formulate resonance forms of A by moving electron pairs. You should try to do so for all such electrons. You will soon find that only one type of electron movement furnishes an all-octet structure, namely, that shown on the left below, leading to B:

\[
\begin{array}{c}
\text{Nitrosyl chloride} \\
\begin{array}{c}
\text{A} \\
\text{B}
\end{array}
\end{array}
\]

This movement is similar to that in the 2-propenyl (allyl) anion (as shown on the right above) and related allylic resonance systems described in this section. Because we started with a charge-neutral formula, the electron movement to its resonance form generates charges: a positive one at the origin of the electron movement, a negative one at its terminus.

* Which one of the two resonance forms of ONCl is better? Inspection of the three guidelines provided in this section helps us to the answer: Guideline 3 tells us that less charge separation is better than more. Thus, charge-neutral A is a better descriptor of nitrosyl chloride than charge-separated B.

Exercise 1-11

Try It Yourself

Draw resonance forms for the following two molecules. Indicate the more favorable resonance contributor in each case. (a) \(\text{CNO}^-\); (b) \(\text{NO}^-\).
To what extent can the assignment of a major resonance form help us predict reactivity? The answer is not simple, as it depends on the reagent, product stability, and other factors. For example, we shall see that the enolate ion can react at either oxygen or carbon with positively charged (or polarized) species (Section 18-1), even though, as shown earlier, more of the negative charge is at the oxygen. Another important example is the case of carbonyl compounds: Although the non-charge-separated form is dominant, the minor dipolar contributor, as shown earlier for formaldehyde, is the origin of the reactivity of the carbon–oxygen double bond, electron-rich species attacking the carbon, electron-poor ones the oxygen (Chapter 17).

In Summary Some molecules cannot be described accurately by one Lewis structure but exist as hybrids of several resonance forms. To find the most important resonance contributor, consider the octet rule, make sure that there is a minimum of charge separation, and place on the relatively more electronegative atoms as much negative and as little positive charge as possible.

1-6 Atomic Orbitals: A Quantum Mechanical Description of Electrons Around the Nucleus

So far, we have considered bonds in terms of electron pairs arranged around the component atoms in such a way as to maximize noble-gas configurations (e.g., Lewis octets) and minimize electron repulsion. This approach is useful as a descriptive and predictive tool with regard to the number and location of electrons in molecules. However, it does not answer some simple questions that you may have asked yourself while dealing with this material. For example, why are some Lewis structures “incorrect” or, ultimately, why are noble gases relatively stable? Why are some bonds stronger than others, and how can we tell? What is so good about the two-electron bond, and what do multiple bonds look like? To get some answers, we start by learning more about how electrons are distributed around the nucleus, both spatially and energetically. The simplified treatment presented here has as its basis the theory of quantum mechanics developed independently in the 1920s by Heisenberg, Schrödinger, and Dirac. In this theory, the movement of an electron around a nucleus is expressed in the form of equations that are very similar to those characteristic of waves. The solutions to these equations, called atomic orbitals, allow us to describe the probability of finding the electron in a certain region in space. The shapes of these regions depend on the energy of the electron.

The electron is described by wave equations

The classical description of the atom (Bohr theory) assumed that electrons move on trajectories around the nucleus. The energy of each electron was thought to relate to the electron’s distance from the nucleus. This view is intuitively appealing because it coincides with our physical understanding of classical mechanics. Yet it is incorrect for several reasons.

First, an electron moving in an orbit would give rise to the emission of electromagnetic radiation, which is characteristic of any moving charge. The resulting energy loss from the system would cause the electron to spiral toward the nucleus, a prediction that is completely at odds with reality.

Second, Bohr theory violates the Heisenberg uncertainty principle, because it defines the precise position and momentum of an electron at the same time.

*Professor Werner Heisenberg (1901–1976), University of Munich, Germany, Nobel Prize 1932 (physics); Professor Erwin Schrödinger (1887–1961), University of Dublin, Ireland, Nobel Prize 1933 (physics); Professor Paul Dirac (1902–1984), Florida State University, Tallahassee, Nobel Prize 1933 (physics).

†Professor Niels Bohr (1885–1962), University of Copenhagen, Denmark, Nobel Prize 1922 (physics).
A better model is afforded by considering the wave nature of moving particles. According to de Broglie’s* relation, a particle of mass $m$ that moves with velocity $v$ has a wavelength $\lambda$.

\[
\lambda = \frac{h}{mv}
\]

in which $h$ is Planck’s† constant. As a result, an orbiting electron can be described by equations that are the same as those used in classical mechanics to describe waves (Figure 1-4). These “matter waves” have amplitudes with alternating positive and negative signs. Points at which the sign changes are called nodes. Waves that interact in phase reinforce each other, as shown in Figure 1-4B. Those out of phase interfere with each other to make smaller waves (and possibly even cancel each other), as shown in Figure 1-4C.

This theory of electron motion is called quantum mechanics. The equations developed in this theory, the wave equations, have a series of solutions called wave functions, usually described by the Greek letter psi, $\psi$. Their values around the nucleus are not directly identifiable with any observable property of the atom. However, the squares ($\psi^2$) of their values at each point in space describe the probability of finding an electron at that point. The physical realities of the atom make solutions attainable only for certain specific energies. The system is said to be quantized.

---

**Exercise 1-12**

Draw a picture similar to Figure 1-4 of two waves overlapping such that their amplitudes cancel each other.

---

†Professor Max K. E. L. Planck (1858–1947), University of Berlin, Germany, Nobel Prize 1918 (physics).

---

**Figure 1-4** (A) A wave. The signs of the amplitude are assigned arbitrarily. At points of zero amplitude, called nodes, the wave changes sign. (B) Waves with amplitudes of like sign (in phase) reinforce each other to make a larger wave. (C) Waves that are out of phase subtract from each other to make a smaller wave.

---

**Note:** The + and − signs in Figure 1-4 refer to signs of the mathematical functions describing the wave amplitudes and have nothing to do with electrical charges.
Atomic orbitals have characteristic shapes

Plots of wave functions in three dimensions typically have the appearance of spheres or dumbbells with flattened or teardrop-shaped lobes. For simplicity, we may regard artistic renditions of atomic orbitals as indicating the regions in space in which the electron is likely to be found. Nodes separate portions of the wave function with opposite mathematical signs. The value of the wave function at a node is zero; therefore, the probability of finding electron density there is zero. Higher-energy wave functions have more nodes than do those of low energy.

Let us consider the shapes of the atomic orbitals for the simplest case, that of the hydrogen atom, consisting of a proton surrounded by an electron. The single lowest-energy solution of the wave equation is called the 1s orbital, the number 1 referring to the first (lowest) energy level. An orbital label also denotes the shape and number of nodes of the orbital. The 1s orbital is spherically symmetric (Figure 1-5) and has no nodes. This orbital can be represented pictorially as a sphere (Figure 1-5A) or simply as a circle (Figure 1-5B).

The next higher-energy wave function, the 2s orbital, also is unique and, again, spherical. The 2s orbital is larger than the 1s orbital; the higher-energy 2s electron is on the average farther from the positive nucleus. In addition, the 2s orbital has one node, a spherical surface of zero electron density separating regions of the wave function of opposite sign (Figure 1-6). As in the case of classical waves, the sign of the wave function on either side of the node is arbitrary, as long as it changes at the node. Remember that the sign of the wave function is not related to “where the electron is.” As mentioned earlier, the probability of electron occupancy at any point of the orbital is given by the square of the value of the wave function. Moreover, the node does not constitute a barrier of any sort to the electron, which, in this description, is regarded not as a particle but as a wave.

After the 2s orbital, the wave equations for the electron around a hydrogen atom have three energetically equivalent solutions, the 2p_x, 2p_y, and 2p_z orbitals. Solutions of equal energy of this type are called degenerate (degenus, Latin, without genus or kind). As shown in Figure 1-7, p orbitals consist of two lobes that resemble a solid figure eight or dumbbell. A p orbital is characterized by its directionality in space. The orbital axis can be aligned with any one of the x, y, and z axes, hence the labels p_x, p_y, and p_z. The two lobes of opposite sign of each orbital are separated by a nodal plane through the atom’s nucleus and perpendicular to the orbital axis.

Figure 1-5 Representations of a 1s orbital. (A) The orbital is spherically symmetric in three dimensions. (B) A simplified two-dimensional view. The plus sign denotes the mathematical sign of the wave function and is not a charge.

Figure 1-6 Representations of a 2s orbital. Notice that it is larger than the 1s orbital and that a node is present. The + and − denote the signs of the wave function. (A) The orbital in three dimensions, with a section removed to allow visualization of the node. (B) The more conventional two-dimensional representation of the orbital.
Chapter 1
Structure and Bonding in Organic Molecules

The third set of solutions furnishes the 3s and 3p atomic orbitals. They are similar in shape to, but more diffuse than, their lower-energy counterparts and have two nodes. Still higher-energy orbitals (3d, 4s, 4p, etc.) are characterized by an increasing number of nodes and a variety of shapes. They are of much less importance in organic chemistry than are the lower orbitals. To a first approximation, the shapes and nodal properties of the atomic orbitals of other elements are very similar to those of hydrogen. Therefore, we may use s and p orbitals in a description of the electronic configurations of helium, lithium, and so forth.

The Aufbau principle assigns electrons to orbitals

Approximate relative energies of the atomic orbitals up to the 5s level are shown in Figure 1-8. With its help, we can give an electronic configuration to every atom in the periodic table. To do so, we follow three rules for assigning electrons to atomic orbitals:

1. Lower-energy orbitals are filled before those with higher energy.
2. No orbital may be occupied by more than two electrons, according to the Pauli* exclusion principle. Furthermore, these two electrons must differ in the orientation of their intrinsic angular momentum, their spin. There are two possible directions of the electron spin, usually depicted by vertical arrows pointing in opposite directions. An orbital is filled when it is occupied by two electrons of opposing spin, frequently referred to as paired electrons.
3. Degenerate orbitals, such as the p orbitals, are first occupied by one electron each, all of these electrons having the same spin. Subsequently, three more, each of opposite spin, are added to the first set. This assignment is based on Hund’s† rule.

*Professor Wolfgang Pauli (1900–1958), Swiss Federal Institute of Technology (ETH) Zurich, Switzerland, Nobel Prize 1945 (physics).
†Professor Friedrich Hund (1896–1997), University of Göttingen, Germany.
With these rules in hand, the determination of electronic configuration becomes simple. Helium has two electrons in the 1s orbital and its electronic structure is abbreviated (1s)². Lithium [(1s)²(2s)¹] has one and beryllium [(1s)²(2s)²] has two additional electrons in the 2s orbital. In boron [(1s)²(2s)²(2p)¹], we begin the filling of the three degenerate 2p orbitals. This pattern continues with carbon and nitrogen, and then the addition of electrons of opposite spin for oxygen, fluorine, and neon fills all p levels. The electronic configurations of four of the elements are depicted in Figure 1-9. Atoms with completely filled sets of atomic orbitals are said to have a **closed-shell configuration**. For example,
helium, neon, and argon have this attribute (Figure 1-10). Carbon, in contrast, has an open-shell configuration.

The process of adding electrons one by one to the orbital sequence shown in Figure 1-8 is called the Aufbau principle (Aufbau, German, build up). It is easy to see that the Aufbau principle affords a rationale for the stability of the electron octet and duet. These numbers are required for closed-shell configurations. For helium, the closed-shell configuration is a 1s orbital filled with two electrons of opposite spin. In neon, the 2s and 2p orbitals are occupied by an additional eight electrons; in argon, the 3s and 3p levels accommodate eight more (Figure 1-10). The availability of 3d orbitals for the third-row elements provides an explanation for the phenomenon of valence-shell expansion (Section 1-4) and the loosening up of the strict application of the octet rule beyond neon.

Experimental verification and quantification of the relative ordering of the orbital energy levels depicted in Figures 1-8 through 1-10 can be obtained by measuring the ionization potentials of the corresponding electrons, that is, the energies required to remove these electrons from their respective orbitals. It takes more energy to do so from a 1s orbital than from a 2s orbital; similarly, ejecting an electron from a 2s level is more difficult than from its 2p counterpart, and so on. This makes intuitive sense: As we go from lower- to higher-lying orbitals, they become more diffuse and their associated electrons are located (on average) at increasing distances from the positively charged nucleus. Coulomb’s law tells us that such electrons become increasingly less “held” by the nucleus.

**Exercise 1-13**

Using Figure 1-8, draw the electronic configurations of sulfur and phosphorus.

**In Summary** The motion of electrons around the nucleus is described by wave equations. Their solutions, atomic orbitals, can be symbolically represented as regions in space, with each point given a positive, negative, or zero (at the node) numerical value, the square of which represents the probability of finding the electron there. The Aufbau principle allows us to assign electronic configurations to all atoms.

**1-7 Molecular Orbitals and Covalent Bonding**

We shall now see how covalent bonds are constructed from the overlap of atomic orbitals.

The bond in the hydrogen molecule is formed by the overlap of 1s atomic orbitals

Let us begin by looking at the simplest case: the bond between the two hydrogen atoms in H\(_2\). In a Lewis structure of the hydrogen molecule, we would write the bond as an electron pair shared by both atoms, giving each a helium configuration. How do we construct H\(_2\) by
using atomic orbitals? An answer to this question was developed by Pauling*: Bonds are made by the in-phase overlap of atomic orbitals. What does this mean? Recall that atomic orbitals are solutions of wave equations. Like waves, they may interact in a reinforcing way (Figure 1-4B) if the overlap is between areas of the wave function of the same sign, or in phase. They may also interact in a destructive way if the overlap is between areas of opposite sign, or out of phase (Figure 1-4C).

The in-phase overlap of the two 1s orbitals results in a new orbital of lower energy called a bonding molecular orbital (Figure 1-11). In the bonding combination, the wave function in the space between the nuclei is strongly reinforced. Thus, the probability of finding the electrons occupying this molecular orbital in that region is very high: a condition for bonding between the two atoms. This picture is strongly reminiscent of that shown in Figure 1-2. The use of two wave functions with positive signs for representing the in-phase combination of the two 1s orbitals in Figure 1-11 is arbitrary. Overlap between two negative orbitals would give identical results. In other words, it is overlap between like lobes that makes a bond, regardless of the sign of the wave function.

On the other hand, out-of-phase overlap between the same two atomic orbitals results in a destabilizing interaction and formation of an antibonding molecular orbital. In the antibonding molecular orbital, the amplitude of the wave function is canceled in the space between the two atoms, thereby giving rise to a node (Figure 1-11). Thus, the net result of the interaction of the two 1s atomic orbitals of hydrogen is the generation of two molecular orbitals. One is bonding and lower in energy; the other is antibonding and higher in energy. Because the total number of electrons available to the system is only two, they are placed in the lower-energy molecular orbital: the two-electron bond. The result is a decrease in total energy, thereby making H₂ more stable than two free hydrogen atoms. This difference in energy levels corresponds to the strength of the H–H bond. The interaction can be depicted schematically in an energy diagram (Figure 1-12A).

It is now readily understandable why hydrogen exists as H₂, whereas helium is monatomic. The overlap of two filled atomic orbitals, as in He₂, with a total of four electrons, leads to bonding and antibonding orbitals, both of which are filled (Figure 1-12B). Therefore, making a He–He bond does not decrease the total energy.

**The overlap of atomic orbitals gives rise to sigma and pi bonds**

The formation of molecular orbitals by the overlap of atomic orbitals applies not only to the 1s orbitals of hydrogen but also to other atomic orbitals. In general, overlap of any n atomic orbitals gives rise to n molecular orbitals. For a simple two-electron bond, n = 2, and the two molecular orbitals are bonding and antibonding, respectively. The amount of energy by which the bonding level drops and the antibonding level is raised is called the

---

*Professor Linus Pauling (1901–1994), Stanford University, Nobel Prizes 1954 (chemistry) and 1963 (peace).
energy splitting. It indicates the strength of the bond being made and depends on a variety of factors. For example, overlap is best between orbitals of similar size and energy. Therefore, two 1s orbitals will interact with each other more effectively than a 1s and a 3s.

Geometric factors also affect the degree of overlap. This consideration is important for orbitals with directionality in space, such as p orbitals. Such orbitals give rise to two types of bonds: one in which the atomic orbitals are aligned along the internuclear axis (parts A, B, C, and D in Figure 1-13) and the other in which they are perpendicular to it (part E). The first type is called a sigma (\(\sigma\)) bond, the second a pi (\(\pi\)) bond. All carbon–carbon single bonds are of the \(\sigma\) type; however, we shall find that double and triple bonds also have \(\pi\) components (Section 1-8).
Exercise 1-14

Working with the Concepts: Orbital Splitting Diagrams

Construct a molecular-orbital and energy-splitting diagram of the bonding in He2+. Is it favorable?

Strategy
To derive the molecular orbitals of the helium–helium bond, we first need to pick the appropriate atomic orbitals for overlap. The periodic table (Table 1-1) and the Aufbau principle (Figure 1-10) tell us that the orbital to use is 1s. Therefore, a bond between two He atoms is made in the same manner as the bond between two H atoms (Figure 1-11)—by the overlap of two 1s atomic orbitals.

Solution
• In-phase interaction results in the lower-energy (relative to the starting 1s orbital) bonding molecular orbital. Out-of-phase interaction produces the higher-energy antibonding molecular orbital. The resulting energy diagram is essentially identical to those shown in Figure 1-12A and B, except that He2+ contains only three electrons.
• The Aufbau principle instructs us to “fill from the bottom up.” Therefore two (bonding) electrons go into the lower energy level and one (antibonding) electron goes into the higher energy level.

\[
\text{He} - \text{He}^+ \quad \text{He}^+ - \text{He}_2^+ \]

• The net effect is a favorable interaction (in contrast to neutral He2, Figure 1-12B). Indeed, He2+ can be made in an electrical discharge of He+ with He, showing that bond formation is favorable.

Exercise 1-15

Try It Yourself

Construct a molecular-orbital and energy-splitting diagram of the bonding in LiH. Is it favorable?

(Caution: The overlapping orbital energies are not the same in this case. Hint: Consult Section 1-6, specifically the part describing the Aufbau principle. What are the electronic configurations of Li and H? The energy splitting between orbitals of unequal energies occurs such as to push the higher-lying level up, the lower-lying one down.)

In Summary
We have come a long way in our description of bonding. First, we thought of bonds in terms of Coulomb forces, then in terms of covalency and shared electron pairs, and now we have a quantum mechanical picture. Bonds are a result of the overlap of atomic orbitals. The two bonding electrons are placed in the bonding molecular orbital. Because it is stabilized relative to the two initial atomic orbitals, energy is given off during bond formation. This decrease in energy represents the bond strength.

1-8 Hybrid Orbitals: Bonding in Complex Molecules

Let us now use quantum mechanics to construct bonding schemes for more complex molecules. How can we use atomic orbitals to build linear (as in BeH2), trigonal (as in BH3), and tetrahedral molecules (as in CH4)?
Consider the molecule beryllium hydride, BeH₂. Beryllium has two electrons in the 1s orbital and two electrons in the 2s orbital. Without unpaired electrons, this arrangement does not appear to allow for bonding. However, it takes a relatively small amount of energy to promote one electron from the 2s orbital to one of the 2p levels (Figure 1-14)—energy that is readily compensated by eventual bond formation. Thus, in the 1s²2s² configuration, there are now two singly filled atomic orbitals available for bonding overlap.

One could propose bond formation in BeH₂ by overlap of the Be 2s orbital with the 1s orbital of one H and the Be 2p orbital with the second H (Figure 1-15). This scheme predicts two different bonds of unequal length, probably at an angle. However, if electron repulsion predicts that compounds such as BeH₂ should have linear structures (Section 1-3). Experiments on related compounds confirm this prediction and also show that the bonds to beryllium are of equal length.*

**sp Hybrids produce linear structures**

How can we explain this geometry in orbital terms? To answer this question, we use a quantum mechanical approach called **orbital hybridization**. Just as the mixing of atomic orbitals on different atoms forms molecular orbitals, the mixing of atomic orbitals on the same atom forms new **hybrid orbitals**.

When we mix the 2s and one of the 2p wave functions on beryllium, we obtain two new hybrids, called sp orbitals, made up of 50% s and 50% p character. This treatment rearranges the orbital lobes in space, as shown in Figure 1-16. The major parts of the orbitals, also called front lobes, point away from each other at an angle of 180°. There are two additional minor back lobes (one for each sp hybrid) with opposite sign. The remaining two p orbitals are left unchanged.

Overlap of the sp front lobes with two hydrogen 1s orbitals yields the bonds in BeH₂. The 180° angle that results from this hybridization scheme minimizes electron repulsion. The oversized front lobes of the hybrid orbitals also overlap better than do lobes of unhybridized orbitals; the result is energy reduction due to improved bonding.

---

*These predictions cannot be tested for BeH₂ itself, which exists as a complex network of Be and H atoms. However, both BeF₂ and Be(CH₃)₂ exist as individual molecules in the gas phase and possess the predicted structures.
Note that hybridization does not change the overall number of orbitals available for bonding. Hybridization of the four orbitals in beryllium gives a new set of four: two \( sp \) hybrids and two essentially unchanged \( 2p \) orbitals. We shall see shortly that carbon uses \( sp \) hybrids when it forms triple bonds.

**\( sp^2 \) Hybrids create trigonal structures**

Now let us consider an element in the periodic table with three valence electrons. What bonding scheme can be derived for borane, BH\(_3\)? Promotion of a \( 2s \) electron in boron to one of the \( 2p \) levels gives the three singly filled atomic orbitals (one \( 2s \), two \( 2p \)) needed for forming three bonds. Mixing these atomic orbitals creates three new hybrid orbitals, which are designated \( sp^2 \) to indicate the component atomic orbitals: 67\% \( p \) and 33\% \( s \) (Figure 1-17). The third \( p \) orbital is left unchanged, so the total number of orbitals stays the same—namely, four.
Chapter 1: Structure and Bonding in Organic Molecules

The front lobes of the three $sp^2$ orbitals of boron overlap the respective $1s$ orbitals of the hydrogen atoms to give trigonal planar $BH_3$. Again, hybridization minimizes electron repulsion and improves overlap, conditions giving stronger bonds. The remaining unchanged $p$ orbital is perpendicular to the plane incorporating the $sp^2$ hybrids. It is empty and does not enter significantly into bonding.

The molecule $BH_3$ is isoelectronic with the methyl cation, $CH_3^+$; that is, they have the same number of electrons. Bonding in $CH_3^+$ requires three $sp^2$ hybrid orbitals, and we shall see shortly that carbon uses $sp^2$ hybrids in double-bond formation.

$sp^3$ Hybridization explains the shape of tetrahedral carbon compounds

Consider the element whose bonding is of most interest to us: carbon. Its electronic configuration is $(1s)^2(2s)^2(2p)^2$, with two unpaired electrons residing in two $2p$ orbitals. Promotion of one electron from $2s$ to $2p$ results in four singly filled orbitals for bonding. We have learned that the arrangement in space of the four $C–H$ bonds of methane that would minimize electron repulsion is tetrahedral (Section 1-3). To be able to achieve this geometry, the $2s$ orbital on carbon is hybridized with all three $2p$ orbitals to make four equivalent $sp^3$ orbitals with tetrahedral symmetry, each of 75% $p$ and 25% $s$ character and occupied by one electron. Overlap with four hydrogen $1s$ orbitals furnishes methane with four equal $C–H$ bonds. The $HCH$ bond angles are typical of a tetrahedron: 109.5° (Figure 1-18).

![Figure 1-18 Hybridization in carbon to create four $sp^3$ hybrids. The resulting bonding gives $CH_4$ and other carbon compounds tetrahedral structures. The $sp^3$ hybrids contain small back lobes of sign opposite that of the front lobes. In analogy to Figure 1-16B, the energy diagram of $sp^3$-hybridized carbon contains four singly occupied, equal-energy $sp^3$ levels, in addition to the filled $1s$ orbital.](image1)

Any combination of atomic and hybrid orbitals may overlap to form bonds. For example, the four $sp^3$ orbitals of carbon can combine with four chlorine $3p$ orbitals, resulting in tetrachloromethane, $CCl_4$. Carbon–carbon bonds are generated by overlap of hybrid orbitals. In ethane, $CH_3–CH_3$ (Figure 1-19), this bond consists of two $sp^3$ hybrids, one from each of two $CH_3$ units. Any hydrogen atom in methane and ethane may be replaced by $CH_3$ or other groups to give new combinations.

In all of these molecules, and countless more, carbon is approximately tetrahedral. It is this ability of carbon to form chains of atoms bearing a variety of additional substituents that gives rise to the extraordinary diversity of organic chemistry.

![Figure 1-19 Overlap of two $sp^3$ orbitals to form the carbon–carbon bond in ethane.](image2)
Hybrid orbitals may contain lone electron pairs: ammonia and water

What sort of orbitals describe the bonding in ammonia and water (see Exercise 1-5)? Let us begin with ammonia. The electronic configuration of nitrogen, $(1s)^2(2s)^2(2p)^3$, explains why nitrogen is trivalent, three covalent bonds being needed for octet formation. We could use $p$ orbitals for overlap, leaving the nonbonding electron pair in the $2s$ level. However, this arrangement does not minimize electron repulsion. The best solution is again $sp^3$ hybridization. Three of the $sp^3$ orbitals are used to bond to the hydrogen atoms, and the fourth contains the lone electron pair. The HNH bond angles (107.3°) in ammonia are almost tetrahedral (Figure 1-20). The effect of the lone electron pair is to reduce the bond angles in NH$_3$ from the ideal tetrahedral value of 109.5°. Because it is not shared, the lone pair is relatively close to the nitrogen. As a result, it exerts increased repulsion on the electrons in the bonds to hydrogen, thereby leading to the observed bond-angle compression.

In principle, the bonding in water could also be described by formal $sp^3$ hybridization on oxygen. However, the energetic cost is now too large (see Exercise 1-17). Nevertheless, for the sake of simplicity, we can extend the picture for ammonia to water as in Figure 1-20, with an HOH bond angle of 104.5°.

Pi bonds are present in ethene (ethylene) and ethyne (acetylene)

The double bond in alkenes, such as ethene (ethylene), and the triple bond in alkynes, such as ethyne (acetylene), are the result of the ability of the atomic orbitals of carbon to adopt $sp^2$ and $sp$ hybridization, respectively. Thus, the $\sigma$ bonds in ethene are derived entirely from carbon-based $sp^2$ hybrid orbitals: C$sp^2$–C$sp^2$ for the C–C bond, and C$sp^2$–H$1s$ for holding the four hydrogens (Figure 1-21). In contrast to BH$_3$, with an empty $p$ orbital on boron, the leftover unhybridized $p$ orbitals on the ethene carbons are occupied by one electron each, overlapping to form a $\pi$ bond (recall Figure 1-13E). In ethyne, the $\sigma$ frame is made up of bonds consisting of C$sp$ hybrid orbitals. The arrangement leaves two singly occupied $p$ orbitals on each carbon and allows the formation of two $\pi$ bonds (Figure 1-21).
Exercise 1-16

Draw a scheme for the hybridization and bonding in methyl cation, CH$_3^+$, and methyl anion, CH$_3^-$.

Exercise 1-17

**Working with the Concepts: Orbital Overlap in Water**

Although it was convenient to describe water as containing an $sp^3$-hybridized oxygen atom, hybridization is unfavorable when compared to C in methane and N in ammonia. The reason is that the energy difference between the 2s and p orbitals in O is now so large that the energetic cost of hybridization can no longer be matched by the smaller number of bonds to H atoms (two, instead of four or three). Instead, the oxygen uses (essentially) unhybridized orbitals. Why is there a larger energy separation between the 2s and p orbitals in O? (**Hint:** As you proceed horizontally from C to F in the periodic table, the positive nuclear charge increases steadily. To review what effect this has on the energies of orbitals, consult the end of Section 1-6.)

Why should this phenomenon affect the process of hybridization adversely? Ponder these questions and then draw a picture of the orbitals in unhybridized O and their bonding in water. Use electron-repulsion arguments to explain the HOH bond angle of 104.5°.

**Strategy**

The intraatomic overlap of orbitals underlying hybridization is affected by the same features governing the quality of a bond made by interatomic overlap of orbitals: Overlap is best between orbitals of similar size and energy. Also, bonding is subject to the geometric constraints imposed by the molecule containing the hybridized atom (see also Problem 48). Proceeding along the series methane, ammonia, water, and hydrogen fluoride, the spherically symmetric 2s orbital is lowered more in energy than the corresponding p orbitals are by the increasing nuclear charge. One way to understand this trend is to picture the electrons in their respective orbitals: Those relatively closer to the nucleus (2s) are held increasingly more tightly than those farther away (2p). To the right of N in the periodic table, this discrepancy in energy makes hybridization of the orbitals difficult, as this process effectively moves the 2s electrons farther away from the nucleus. Thus the reduction in electron repulsion by hybridization is offset by the cost in Coulomb energy. However, we can still draw a reasonable overlap picture.

**Solution**

- We use the two singly occupied p orbitals on oxygen to overlap with the two respective hydrogen 1s orbitals (margin). In this picture, the two lone electron pairs reside in a p and the 2s orbital, respectively.
- Why, then, is the bond angle in water not 90°? Well, Coulomb’s law (electron repulsion) still operates, whether we hybridize or not. Thus the two pairs of bonding electrons increase their distance by distorting bond angles to the observed value.

Exercise 1-18

**Try It Yourself**

Extrapolate the picture for water in the preceding exercise to the bonding in HF, which also uses unhybridized orbitals.

**In Summary**

To minimize electron repulsion and maximize bonding in triatomic and larger molecules, we apply the concept of atomic-orbital hybridization to construct orbitals of appropriate shape. Combinations of s and p atomic orbitals create hybrids. Thus, a 2s and a 2p orbital mix to furnish two linear $sp$ hybrids, the remaining two p orbitals being unchanged. Combination of the 2s with two p orbitals gives three $sp^2$ hybrids used in trigonal molecules. Finally, mixing the 2s with all three p orbitals results in the four $sp^3$ hybrids that produce the geometry around tetrahedral carbon.
1-9 Structures and Formulas of Organic Molecules

A good understanding of the nature of bonding allows us to learn how chemists determine the identity of organic molecules and depict their structures. Do not underestimate the importance of drawing structures. Sloppiness in drawing molecules has been the source of many errors in the literature and, perhaps of more immediate concern, in organic chemistry examinations.

To establish the identity of a molecule, we determine its structure

Organic chemists have many diverse techniques at their disposal with which to determine molecular structure. **Elemental analysis** reveals the **empirical formula**, which summarizes the kinds and ratios of the elements present. However, other procedures are usually needed to determine the molecular formula and to distinguish between structural alternatives. For example, the molecular formula \( \text{C}_2\text{H}_6\text{O} \) corresponds to two known substances: ethanol and methoxymethane (dimethyl ether). We can tell them apart on the basis of their physical properties—for example, their melting points, boiling points (b.p.’s), refractive indices, specific gravities, and so forth. Thus ethanol is a liquid (b.p. 78.5°C) commonly used as a laboratory and industrial solvent and present in alcoholic beverages. In contrast, methoxymethane is a gas (b.p. –23°C) used as a refrigerant. Their other physical and chemical properties differ as well. Molecules such as these, which have the same molecular formula but differ in the sequence (connectivity) in which the atoms are held together, are called **constitutional** or **structural isomers** (see also Chemical Highlight 1-1).

**Exercise 1-19**

Draw the two constitutional isomers with the molecular formula \( \text{C}_4\text{H}_{10} \), showing all atoms and their bonds.

Two naturally occurring substances illustrate the biological consequences of such structural differences. Prostacyclin \( \text{I}_2 \) prevents blood inside the circulatory system from clotting. Thromboxane \( \text{A}_2 \), which is released when bleeding occurs, *induces* platelet aggregation, causing clots to form over wounds. Incredibly, these compounds are constitutional isomers (both have the molecular formula \( \text{C}_{20}\text{H}_{32}\text{O}_5 \)) with only relatively minor connectivity differences. Indeed, they are so closely related that they are synthesized in the body from a common starting material (see Section 19-13 for details).

When a compound is isolated in nature or from a reaction, a chemist may attempt to identify it by matching its properties with those of known materials. Suppose, however, that the chemical under investigation is new. In this case, structural elucidation requires the use of other methods, most of which are various forms of spectroscopy. These methods will be dealt with and applied often in later chapters.

The most complete methods for structure determination are X-ray diffraction of single crystals and electron diffraction or microwave spectroscopy of gases. These techniques reveal the exact position of every atom, as if viewed under very powerful magnification. The structural details that emerge in this way for the two isomers ethanol and methoxymethane are depicted in the form of ball-and-stick models in Figure 1-22A and B.

![Figure 1-22](image)

Three-dimensional representations of (A) ethanol and (B) methoxymethane, depicted by ball-and-stick molecular models. Bond lengths are given in angstrom units, bond angles in degrees. (C) Space-filling rendition of methoxymethane, taking into account the effective size of the electron “clouds” around the component nuclei.
Note the tetrahedral bonding around the carbon atoms and the bent arrangement of the bonds to oxygen, which is similar to that in water. A more accurate picture of the relative size of the component atoms in methoxymethane is given in Figure 1-22C, a space-filling model.

The visualization of organic molecules in three dimensions is essential for understanding their structures and, frequently, their reactivities. You may find it difficult to visualize the spatial arrangements of the atoms in even very simple systems. A good aid is a molecular model kit. You should acquire one and practice the assembly of organic structures. To encourage you in this practice and to indicate particularly good examples where building a molecular model can help you, the icon displayed in the margin will appear at the appropriate places in the text.

**Exercise 1-20**

Use your molecular model kit to construct the two isomers with the molecular formula C₄H₁₀.

### Several types of drawings are used to represent molecular structures

The representation of molecular structures was first addressed in Section 1-4, which outlined rules for drawing Lewis structures. We learned that bonding and nonbonding electrons are depicted as dots. A simplification is the straight-line notation (Kekulé structure), with lone pairs (if present) added again as dots. To simplify even further, chemists use **condensed formulas** in which most single bonds and lone pairs are omitted. The main carbon chain is written horizontally, the attached hydrogens usually to the right of the associated carbon atom. Other groups (the **substituents** on the main stem) are added through connecting vertical lines.

The most economical notation of all is the **bond-line formula**. It portrays the carbon frame by zigzag straight lines, omitting all hydrogen atoms. Each unsubstituted terminus represents a methyl group, each apex a carbon atom, and all unspecified valences are assumed to be satisfied by single bonds to hydrogen.
Figure 1-22 calls attention to a problem: How can we draw the three-dimensional structures of organic molecules accurately, efficiently, and in accord with generally accepted conventions? For tetrahedral carbon, this problem is solved by the **hashed-wedged/solid-wedged line notation**. It uses a zigzag convention to depict the main carbon chain, now defined to lie in the plane of the page. Each apex (carbon atom) is then connected to two additional lines, one hashed wedged and one solid wedged, both pointing away from the chain. These represent the remaining two bonds to carbon; the hashed-wedged line corresponds to the bond that lies below the plane of the page, and the solid-wedged line to that lying above that plane (Figure 1-23). Substituents are placed at the appropriate termini. This convention is applied to molecules of all sizes, even methane (see Figure 1-23B–E). For simplicity, we will refer to the two types of bonds as “hashed” (instead of “hashed wedged”) and “wedged” (instead of “solid wedged”).

**Exercise 1-21**

Draw condensed and bond-line formulas for each C₄H₁₀ isomer.

**Exercise 1-22**

Draw hashed-wedged line formulas for each C₄H₁₀ isomer.

**In Summary** Determination of organic structures relies on the use of several experimental techniques, including elemental analysis and various forms of spectroscopy. Molecular models are useful aids for the visualization of the spatial arrangements of the atoms in structures. Condensed and bond-line notations are useful shorthand approaches to drawing two-dimensional representations of molecules, whereas hashed-wedged line formulas provide a means of depicting the atoms and bonds in three dimensions.

**THE BIG PICTURE**

What have we learned and where do we go from here?

Much of the material covered in this introductory chapter is probably familiar to you from introductory chemistry or even high school, perhaps in a different context. Here, the purpose was to recapitulate this knowledge as it pertains to the structure and reactivity of organic molecules. The fundamental take-home lessons for organic chemistry are these:

1. The importance of Coulomb’s law (Section 1-2), as evidenced, for example, by atomic attraction (Section 1-3), relative electronegativity (Table 1-2), the electron repulsion model for the shapes of molecules (Section 1-3), and the choice of dominant resonance contributors (Section 1-5).

2. The tendency of electrons to spread out (delocalize), as manifested in resonance forms (Section 1-5) or bonding overlap (Section 1-7).

3. The correlation of the valence electron count (Sections 1-3 and 1-4) with the Aufbau principle (Section 1-6), and the associated stability of the elements in noble-gas–octet–closed-shell configurations obtained by bond formation (Sections 1-3, 1-4, and 1-7).
4. The characteristic shapes of atomic and molecular orbitals (Section 1-6), which provide a feeling for the location of the “reacting” electrons around the nuclei.

5. The overlap model for bonding (Section 1-7), which allows us to make judgments with respect to the energetics, directions, and overall feasibility of reactions.

With all this information in our grasp, we now have the tools to examine the structural and dynamic diversity of organic molecules, as well as their sites of reactivity.

CHAPTER INTEGRATION PROBLEMS

1-23. Sodium borohydride, Na\(^+\)\(\text{BH}_4\), is a reagent used in the conversion of aldehydes and ketones to alcohols (Section 8-6). It can be made by treating BH\(_3\) with Na\(^+\)H\(^-\):

\[
\text{BH}_3 + \text{Na}^+\text{H}^- \rightarrow \text{Na}^+\left[ \begin{array}{c} \text{H} \\ \text{H} \\ \text{B} \\ \text{H} \end{array} \right]^{-}
\]

a. Draw the Lewis structure of \(\text{BH}_4\).

SOLUTION

We follow the rules of Section 1-4.

Step 1. The molecular skeleton (Rule 1) is indicated in the bracketed part of the above equation: a boron atom surrounded by four hydrogen atoms.

Step 2. What is the number of valence electrons? Answer (Rule 2):

\[
\begin{aligned}
4 \text{ H} & = 4 \times 1 \text{ electron} = 4 \text{ electrons} \\
1 \text{ B} & = 3 \text{ electrons} \\
\text{Charge} = -1 & = 1 \text{ electron} \\
\text{Total} & = 8 \text{ electrons}
\end{aligned}
\]

Step 3. What is the Lewis structure? Answer (Rule 3): This one is simple; just placing two electrons each between boron and its four bonded hydrogens consumes all the valence electrons at our disposal:

\[
\begin{array}{c}
\text{H} \\
\text{H} \\
\text{B} \\
\text{H}
\end{array}
\]

Step 4. Where is the charge? Answer (Rule 4): Because each hydrogen has a valence electron count of one, namely, that of the neutral atom, the charge has to reside on boron. This conclusion can be verified by counting the valence electrons around boron: four, one more than the number associated with the atom. The correct Lewis structure is therefore

\[
\begin{array}{c}
\text{H} \\
\text{H} \\
\text{B} \\
\text{H}
\end{array}
\]

b. What is the shape of the borohydride ion?

SOLUTION

For the answer, we have to remember that electron repulsion controls the shape of simple molecules (Section 1-3). The best arrangement for \(\text{BH}_4\) is therefore the same as that for CH\(_4\): tetrahedral and, hence, \(sp^3\) hybridized (margin).

c. Draw an orbital picture of the attack of H\(^-\) on BH\(_3\). Which are the orbitals involved in overlap for bond formation?
SOLUTION
To approach the answer to this question, let us draw the orbital pictures of the species involved (Sections 1-6 and 1-8). For $\text{H}^+$, it is a doubly occupied 1$s$ orbital; for BH$_3$ it is an $sp^3$-hybridized, trigonal boron with its characteristic three bonds to hydrogen and a remaining empty 2$p$ orbital perpendicular to the molecular plane (Figure 1-17).

Which part of BH$_3$ is the hydride ion most likely to attack? Hybridization provides the answer: the empty $p$ orbital. You can readily imagine how the boron atom undergoes rehybridization from $sp^2$ to $sp^3$ during the course of the reaction. The initial overlap of the hydrogen 1$s$ orbital with the boron 2$p$ orbital changes to the final overlap of the hydrogen 1$s$ with the boron $sp^3$ hybrid orbital.

1-24. Propyne can be deprotonated twice with very strong base (i.e., the base removes the two protons labeled by arrows) to give a dianion.

Two resonance forms of the anion can be constructed in which all three carbons have Lewis octets.

a. Draw both structures and indicate which is the more important one.

SOLUTION
Let us analyze the problem one step at a time:

Step 1. What structural information is embedded in the picture given for propyne dianion? Answer (Section 1-4, Rule 1): The picture shows the connectivity of the atoms: a chain of three carbons, one of the terminal atoms bearing two hydrogens.

Step 2. How many valence electrons are available? Answer (Section 1-4, Rule 2):

- $2 \text{H} = 2 \times 1 \text{ electron} = 2 \text{ electrons}$
- $3 \text{C} = 3 \times 4 \text{ electrons} = 12 \text{ electrons}$
- Charge $= -2$
- Total $= 16 \text{ electrons}$

Step 3. How do we get a Lewis octet structure for this ion? Answer (Section 1-4, Rule 3): Using the connectivity given in the structure for propyne dianion, we can immediately dispose of eight of the available electrons:

$\text{H} - \text{C} = \text{C} - \text{C} - \text{H}$

Now, let us use the remaining eight electrons in the form of lone electron pairs to surround as many carbons as possible with octets. A good place to start is at the right, because that carbon requires...
only two electrons for this purpose. The center carbon needs two lone pairs and the carbon at the left
has to make do (for the time being) with one additional pair of electrons:

\[
\begin{align*}
\text{H} & \quad \overset{\cdot}{\text{C}} \quad \overset{\cdot}{\text{C}} : \text{H} \\
\text{H} & \quad \overset{\cdot}{\text{C}} \\
\text{C} & \quad \overset{\cdot}{\text{C}} \\
\text{C} & \quad \overset{\cdot}{\text{C}} : \text{H}
\end{align*}
\]

This structure leaves the carbon at the left with only four electrons. Thus, we have to change the two
lone pairs at the center into two shared pairs, furnishing the following dot structure:

\[
\begin{align*}
\text{H} & \quad \overset{\cdot}{\text{C}} \\
\text{H} & \quad \\
\text{C} & \quad \\
\text{C} & \quad \\
\text{C} & \quad \\
\text{C} & \quad \overset{\cdot}{\text{C}} : \text{H}
\end{align*}
\]

**Step 4.** Now every atom has its duet or octet satisfied, but we still have to concern ourselves with
charges. What are the charges on each atom? Answer (Section 1-4, Rule 4): Starting again at the
right, we can quickly ascertain that the hydrogens are charge neutral. Each is attached to carbon
through a shared electron pair, giving it an effective electron count of one, the same as in a free,
non-charged hydrogen atom. On the other hand, the carbon atom bears three shared electron pairs and one
lone pair, thus having an effective electron count of five, one more electron than the number associ-
ated with the neutral nucleus. Hence one of the negative charges is located on the carbon at the right.
The central carbon nucleus is surrounded by four shared electron pairs and is therefore neutral. Finally,
the carbon at the left is attached to its neighbor by three shared pairs and has, in addition, two unbound
electrons, giving it the other negative charge. The result is

\[
\begin{align*}
\text{H} & \quad \overset{\cdot}{\text{C}} \\
\text{H} & \quad \overset{\cdot}{\text{C}} : \text{H}
\end{align*}
\]

**Step 5.** We can now address the question of resonance forms. Is it possible to move pairs of electrons
in such a way as to generate another Lewis octet form? Answer (Section 1-5): Yes, by shifting the
lone pair on the carbon at the right into a sharing position and at the same time moving one of the
three shared pairs to the left into an unshared location:

\[
\begin{align*}
\overset{\cdot}{\text{C}} : \text{C} & \quad \overset{\cdot}{\text{C}} : \text{H} \\
\overset{\cdot}{\text{C}} : \text{C} & \quad \overset{\cdot}{\text{C}} : \text{H}
\end{align*}
\]

The consequence of this movement is the transfer of the negative charge from the carbon at the right
to the carbon at the left, which therefore becomes doubly negative.

**Step 6.** Which one of the two resonance pictures is more important? Answer (Section 1-5): Electron
repulsion makes the structure at the left a more important resonance contributor.

A final point: You could have derived the first resonance structure much more quickly by con-
sidering the information given in the reaction scheme leading to the dianion. Thus, the bond-line
formula of propyne represents its Lewis structure and the process of removing a proton each from
the respective terminal carbons leaves these carbons with two lone electron pairs and the associated
charges:

\[
\begin{align*}
\text{H} & \quad \overset{\cdot}{\text{C}} \\
\text{H} & \quad \overset{\cdot}{\text{C}} : \text{H} \\
\text{H} & \quad \overset{\cdot}{\text{C}} \\
\text{H} & \quad \overset{\cdot}{\text{C}} : \text{H}
\end{align*}
\]

The important lesson to be learned from this final point is that, whenever you are confronted with a
problem, you should take the time to complete an inventory (write it down) of all the information
given explicitly or implicitly in stating the problem.

b. Propyne dianion adopts the following hybridization: \([\text{Csp}^2\text{Csp}^2\text{Csp}^2\text{H}_3]^2^-\), in which the CH\(_2\) termi-
nus is \(sp^3\) hybridized, unlike methyl anion, in which the carbon is \(sp^3\) hybridized (Exercise 1-16).
Provide an orbital drawing of the dianion to explain this preference in hybridization.
SOLUTION
You can construct an orbital picture simply by attaching one half (the CH₂ group) of the rendition of ethene in Figure 1-21 to that of ethyne without its hydrogens.

You can clearly see how the doubly filled p orbital of the CH₂ group enters into overlap with one of the π bonds of the alkyne unit, allowing the charge to delocalize as represented by the two resonance structures.

Important Concepts
1. Organic chemistry is the chemistry of carbon and its compounds.
2. Coulomb’s law relates the attractive force between particles of opposite electrical charge to the distance between them.
3. Ionic bonds result from coulombic attraction of oppositely charged ions. These ions are formed by the complete transfer of electrons from one atom to another, typically to achieve a noble-gas configuration.
4. Covalent bonds result from electron sharing between two atoms. Electrons are shared to allow the atoms to attain noble-gas configurations.
5. Bond length is the average distance between two covalently bonded atoms. Bond formation releases energy; bond breaking requires energy.
6. Polar bonds are formed between atoms of differing electronegativity (a measure of an atom’s ability to attract electrons).
7. The shape of molecules is strongly influenced by electron repulsion.
8. Lewis structures describe bonding by the use of valence electron dots. They are drawn so as to give hydrogen an electron duet and the other atoms electron octets (octet rule). Formal charge separation should be minimized but may be enforced by the octet rule.
9. When two or more Lewis structures differing only in the positions of the electrons are needed to describe a molecule, they are called resonance forms. None correctly describes the molecule, its true representation being an average (hybrid) of all its Lewis structures. If the resonance forms of a molecule are unequal, those which best satisfy the rules for writing Lewis structures and the electronegativity requirements of the atoms are more important.
10. The motion of electrons around the nucleus can be described by wave equations. The solutions to these equations are atomic orbitals, which roughly delineate regions in space in which there is a high probability of finding electrons.
11. An s orbital is spherical; a p orbital looks like two touching teardrops or a “spherical figure eight.” The mathematical sign of the orbital at any point can be positive, negative, or zero (node). With increasing energy, the number of nodes increases. Each orbital can be occupied by a maximum of two electrons of opposite spin (Pauli exclusion principle, Hund’s rule).
12. The process of adding electrons one by one to the atomic orbitals, starting with those of lowest energy, is called the Aufbau principle.
13. A molecular orbital is formed when two atomic orbitals overlap to generate a bond. Atomic orbitals of the same sign overlap to give a bonding molecular orbital of lower energy. Atomic orbitals of opposite sign give rise to an antibonding molecular orbital of higher energy and containing a node. The number of molecular orbitals equals the number of atomic orbitals from which they derive.
14. Bonds made by overlap along the internuclear axis are called σ bonds; those made by overlap of p orbitals perpendicular to the internuclear axis are called π bonds.
15. The mixing of orbitals on the same atom results in new hybrid orbitals of different shape. One s and one p orbital mix to give two linear \( sp \) hybrids, used, for example, in the bonding of \( \text{BeH}_2 \). One s and two p orbitals result in three \( sp^2 \) hybrids, used, for example, in \( \text{BH}_3 \). One s and three p orbitals furnish four \( sp^3 \) hybrids, used, for example, in \( \text{CH}_4 \). The orbitals that are not hybridized stay unchanged. Hybrid orbitals may overlap with each other. Overlapping \( sp^3 \) hybrid orbitals on different carbon atoms form the carbon–carbon bonds in ethane and other organic molecules. Hybrid orbitals may also be occupied by lone electron pairs, as in \( \text{NH}_3 \).

16. The composition (i.e., ratios of types of atoms) of organic molecules is revealed by elemental analysis. The molecular formula gives the number of atoms of each kind.

17. Molecules that have the same molecular formula but different connectivity order of their atoms are called constitutional or structural isomers. They have different properties.

**Problems**

25. Draw a Lewis structure for each of the following molecules and assign charges where appropriate.

(a) \( \text{ClF} \)  
(b) \( \text{BrCN} \)  
(c) \( \text{SOCl}_2(\text{ClSCl}) \)
(d) \( \text{CH}_3\text{NH}_2 \)  
(e) \( \text{CH}_3\text{OCH}_3 \)  
(f) \( \text{H}_2\text{N}\text{H}_2 \)  
(g) \( \text{CH}_2\text{CO} \)  
(h) \( \text{HN}_3 \)  
(i) \( \text{N}_2\text{O} \)

26. Using electronegativity values from Table 1-2 (in Section 1-3), identify polar covalent bonds in several of the structures in Problem 25 and label the atoms \( \delta^+ \) and \( \delta^- \), as appropriate.

27. Draw a Lewis structure for each of the following species. Again, assign charges where appropriate.

(a) \( \text{H}^- \)  
(b) \( \text{CH}_3^- \)  
(c) \( \text{CH}_3^+ \)
(d) \( \text{CH}_4 \)  
(e) \( \text{CH}_3\text{NH}_3^+ \)  
(f) \( \text{CH}_2\text{O}^- \)
(g) \( \text{CH}_2 \)  
(h) \( \text{H}_2\text{C}_2^- \) (HCC)  
(i) \( \text{H}_2\text{O}_2 \) (HOOH)

28. For each of the following species, add charges wherever required to give a complete, correct Lewis structure. All bonds and nonbonded valence electrons are shown.

(a) \[ \begin{array}{c} \text{H} \\
\text{O} \\
\text{C} \\
\text{H} \\
\text{H} \end{array} \]  
(b) \[ \begin{array}{c} \text{H} \\
\text{C} \\
\text{O} \\
\text{H} \end{array} \]  
(c) \[ \begin{array}{c} \text{H} \\
\text{C} \\
\text{H} \end{array} \]

(d) \[ \begin{array}{c} \text{H} \\
\text{N} \\
\text{O} \\
\text{H} \\
\text{H} \end{array} \]  
(e) \[ \begin{array}{c} \text{H} \\
\text{O} \\
\text{B} \\
\text{O} \\
\text{H} \end{array} \]  
(f) \[ \begin{array}{c} \text{H} \\
\text{O} \\
\text{N} \\
\text{O} \\
\text{H} \end{array} \]

29. (a) The structure of the bicarbonate (hydrogen carbonate) ion, \( \text{HCO}_3^- \), is best described as a hybrid of several contributing resonance forms, two of which are shown here.

\[ \text{HCO}_3^- \]

(i) Draw at least one additional resonance form. (ii) Using curved “electron-pushing” arrows, show how these Lewis structures may be interconverted by movement of electron pairs. (iii) Determine which form or forms will be the major contributor(s) to the real structure of bicarbonate, explaining your answer on the basis of the criteria in Section 1-5.

(b) Draw two resonance forms for formaldehyde oxime, \( \text{H}_2\text{CNOH} \). As in parts (ii) and (iii) of (a), use curved arrows to interconvert the resonance forms and determine which form is the major contributor.

(c) Repeat the exercises in (b) for formaldehyde oximate ion, \( [\text{H}_2\text{CNO}]^- \).
30. Several of the compounds in Problems 25 and 28 can have resonance forms. Identify these mole-
cules and write an additional resonance Lewis structure for each. Use electron-pushing arrows to
illustrate how the resonance forms for each species are derived from one another, and in each
case indicate the major contributor to the resonance hybrid.

31. Draw two or three resonance forms for each of the following species. Indicate the major contri-
butor or contributors to the hybrid in each case.

(a) OCN\(^-\) (b) CH\(_2\)CHNH\(^-\) (c) HCONH\(_2\) (HCNH\(_2\))
(d) O\(_3\) (OOO) (e) CH\(_2\)CHCH\(_2\)\(^-\) (f) ClO\(_2\)\(^-\) (OCIO)
(g) HOCHNH\(_2\)\(^+\) (h) CH\(_3\)CNO

32. Compare and contrast the Lewis structures of nitromethane, CH\(_3\)NO\(_2\), and methyl nitrite, CH\(_3\)ONO.
Write at least two resonance forms for each molecule. Based on your examination of the reso-
nance forms, what can you say about the polarity and bond order of the two NO bonds in each
substance?

33. Write a Lewis structure for each substance. Within each group, compare (i) number of electrons,
(ii) charges on atoms, if any, (iii) nature of all bonds, and (iv) geometry.

(a) chlorine atom, Cl, and chloride ion, Cl\(^-\)
(b) borane, BH\(_3\), and phosphine, PH\(_3\)
(c) CF\(_4\) and BrF\(_4\)\(^-\) (C and Br are in the middle)
(d) nitrogen dioxide, NO\(_2\), and nitrite ion, NO\(_2\)\(^-\) (nitrogen is in the middle)
(e) NO\(_2\), SO\(_2\), and ClO\(_2\) (N, S, and Cl are in the middle)

34. Use a molecular-orbital analysis to predict which species in each of the following pairs has the
stronger bonding between atoms. (Hint: Refer to Figure 1-12.)

(a) H\(_2\) or H\(_2\)\(^+\) (b) He\(_2\) or He\(_2\)\(^+\) (c) O\(_2\) or O\(_2\)\(^+\) (d) N\(_2\) or N\(_2\)\(^+\)

35. For each molecule below, predict the approximate geometry about each indicated atom. Give the
hybridization that explains each geometry.

(a) Br\(_2\) (b) H\(_2\)C\(-\)C\(-\)CH\(_3\) (c) H\(_2\)C\(-\)O\(-\)CH\(-\)CH\(_2\)
(d) H\(_2\)C\(-\)NH\(_2\) (e) HC\(=\)+C\(-\)CH\(_2\)\(-\)OH (f) H\(_2\)C\(-\)CH\(_2\)

36. For each molecule in Problem 35, describe the orbitals that are used to form every bond to each
of the indicated atoms (atomic s, p, hybrid sp, sp\(^2\), or sp\(^3\)).

37. Draw and show the overlap of the orbitals involved in the bonds discussed in Problem 36.

38. Describe the hybridization of each carbon atom in each of the following structures. Base your
answer on the geometry about the carbon atom.

(a) CH\(_3\)Cl (b) CH\(_3\)OH (c) CH\(_3\)CH\(_2\)CH\(_3\) (d) CH\(_2\)\(=\)CH (trigonal carbons)
(e) HC\(=\)CH (linear structure) (f) O\(-\)O (g) O\(-\)O

39. Depict the following condensed formulas in Kekulé (straight-line) notation. (See also
Problem 42.)

(a) CH\(_3\)CN (b) (CH\(_3\))\(_2\)CCHCHOH (c) CH\(_3\)CHCH\(_2\)CH\(_3\)
(d) CH\(_2\)BrCHBr\(_2\) (e) CH\(_3\)CCH\(_2\)COCH\(_3\) (f) HOCH\(_2\)CH\(_2\)OCH\(_2\)CH\(_2\)OH
40. Convert the following bond-line formulas into Kekulé (straight-line) structures.

(a)  
(b)  
(c)  
(d)  
(e)  
(f)  

41. Convert the following hashed-wedged line formulas into condensed formulas.

(a)  
(b)  
(c)  
(d)  
(e)  
(f)  

42. Depict the following Kekulé (straight-line) formulas in their condensed forms.

(a)  
(b)  
(c)  
(d)  
(e)  
(f)  

43. Redraw the structures depicted in Problems 39 and 42 using bond-line formulas.

44. Convert the following condensed formulas into hashed-wedged line structures.

(a)  
(b)  
(c)  
(d)  

45. Construct as many constitutional isomers of each molecular formula as you can for (a) C₅H₁₂; (b) C₃H₇O. Draw both condensed and bond-line formulas for each isomer.

46. Draw condensed formulas showing the multiple bonds, charges, and lone electron pairs (if any) for each molecule in the following pairs of constitutional isomers. (Hint: First make sure that you can draw a proper Lewis structure for each molecule.) Do any of these pairs consist of resonance forms?

(a)  
(b)  
(c)  

47. Two resonance forms can be written for a bond between trivalent boron and an atom with a lone pair of electrons. (a) Formulate them for (i) (CH₃)₂BN(CH₃)₂; (ii) (CH₃)₂BOCH₃; (iii) (CH₃)₂BF. (b) Using the guidelines in Section 1-5, determine which form in each pair of resonance forms is more important. (c) How do the electronegativity differences between N, O, and F affect the relative importance of the resonance forms in each case? (d) Predict the hybridization of N in (i) and O in (ii).

48. The unusual molecule [2.2.2]propellane is pictured in the margin. On the basis of the given structural parameters, what hybridization scheme best describes the carbons marked by asterisks? (Make a model to help you visualize its shape.) What types of orbitals are used in the bond between them? Would you expect this bond to be stronger or weaker than an ordinary carbon–carbon single bond (which is usually 1.54 Å long)?

49. (a) On the basis of the information in Problem 38, give the likely hybridization of the orbital that contains the unshared pair of electrons (responsible for the negative charge) in each of the following species: CH₃CH₂; CH₂=CH⁻; HCC≡C⁻. (b) Electrons in sp, sp², and
sp^3 orbitals do not have identical energies. Because the 2s orbital is lower in energy than aΔ2p, the more s character a hybrid orbital has, the lower its energy will be. Therefore the sp^3 (\frac{1}{2}s \text{ and } \frac{3}{4}p \text{ in character}) is highest in energy, and the sp (\frac{1}{2}s, \frac{1}{2}p) lowest. Use this information to determine the relative abilities of the three anions in (a) to accommodate the negative charge. (c) The strength of an acid HA is related to the ability of its conjugate base A^- to accommodate negative charge. In other words, the ionization HA \rightleftharpoons H^+ + A^- is favored for a more stable A^-.

Although CH_3CH_3, CH_2=CH_2, and HC=CH are all weak acids, they are not equally so. On the basis of your answer to (b), rank them in order of acid strength.

50. A number of substances containing positively polarized carbon atoms have been labeled as “cancer suspect agents” (i.e., suspected carcinogens or cancer-inducing compounds). It has been suggested that the presence of such carbon atoms is responsible for the carcinogenic properties of these molecules. Assuming that the extent of polarization is proportional to carcinogenic potential, how would you rank the following compounds with regard to cancer-causing potency?

(a) CH_3Cl  (b) (CH_3)_3Si  (c) ClCH_2OCH_2Cl
(d) CH_2OCH_2Cl  (e) (CH_3)_3C^+

(Note: Polarization is only one of the many factors known to be related to carcinogenicity. Moreover, none of them shows the type of straightforward correlation implied in this question.)

51. Certain compounds, such as the one pictured below, show strong biological activity against cell types characteristic of prostate cancer. In this structure, locate an example of each of the following types of atoms or bonds: (a) a highly polarized covalent single bond; (b) a highly polarized covalent double bond; (c) a nearly nonpolar covalent bond; (d) an sp-hybridized carbon atom; (e) an sp^2-hybridized carbon atom; (f) an sp^3-hybridized carbon atom; (g) a bond between atoms of different hybridization; (h) the longest bond in the molecule; (i) the shortest bond in the molecule (excluding bonds to hydrogen).

![Chemical structure](image)

Team Problems

Team problems are meant to encourage discussion and collaborative learning. Try to solve team problems with a partner or small study group. Notice that the problems are divided into parts. Rather than tackling each part individually, discuss each section of the problem together. Try out the vocabulary that you learned in the chapter to question and convince yourselves that you are on the right track before you move to the next part. In general, the more you use the terms and apply the concepts presented in the text, the better you will become at correlating molecular structure and reactivity and thus visualizing bond breaking and bond making. You will begin to see the elegant patterns of organic chemistry and will not be a slave to memorization. The collaborative process used in partner or group study will force you to articulate your ideas. Talking out a solution with an “audience” instead of to yourself builds in checks and balances. Your teammates will not let you get away with, “Well, you know what I mean,” because they probably do not. You become responsible to others as well as yourself. By learning from and teaching others, you solidify your own understanding.

52. Consider the following reaction:

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 + \text{HCN} \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CCH}_1
\]
(a) Draw these condensed formulas as Lewis dot structures. Label the geometry and hybridization of the bold carbons in compounds A and B. Did the hybridization change in the course of the reaction?

(b) Draw the condensed formulas as bond-line structures.

(c) Examine the components of the reaction in light of bond polarity. Using the notation for partial charge separation, $\delta^+$ and $\delta^-$, indicate, on the bond-line structures, any polar bonds.

(d) This reaction is actually a two-step process: cyanide attack followed by protonation. Depict these processes by using the same “electron pair pushing” technique that we employed for resonance structures in Section 1-5, but now show the flow of electrons for the two steps. Clearly position the beginning (an electron pair) and the end (a positively polarized or charged nucleus) of your arrows.

**Preprofessional Problems**

Preprofessional problems are included to give you practice solving the type of problems found on exams required for entry into professional schools, such as the MCAT, DAT, chemistry GRE, and ACS exams, as well as on many undergraduate tests. Do these multiple-choice questions as you go through this course and then return to them before you take a professional school exam. These questions are to be answered “closed book”—that is, no periodic table, calculator, or the like.

53. A certain organic compound was found on combustion analysis to contain 84% carbon and 16% hydrogen ($C = 12.0, H = 1.00$). A molecular formula for the compound could be

(a) $CH_4O$  
(b) $C_6H_{12}O_2$  
(c) $C_7H_{16}$  
(d) $C_6H_{10}$  
(e) $C_{14}H_{22}$

54. The compound $\text{Br-}\text{Al-N-CH}_2\text{CH}_3$ has a formal charge of

(a) $-1$ on $N$  
(b) $+2$ on $N$  
(c) $-1$ on Al  
(d) $+1$ on Br  
(e) none of the above

55. The arrow in the structure in the margin points to a bond that is formed by

(a) overlap of an $s$ orbital on H and an $sp^2$ orbital on C  
(b) overlap of an $s$ orbital on H and an $sp^3$ orbital on C  
(c) overlap of an $s$ orbital on H and an $sp^2$ orbital on C  
(d) none of the above

56. Which compound has bond angles nearest to 120°?

(a) $\equiv\text{C}=\equiv\text{S}$  
(b) $\text{CH}_3$  
(c) $\text{H}_2\text{C}=\equiv\text{O}$  
(d) $\text{H}-\text{C}=\equiv\text{C}-\text{H}$  
(e) $\text{CH}_4$

57. The pair of structures that are resonance hybrids is

(a) $\text{HO-CHCH}_3$ and $\text{HO}^+=\text{CHCH}_3$  
(b) $\text{CH}_2=\text{CH}_2$  
(c) $\text{CH}_3\text{CH}_2\text{CH}^+$ and $\text{CH}_3\text{CH}_2\text{CH}^+$

(d) $\text{CH}_3\text{CH}_2^+$ and $\text{CH}_3\text{CH}_2^+$
In Chapter 1, we saw organic molecules containing several different types of bonds between various elements. Can we predict, on the basis of these structures, what kinds of chemical reactivity these substances will display? This chapter will begin to answer this question by showing how certain structural combinations of atoms in organic molecules, called functional groups, display characteristic and predictable behavior. We will see how the chemistry of acids and bases serves as a simple model for understanding the reactions of many functional groups, especially those containing polar bonds. We will pursue this analogy throughout the course, through the concepts of electrophiles and nucleophiles.

Most organic molecules contain a structural skeleton that carries the functional groups. This skeleton is a relatively nonpolar assembly consisting of carbon and hydrogen atoms connected by single bonds. The simplest class of organic compounds, the alkanes, lacks functional groups and is constructed entirely of singly bonded carbon and hydrogen. Therefore, alkanes serve as excellent models for the backbones of functionalized organic molecules. They are also useful compounds in their own right, as illustrated by the structure shown at the top of this page, which is called 2,2,4-trimethylpentane and is an alkane in gasoline. By studying the alkanes we can prepare ourselves to better understand the properties of molecules containing functional groups. Therefore, in this chapter we will explore the names, physical properties, and structural characteristics of the members of the alkane family.

The branched alkane 2,2,4-trimethylpentane is an important component of gasoline and the standard on which the “octane rating” system for fuel efficiency is based. The car engine shown above requires high-octane fuel to achieve the performance for which it is famous.
2-1 Kinetics and Thermodynamics of Simple Chemical Processes

The simplest chemical reactions may be described as equilibration between two distinct species. Such processes are governed by two fundamental considerations:

1. **Chemical thermodynamics**, which deals with the changes in energy that take place when processes such as chemical reactions occur. Thermodynamics controls the extent to which a reaction goes to completion.

2. **Chemical kinetics**, which concerns the velocity or rate at which the concentrations of reactants and products change. In other words, kinetics describes the speed at which a reaction goes to completion.

These two principles are frequently related, but not necessarily so. Reactions that are thermodynamically very favorable often proceed faster than do less favorable ones. Conversely, some reactions are faster than others even though they result in a comparatively less stable product. A transformation that yields the most stable products is said to be under thermodynamic control. Its outcome is determined by the net favorable change in energy in going from starting materials to products. A reaction in which the product obtained is the one formed fastest is defined as being under kinetic control. Such a product may not be the thermodynamically most stable one. Let us put these statements on a more quantitative footing.

**Equilibria are governed by the thermodynamics of chemical change**

All chemical reactions are reversible, and reactants and products interconvert to various degrees. When the concentrations of reactants and products no longer change, the reaction is in a state of equilibrium. In many cases, equilibrium lies extensively (say, more than 99.9%) on the side of the products. When this occurs, the reaction is said to go to completion. (In such cases, the arrow indicating the reverse reaction is usually omitted and, for practical purposes, the reaction is considered to be irreversible.)

Equilibria are described by equilibrium constants, \( K \). To find an equilibrium constant, divide the arithmetic product of the concentrations of the components on the right side of the reaction by that of the components on the left, all given in units of moles per liter (mol L\(^{-1}\)). A large value for \( K \) indicates that a reaction goes to completion; it is said to have a large driving force.

\[
\begin{align*}
&\text{Reaction} & & \text{Equilibrium Constant} \\
&A & \overset{\kappa}{\rightleftharpoons} & B \\
&K = \frac{[B]}{[A]} \\
&A + B & \overset{\kappa}{\rightleftharpoons} & C + D \\
&K = \frac{[C][D]}{[A][B]} \\
\end{align*}
\]

If a reaction has gone to completion, a certain amount of energy has been released. The equilibrium constant can be related directly to the thermodynamic function called the Gibbs\(^*\) standard free energy change, \( \Delta G^\circ \). At equilibrium,

\[
\Delta G^\circ = -RT \ln K = -2.303 \, RT \log K \text{ (in kcal mol}^{-1} \text{ or kJ mol}^{-1})
\]

---

\(^*\)Professor Josiah Willard Gibbs (1839–1903), Yale University, Connecticut.

\(^\dagger\)The symbol \( \Delta G^\circ \) refers to the free energy of a reaction with the molecules in their standard states (e.g., ideal molar solutions) after the reaction has reached equilibrium.
in which \( R \) is the gas constant (1.986 cal K\(^{-1}\) mol\(^{-1}\) or 8.315 J K\(^{-1}\) mol\(^{-1}\)) and \( T \) is the absolute temperature in kelvin\(^*\) (K). A negative \( \Delta G^\circ \) signifies a release of energy. The equation shows that a large value for \( K \) indicates a large favorable free energy change. At room temperature (25°C, 298 K), the preceding equation becomes

\[
\Delta G^\circ = -1.36 \log K \text{ (in kcal mol}^{-1})
\]

This expression tells us that an equilibrium constant of 10 would have a \( \Delta G^\circ \) of -1.36 kcal mol\(^{-1}\) and, conversely, a \( K \) of 0.1 would have a \( \Delta G^\circ = +1.36 \text{ kcal mol}^{-1} \). Because the relation is logarithmic, changing the \( \Delta G^\circ \) value affects the \( K \) value exponentially. When \( K = 1 \), starting materials and products are present in equal concentrations and \( \Delta G^\circ \) is zero (Table 2-1).

### The free energy change is related to changes in bond strengths and the degree of energy dispersal in the system

The Gibbs standard free energy change is related to two other thermodynamic quantities: the change in enthalpy, \( \Delta H^\circ \), and the change in entropy, \( \Delta S^\circ \).

\[
\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ
\]

In this equation, \( T \) is again in kelvin and \( \Delta H^\circ \) in kcal mol\(^{-1}\) or kJ mol\(^{-1}\), whereas \( \Delta S^\circ \) is in cal K\(^{-1}\) mol\(^{-1}\), also called entropy units (e.u.), or J K\(^{-1}\) mol\(^{-1}\).

The enthalpy change of a reaction, \( \Delta H^\circ \), is the heat absorbed or released at constant pressure during the course of the reaction. Enthalpy changes in chemical reactions relate mainly to differences between the strengths of the bonds in the products compared with those in the starting materials. Bond strengths are described quantitatively by bond-dissociation energies, \( DH^\circ \). The value of \( \Delta H^\circ \) for a reaction may be estimated by subtracting the sum of the \( DH^\circ \) values of the bonds formed from those of the bonds broken. Chapter 3 explores in detail bond-dissociation energies and their value in understanding chemical reactions.

\*Temperature intervals in kelvin and degrees Celsius are identical. Temperature units are named after Lord Kelvin, Sir William Thomson (1824–1907), University of Glasgow, Scotland, and Anders Celsius (1701–1744), University of Uppsala, Sweden.
Enthalpy Change in a Reaction

\[
\left( \text{Sum of } DH^\circ \text{ of bonds broken} \right) - \left( \text{sum of } DH^\circ \text{ of bonds formed} \right) = \Delta H^\circ
\]

If the bonds formed are stronger than those broken, the value of \( \Delta H^\circ \) is negative and the reaction is defined as **exothermic** (releasing heat). In contrast, a positive \( \Delta H^\circ \) is characteristic of an **endothermic** (heat-absorbing) process. An example of an exothermic reaction is the combustion of methane, the main component of natural gas, to carbon dioxide and liquid water.

\[\text{CH}_4 + 2 \text{O}_2 \rightarrow \text{CO}_2 + 2 \text{H}_2\text{O}_{\text{liq}} \quad \Delta H^\circ = -213 \text{ kcal mol}^{-1} (-891 \text{ kJ mol}^{-1}) \]

The exothermic nature of this reaction is due to the very strong bonds formed in the products. Many hydrocarbons release a lot of energy on combustion and are therefore valuable fuels.

If the enthalpy of a reaction depends strongly on changes in bond strength, what is the significance of \( \Delta S^\circ \), the **entropy change**? You may be familiar with the concept that entropy is related to the order of a system: Increasing disorder correlates with an increase in the value of \( S^\circ \). However, the concept of “disorder” is not readily quantifiable and cannot be applied in a precise way to scientific situations. Instead, for chemical purposes, \( \Delta S^\circ \) is used to describe changes in energy dispersal. Thus, the value of \( S^\circ \) increases with increasing **dispersal of energy content** among the constituents of a system. Because of the negative sign in front of the \( T \Delta S^\circ \) term in the equation for \( \Delta G^\circ \), a positive value for \( \Delta S^\circ \) makes a negative contribution to the free energy of the system. In other words, going from lesser to greater energy dispersal is thermodynamically favorable.

What is meant by energy dispersal in a chemical reaction? Consider a transformation in which the number of reacting molecules differs from the number of product molecules formed. For example, upon strong heating, 1-pentene undergoes cleavage into ethene and propene. This process is endothermic, primarily because a C–C bond is lost. It would not occur, were it not for entropy. Thus, two molecules are made from one, and this is associated with a relatively large positive \( \Delta S^\circ \). After bond cleavage, the energy content of the system is distributed over a greater number of particles. At high temperatures, the \(-T \Delta S^\circ \) term in our expression for \( \Delta G^\circ \) overrides the unfavorable enthalpy, making this a feasible reaction.

\[\text{CH}_3\text{CH}_2\text{CH}==\text{CH}_2 \rightarrow \text{CH}_2==\text{CH}_2 + \text{CH}_3\text{CH}==\text{CH}_2 \quad \Delta H^\circ = +22.4 \text{ kcal mol}^{-1} (+93.7 \text{ kJ mol}^{-1}) \]

Endothermic

\[\Delta S^\circ = +33.3 \text{ cal K}^{-1} \text{ mol}^{-1} \text{ or e.u. } (+139.3 \text{ J K}^{-1} \text{ mol}^{-1}) \]

**Exercise 2-1**

Calculate the \( \Delta G^\circ \) at 25°C for the preceding reaction. Is it thermodynamically feasible at 25°C? What is the effect of increasing \( T \) on \( \Delta G^\circ \)? What is the temperature at which the reaction becomes favorable? (Caution: \( \Delta S^\circ \) is in the units of cal K\(^{-1}\) mol\(^{-1}\), whereas \( \Delta H^\circ \) is in kcal mol\(^{-1}\). Don’t forget that factor of 1000!)

In contrast, energy dispersal and entropy decrease when the number of product molecules is less than the number of molecules of starting materials. For example, the reaction of
ethene (ethylene) with hydrogen chloride to give chloroethane is exothermic by $-15.5 \text{ kcal mol}^{-1}$, but the entropy makes an unfavorable contribution to the $\Delta G^\circ$; $\Delta S^\circ = -31.3 \text{ e.u.}$

$$\text{CH}_2=\text{CH}_2 + \text{HCl} \rightarrow \text{CH}_3\text{CH}_2\text{Cl}$$

$\Delta H^\circ = -15.5 \text{ kcal mol}^{-1} (-64.9 \text{ kJ mol}^{-1})$

$\Delta S^\circ = -31.3 \text{ e.u.} (-131.0 \text{ J K}^{-1} \text{ mol}^{-1})$

**Exercise 2-2**

Calculate the $\Delta G^\circ$ at 25°C for the preceding reaction. In your own words, explain why a reaction that combines two molecules into one should have a large negative entropy change.

In many organic reactions the change in entropy is small, and it often suffices to consider only the changes in bonding energy to estimate whether they are likely to occur or not. In those cases we will equate approximately $\Delta G^\circ$ to $\Delta H^\circ$. Exceptions are transformations in which the number of molecules on each side of the chemical equation differ (as shown in the examples above) or in which energy dispersal is greatly affected by profound structural changes, such as, for example, ring closures and ring openings.

**The rate of a chemical reaction depends on the activation energy**

How fast is equilibrium established? The thermodynamic features of chemical reactions do not by themselves tell us anything about their rates. Consider the combustion of methane, mentioned earlier. This process releases 213 kcal mol$^{-1}$ ($-891 \text{ kJ mol}^{-1}$), a huge amount of energy, but we know that methane does not spontaneously ignite in air at room temperature. Why is this highly favorable combustion process so slow? The answer is that during the course of this reaction the potential energy of the system changes in the manner shown in Figure 2-1. This figure, which is an example of a potential-energy diagram, plots energy as a function of reaction progress. We measure reaction progress by the reaction coordinate, which describes the combined processes of bond breaking and bond formation that constitute the overall change from the structures of the starting compounds into those of the products. The energy first rises to a maximum, a point called the transition state (TS), before decreasing to the final value, which is the energy content of the product molecules. The energy of the transition state may be viewed as a barrier to be overcome in order for the reaction to take place. The energy input required to raise the energy of the starting compounds to that of the transition state is called the activation energy, $E_a$, of the reaction.

![Figure 2-1](https://example.com/figure2-1.png)

A (highly oversimplified) potential-energy diagram for the combustion reaction of methane. Despite its thermodynamic favorability, as shown by the large negative $\Delta H^\circ$, the process is very slow because it has a high-energy transition state and a large activation energy. (In actuality, the process has many individual bond-breaking and bond-forming steps, and the applicable potential-energy diagram therefore has multiple maxima and minima.)
reaction. The higher its value, the slower the process. The transition state for methane combustion is very high in energy, corresponding to a high $E_a$ and a very low rate.

How can exothermic reactions have such high activation energies? As atoms move from their initial positions in the starting molecules, energy input is required for bond breaking to begin. At the transition state, where both partially broken old bonds and incompletely formed new ones are present, the overall loss of bonding reaches its greatest extent, and the energy content of the system is at its maximum. Beyond this point, continued strengthening of the new bonds releases energy until the atoms reach their final, fully bonded positions in the products.

**Collisions supply the energy to get past the activation-energy barrier**

Where do molecules get the energy to overcome the barrier to reaction? Molecules have kinetic energy as a result of their motion, but at room temperature the average kinetic energy is only about 0.6 kcal mol$^{-1}$ (2.5 kJ mol$^{-1}$), far below many activation-energy barriers. To pick up enough energy, molecules must collide with each other or with the walls of the container. Each collision transfers energy between molecules.

A graph called a Boltzmann* distribution curve depicts the distribution of kinetic energy. Figure 2-2 shows that, although most molecules have only average speed at any given temperature, some molecules have kinetic energies that are much higher.

The shape of the Boltzmann curve depends on the temperature. At higher temperatures, as the average kinetic energy increases, the curve flattens and shifts toward higher energies. More molecules now have energy higher than is required by the transition state, so the speed of reaction increases. Conversely, at lower temperatures, the reaction rate decreases.

**The concentration of reactants can affect reaction rates**

Consider the addition of reagent A to reagent B to give product C:

$$A + B \rightarrow C$$

In many transformations of this type, increasing the concentration of either reactant increases the rate of the reaction. In such cases, the transition-state structure incorporates both molecules A and B. The experimentally observed rate is expressed by

$$\text{Rate} = k[A][B] \text{ in units of mol L}^{-1} \text{ s}^{-1}$$

in which the proportionality constant, $k$, is also called the rate constant of the reaction. The rate constant equals the rate of the reaction at 1 molar concentrations of the two reactants.

*Professor Ludwig Boltzmann (1844–1906), University of Vienna, Austria.
A and B. A reaction for which the rate depends on the concentrations of two molecules in this way is said to be a **second-order** reaction.

In some processes, the rate depends on the concentration of only one reactant, such as the hypothetical reaction

\[
A \rightarrow B
\]

Rate = \( k[A] \) in units of \( \text{mol L}^{-1} \text{ s}^{-1} \)

A reaction of this type is said to be of **first order**.

### Exercise 2-3

**Working with the Concepts: Using Rate Equations**

What would be the reduction in rate for a reaction following the first-order rate law, \( \text{rate} = k[A] \), when half of A is consumed (i.e., after 50% conversion of the starting material)? Answer the same question for a second-order reaction for which the rate \( \text{rate} = k[A][B] \).

**Strategy**

Let us denote the initial concentration of A as \([A_0]\). The first question asks us to compare the initial rate, which equals \( k[A_0] \), with the new rate when \([A]\) has dropped to \(0.5[A_0]\). We write out the first-order rate law, substituting the new concentration, and compare the two rates.

**Solution**

* The rate constant \( k \) does not change, so

\[
\text{new rate} = k[A_{\text{new}}] = k(0.5[A_0]) = 0.5k[A_0] = 0.5(\text{initial rate})
\]

The rate is decreased to one-half its initial value.

* In the second-order process, we follow the same approach. Assuming that the initial concentrations of A and B are equal, after 50% conversion, \([A_{\text{new}}] = 0.5[A_0] \) and \([B_{\text{new}}] = 0.5[B_0] \). Replacing \([A] \) and \([B] \) in the rate law with \(0.5[A_0] \) and \(0.5[B_0] \), respectively, we obtain

\[
\text{new rate} = k[A_{\text{new}}][B_{\text{new}}] = k(0.5[A_0])(0.5[B_0]) = 0.25k[A_0][B_0] = 0.25(\text{initial rate})
\]

The rate drops to one-quarter its initial value.

### Exercise 2-4

**Try It Yourself**

The reaction described by the equation

\[
\text{CH}_3\text{Cl} + \text{NaOH} \rightarrow \text{CH}_3\text{OH} + \text{NaCl}
\]

follows the second-order rate law, \( \text{rate} = k[\text{CH}_3\text{Cl}][\text{NaOH}] \). When this reaction is carried out with starting concentrations \([\text{CH}_3\text{Cl}] = 0.2 \text{ M} \) and \([\text{NaOH}] = 1.0 \text{ M} \), the measured rate is \(1 \times 10^{-4} \text{ mol L}^{-1} \text{ s}^{-1} \). What is the rate after one-half of the \(\text{CH}_3\text{Cl}\) has been consumed? (Caution: The initial concentrations of the starting materials are not identical in this experiment. Hint: Determine how much of the NaOH has been consumed at this point and what its new concentration is, compared with its initial concentration.)

**The Arrhenius equation describes how temperature affects reaction rates**

The kinetic energy of molecules increases when they are heated, which means that a larger fraction of them have sufficient energy to overcome the activation barrier \( E_a \) (Figure 2-2). A useful rule of thumb applies to many reactions: Raising the reaction temperature by 10 degrees (Celsius) causes the rate to increase by a factor of 2 to 3. The Swedish chemist
Arrhenius* noticed the dependence of reaction rate \( k \) on temperature \( T \). He found that his measured data conformed to the equation

\[
\text{Arrhenius Equation} \quad k = A e^{-\frac{E_a}{RT}} = A e^{\frac{1}{e^{\frac{E_a}{RT}}}}
\]

The Arrhenius equation describes how rates of reactions with different activation energies vary with temperature. In this equation \( R \) is again the gas constant and \( A \) is a factor with a value characteristic of a specific reaction. You can see readily that the larger the activation energy \( E_a \), the slower the reaction. Conversely, the higher the temperature \( T \), the faster the reaction. The \( A \) term can be imagined as the maximum rate constant that the reaction would have if every molecule had sufficient collisional energy to overcome the activation barrier. This will occur at very high temperature, when \( E_a/RT \) will be close to zero and \( e^{-\frac{E_a}{RT}} \) approaches 1, thus rendering \( k \) nearly equal to \( A \).

**Exercise 2-5**

(a) Calculate \( \Delta G^o \) at 25°C for the reaction \( \text{CH}_3\text{CH}_2\text{Cl} \rightarrow \text{CH}_2==\text{CH}_2 + \text{HCl} \) (the reverse of the reaction in Exercise 2-2). (b) Calculate \( \Delta G^o \) at 500°C for the same reaction. (Hint: Apply \( \Delta G^o = \Delta H^o - T\Delta S^o \) and do not forget to first convert degrees Celsius into kelvin.)

**Exercise 2-6**

For the reaction in Exercise 2-5, \( A = 10^{14} \) and \( E_a = 58.4 \text{ kcal mol}^{-1} \). Using the Arrhenius equation, calculate \( k \) at 500°C for this reaction. \( R = 1.986 \text{ cal K}^{-1} \text{ mol}^{-1} \). (Caution: Activation energies are given in the units of \( \text{kcal mol}^{-1} \), while \( R \) is in \( \text{cal K}^{-1} \text{ mol}^{-1} \). Don’t forget that factor of 1000!)

**In Summary** All reactions are described by equilibrating the concentrations of starting materials and products. On which side the equilibrium lies depends on the size of the equilibrium constant, which in turn is related to the Gibbs free energy changes, \( \Delta G^o \). An increase in the equilibrium constant by a factor of 10 is associated with a change in \( \Delta G^o \) of about \(-1.36 \text{ kcal mol}^{-1} (-5.69 \text{ kJ mol}^{-1}) \) at 25°C. The free energy change of a reaction is composed of changes in enthalpy, \( \Delta H^o \), and entropy, \( \Delta S^o \). Contributions to enthalpy changes stem mainly from variations in bond strengths; contributions to entropy changes arise from the relative dispersal of energy in starting materials and products. Whereas these terms define the position of an equilibrium, the rate at which it is established depends on the concentrations of starting materials, the activation barrier separating reactants and products, and the temperature. The relation among rate, \( E_a \), and \( T \) is expressed by the Arrhenius equation.

**2-2 Acids and Bases; Electrophiles and Nucleophiles; Using Curved “Electron-Pushing” Arrows**

Let us turn to a fundamental application of thermodynamics: the chemistry of acids and bases. This section reviews the way in which acids and bases interact and how we quantify this process. Acid-base reactions provide a model for the reactivity of organic molecules that possess polar covalent bonds. We first introduce the use of curved arrows to indicate how the electrons move when a chemical reaction takes place.

*Professor Svante Arrhenius (1859–1927), Technical Institute of Stockholm, Sweden, Nobel Prize 1903 (chemistry), director of the Nobel Institute from 1905 until shortly before his death.*
Curved arrows show how starting materials convert to products

Bonds consist of electrons. Chemical change is defined as a process in which bonds are broken and/or formed. Therefore, when chemistry takes place, electrons move. Following the basic principles of electrostatics, electrons, being negatively charged, are attracted to sites of electron deficiency, or positive charge. Either highly electronegative or electron-deficient (and, therefore, electron-attracting) atoms, positively charged ions, or the $\delta^+$ atom in a polar covalent bond can be the destination for electron movement. The vast majority of chemical processes we will introduce in this text will involve the movement of one or more pairs of electrons.

A curved arrow ($\rightarrow$) will show the flow of an electron pair from its point of origin, either a lone pair or a covalent bond, to its destination. The electron-pair movement that interconverts resonance forms (Section 1-5) follows these same principles. However, we know that resonance forms do not represent distinct entities. When we use curved arrows to depict the electron movement associated with a chemical reaction, we are describing an actual structural change, from the Lewis structures of the starting materials to those of the products. The examples below illustrate the various ways in which curved arrows are employed in this movement. In each case a red color denotes an electron pair that moves.

1. **Dissociation of a polar covalent bond into ions (B more electronegative than A)**

   \[ A \overset{\rightarrow}{B} \longrightarrow A^+ + B^- \]

   Movement of an electron pair converts the A–B covalent bond into a lone pair on atom B

2. **Formation of a polar covalent bond from ions**

   \[ A^+ + B^- \longrightarrow A \overset{\rightarrow}{B} \]

   The reverse of the previous process: A lone pair on B moves toward A, becoming a new covalent bond between them

   As these examples show, both the formation and the cleavage of a covalent bond by electron-pair movement changes the formal charges on the atoms involved. Notice that the arrow usage in Example 2 does *not* imply that the electron pair originally on atom B leaves that atom entirely. It simply converts from a lone pair to a shared pair.

3. **Simultaneous formation and dissociation of two covalent bonds (A–B polarized as shown)**

   \[ X^- + \overset{\rightarrow}{\delta^+} A \overset{\rightarrow}{B^-} \longrightarrow X \overset{\rightarrow}{A} + \overset{\rightarrow}{B^-} \]

   Movement of two electron pairs results in substitution of one bond for another

4. **Addition of (a) an electron-pair donor or (b) an electron-pair acceptor to a multiple bond**

   (a) \[ X^- + \overset{\rightarrow}{\delta^+} A \overset{\rightarrow}{B^-} \longrightarrow X \overset{\rightarrow}{A} - B^- \]

   (b) \[ A \overset{\rightarrow}{B} + \overset{\rightarrow}{Y^+} \longrightarrow + A \overset{\rightarrow}{B} - Y \]

   As in Example 3, but A remains bonded to B in each product, because only one of the two original bonds between them is broken

   These are among the most common types of transformations that occur in organic chemistry. Notice that proper use of curved arrows automatically generates the correct Lewis structure of the product of the reaction. As you read further, try to associate each new reaction with one of the electron-movement patterns shown above.

**Exercise 2-7**

From the categories above, identify the one to which each of the following reactions belongs. Draw appropriate curved arrows to show electron movement, and give the structure of the product. *(Hint: First complete all Lewis structures by adding any missing lone pairs.)*

(a) \( \text{HO}^- + \text{H}^+ \); (b) \( \text{H}^+ + \text{H}_2\text{C} = \text{CH}_2 \); (c) \( \text{CH}_3\text{N}^- + \text{HCl} \); (d) \( \text{CH}_3\text{O}^- + \text{H}_2\text{C} = \text{O} \).
Acid and base strengths are measured by equilibrium constants

Brønsted and Lowry* have given us a simple definition of acids and bases: An acid is a proton donor and a base is a proton acceptor. Acidity and basicity are commonly measured in water. An acid donates protons to water, forming hydronium ions, whereas a base removes protons from water, forming hydroxide ions. Examples are the acid hydrogen chloride and the base ammonia. In these equations we employ curved arrows to indicate the shift of a pair of electrons, much as we did in Section 1-5. In each case, a lone pair from the base creates a new bond with an acidic proton, and the electron pair originally linking the proton to the remainder of the acid shifts to become a lone pair on the departing conjugate base. The electron flow in the case of the reaction of water with hydrogen chloride is indicated in the electrostatic potential maps below the equation. The red oxygen of water is protonated by the blue hydrogen in the acid to furnish as products the blue hydronium ion and red chloride ion.

Notice that the arrow does not point to show the H moving from the acid to the base. Instead, it shows the electron pair of the base “grabbing” the H away from the acid.

Water itself is neutral. It forms an equal number of hydronium and hydroxide ions by self-dissociation. The process is described by the equilibrium constant \( K_w \), the self-ionization constant of water. At 25°C,

\[
H_2O + H_2O \rightleftharpoons H_3O^+ + OH^- \quad K_w = [H_3O^+][OH^-] = 10^{-14} \text{ mol}^2 \text{ L}^{-2}
\]

From the value for \( K_w \), it follows that the concentration of \( H_3O^+ \) in pure water is \( 10^{-7} \text{ mol L}^{-1} \).

The pH is defined as the negative logarithm of the value for \( [H_3O^+] \).

\[
pH = -\log [H_3O^+]
\]

Thus, for pure water, the pH is +7. An aqueous solution with a pH lower than 7 is acidic; one with a pH higher than 7 is basic.

---

*Professor Johannes Nicolaus Brønsted (1879–1947), University of Copenhagen, Denmark. Professor Thomas Martin Lowry (1874–1936), University of Cambridge, England.
The acidity of a general acid, HA, is expressed by the following general equation, together with its associated equilibrium constant.  

\[
\text{HA} + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{A}^- \\
K = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}][\text{H}_2\text{O}]} 
\]

In dilute aqueous solution, [H\textsubscript{2}O] is constant at 55 mol L\textsuperscript{-1}, so this number may be incorporated into a new constant, the \textbf{acid dissociation constant}, $K_a$.  

\[
K_a = K[H_2O] = \frac{[H_3O^+][A^-]}{[HA]} \text{ mol L}^{-1}
\]

Like the concentration of H\textsubscript{3}O\textsuperscript{+} and its relation to pH, this measurement may be put on a logarithmic scale by the corresponding definition of $pK_a$.  

\[
pK_a = -\log K_a^*
\]

*K\textsubscript{a} carries the units of molarity, or mol L\textsuperscript{-1}, because it is the product of a dimensionless equilibrium constant $K$ and the concentration [H\textsubscript{2}O], which equals 55 mol L\textsuperscript{-1}. However, the logarithm function can operate only on dimensionless numbers. Therefore, pK\textsubscript{a} is properly defined as the negative log of the \textit{numerical value} of $K_a$, which is $K_a$ divided by the units of concentration. (For purposes of simplicity, we will omit the units of $K_a$ in exercises and problems.)
The $pK_a$ is the pH at which the acid is 50% dissociated. An acid with a $pK_a$ lower than 1 is defined as strong, one with a $pK_a$ higher than 4 as weak. The acidities of several common acids are compiled in Table 2-2 and compared with those of compounds with higher $pK_a$ values. Sulfuric acid and, with the exception of HF, the hydrogen halides, are very strong acids. Hydrogen cyanide, water, methanol, ammonia, and methane are decreasingly acidic, the last two being exceedingly weak.

The species $A^-$ derived from acid HA is frequently referred to as its conjugate base (conjugatus, Latin, joined). Conversely, HA is the conjugate acid of base $A^-$. The strengths of two substances that are related as a conjugate acid-base pair are inversely related: The conjugate bases of strong acids are weak, as are the conjugate acids of strong bases. For example, HCl is a strong acid, because the equilibrium for its dissociation into $H^+$ and $Cl^-$ is very favorable. The reverse process, reaction of $Cl^-$ to combine with $H^+$, is unfavorable, therefore identifying $Cl^-$ as a weak base.

\[
\begin{align*}
H^+ + Cl^- &\rightleftharpoons HCl \\
\text{Strong acid} &\quad \implies \quad \text{Conjugate base is weak}
\end{align*}
\]

In contrast, dissociation of $CH_3OH$ to produce $CH_3O^-$ and $H^+$ is unfavorable; $CH_3OH$ is a weak acid. The reverse, combination of $CH_3O^-$ with $H^+$ is favorable; we therefore consider $CH_3O^-$ to be a strong base.

\[
\begin{align*}
CH_3O^- + H^+ &\rightleftharpoons CH_3OH \\
\text{Weak acid} &\quad \implies \quad \text{Conjugate base is strong}
\end{align*}
\]

---

### Table 2-2 Relative Acidities of Common Compounds (25°C)

<table>

Note: $K_a = [H_3O^+] [A^-] / [HA]$ mol L$^-1$.

$^a$First dissociation equilibrium.
In these examples we have used curved arrows to show the electron-pair movement in both the forward and reverse directions. For the sake of simplicity, we have also used the symbol $H^+$ to depict the dissociating proton. In reality, the free proton does not exist in solution, but is always associated with the electron pair of another species present, typically the solvent. As we have seen, in water, $H^+$ is represented by the hydronium ion, $H_3O^+$. In methanol, it would be methoxonium ion $CH_3OH^+$, in methoxymethane (Figure 1-22B) it would be $(CH_3)_2OH^+$, and so on. We shall see later that in many organic reactions carried out under acidic conditions, there are several potential recipients of a dissociating proton, and it becomes cumbersome to show them all. In these cases, we will stick with the short notation $H^+$.

### Exercise 2-8

Write the formula for the conjugate base of each of the following acids. (a) Sulfurous acid, $H_2SO_3$; (b) chloric acid, $HClO_3$; (c) hydrogen sulfide, $H_2S$; (d) dimethoxonium, $(CH_3)_2OH^+$; (e) hydrogen sulfate, $HSO_4^-$.

### Exercise 2-9

Write the formula for the conjugate acid of each of the following bases. (a) Dimethylamide, $(CH_3)_2N^-$; (b) sulfide, $S^-$; (c) ammonia, $NH_3$; (d) acetone, $(CH_3)_2C=O$; (e) 2,2,2-trifluoroethoxide, $CF_3CH_2O^-$.

### Exercise 2-10

Which is the stronger acid, nitrous ($HNO_2$, $pK_a = 3.3$) or phosphorous acid ($H_3PO_3$, $pK_a = 1.3$)? Calculate $K_a$ for each.

### We can estimate relative acid and base strengths from a molecule’s structure

The relationship between structure and function is very evident in acid-base chemistry. Indeed, three structural features allow us to estimate, at least qualitatively, the relative strength of an acid HA (and hence the weakness of its conjugate base):

1. The increasing electronegativity of $A$ as we proceed from left to right across a row in the periodic table. The more electronegative the atom to which the acidic proton is attached, the more polar the bond, and the more acidic the proton will be. For example, the increasing order of acidity in the series $H_4C$, $H_3N$, $H_2O$, $HF$ parallels the increasing electronegativity of $A$ (Table 1-2).

2. The increasing size of $A$ as we proceed down a column in the periodic table. The acid strengths of the hydrogen halides increase in the order $HF < HCl < HBr < HI$. Dissociation to give $H^+$ and $A^-$ is favored for larger $A$, because the overlap of its larger outer-shell orbital with the $1s$ hydrogen orbital is poor, weakening the $H–A$ bond. In
addition, the larger outer-shell orbitals permit the electrons to occupy a larger volume of space, thus reducing electron–electron repulsion in the resulting anion.*

3. The resonance in \( A^- \) that allows delocalization of charge over several atoms. This effect is frequently enhanced by the presence of additional electronegative atoms in \( A^- \). For example, acetic acid is more acidic than methanol. In both cases, an \( \text{O}–\text{H} \) bond dissociates into ions. Methoxide, the conjugate base of methanol, possesses a localized negative charge on oxygen. In contrast, the acetate ion has two resonance forms and is able to delocalize its charge onto a second oxygen atom. Thus in the acetate ion the negative charge is better accommodated (Section 1-5), stabilizing acetate and making it the weaker base.

**Acetic Acid Is Stronger than Methanol Because Acetate Is Stabilized by Resonance**

\[
\text{CH}_3\overset{\cdot}{\text{O}}^-\text{H} + \text{H}_2\overset{\cdot}{\text{O}} \rightleftharpoons \text{CH}_3\overset{\cdot}{\text{O}}^- + \text{H}_3\overset{\cdot}{\text{O}}^+ \\
\text{Weaker acid} \quad \text{Stronger base}
\]

\[
\text{CH}_3\overset{\cdot}{\text{O}}^-\text{H} + \text{H}_2\overset{\cdot}{\text{O}} \rightleftharpoons \left[ \text{CH}_3\overset{\cdot}{\text{O}}^- \right] \leftrightarrow \text{CH}_3\overset{\cdot}{\text{O}}^- + \text{H}_2\overset{\cdot}{\text{O}}^+ \\
\text{Stronger acid} \quad \text{Weaker base}
\]

The effect of resonance is even more pronounced in sulfuric acid. The availability of \( d \) orbitals on sulfur enables us to write valence-shell-expanded Lewis structures containing as many as 12 electrons (Sections 1-4 and 1-5). Alternatively, charge-separated structures with one or two positive charges on sulfur can be used. Both representations indicate that the \( pK_a \) of \( \text{H}_2\text{SO}_4 \) should be low.

\[
\left[ \begin{array}{c}
\overset{\cdot}{\text{O}}^- \\
\text{H} \downarrow \overset{\cdot}{\text{O}}^- 
\end{array} \right] \leftrightarrow \left[ \begin{array}{c}
\overset{\cdot}{\text{O}}^- \\
\text{H} \downarrow \overset{\cdot}{\text{O}}^- 
\end{array} \right] \leftrightarrow \left[ \begin{array}{c}
\overset{\cdot}{\text{O}}^- \\
\text{H} \downarrow \overset{\cdot}{\text{O}}^- 
\end{array} \right] \leftrightarrow \left[ \begin{array}{c}
\overset{\cdot}{\text{O}}^- \\
\text{H} \downarrow \overset{\cdot}{\text{O}}^- 
\end{array} \right] \leftrightarrow \text{etc.}
\]

**Hydrogen sulfate ion**

As a rule, the acidity of HA increases to the right and down in the periodic table. Therefore, the basicity of \( A^- \) decreases in the same fashion.

---

*The bond-strength argument is often the only reason given for the acidity order in the hydrogen halides: HF possesses the strongest bond, HI the weakest. However, this correlation fails for the series \( \text{H}_2\text{C}, \text{H}_2\text{N}, \text{H}_2\text{O}, \text{HF} \), in which the weakest acid, \( \text{CH}_4 \), also has the weakest \( \text{H}–\text{A} \) bond. As we will see in Chapter 3, bond strengths are only indirectly applicable to the process of dissociation of a bond into ions.*
The same molecule may act as an acid under one set of conditions and as a base under another. Water is the most familiar example of this behavior, but many other substances possess this capability as well. For instance, nitric acid acts as an acid in the presence of water but behaves as a base toward the more powerfully acidic H₂SO₄:

**Nitric Acid Acting as an Acid**

\[
\begin{align*}
\text{HNO}_3 & \quad + \quad \text{H}_2\text{O} \\
\text{H}_3\text{O}^+ & \quad + \quad \text{NO}_3^- \\
\end{align*}
\]

**Nitric Acid Acting as a Base**

\[
\begin{align*}
\text{H}_2\text{SO}_4 & \quad + \quad \text{HNO}_2 \\
\text{H}_2\text{NO}_2^+ & \quad + \quad \text{SO}_4^{2-} \\
\end{align*}
\]

Similarly, acetic acid protonates water, as shown earlier in this section, but is protonated by stronger acids such as HBr:

\[
\begin{align*}
\text{Br} & \quad + \quad \text{CH}_3\text{COOH} \\
\text{Br}^- & \quad + \quad \text{CH}_3\text{COOH} \\
\end{align*}
\]

**Exercise 2-11**

Explain the site of protonation of acetic acid in the preceding equation. (Hint: Try placing the proton first on one, and then on the other of the two oxygen atoms in the molecule, and consider which of the two resulting structures is better stabilized by resonance.)

**Exercise 2-12**

**Working with the Concepts: Determining pKₐ**

Benzoic acid, C₆H₅CO₂H (margin), undergoes dissociation in water at 25°C according to the following dissociation equation:

\[
\text{C}_6\text{H}_5\text{CO}_2\text{H} \quad ⇌ \quad \text{C}_6\text{H}_5\text{CO}_2^- \quad + \quad \text{H}^+ \\
\]

The thermodynamic parameters for this process are \( \Delta H^\circ = -67 \text{ cal mol}^{-1} \) and \( \Delta S^\circ = -19.44 \text{ cal K}^{-1} \text{ mol}^{-1} \). Calculate the acid dissociation constant, \( K_a \), as well as the pKₐ for benzoic acid. How does benzoic acid compare in strength with acetic acid, whose pKₐ = 4.7?

**Strategy**

Acid dissociation constants describe equilibria and are related directly to \( \Delta G^\circ \) values. Therefore, to calculate the acid dissociation constant we must first determine \( \Delta G^\circ \) for the dissociation reaction at 25°C (298 K). Then we need to convert \( K_a \) to pKₐ; the lower pKₐ will indicate the stronger acid.

**Solution**

\[
\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ = -(67 \text{ cal mol}^{-1}) - [(298 K) \times (-19.44 \text{ cal K}^{-1} \text{ mol}^{-1})] \\
= -(67 \text{ cal mol}^{-1}) + (5793 \text{ cal mol}^{-1}) = +5726 \text{ cal mol}^{-1} = +5.726 \text{ kcal mol}^{-1} \\
\]

- Using \( \Delta G^\circ = -1.36 \log K \), we obtain \( \log K = -4.2 \), corresponding to a pKₐ of 4.2, and a \( K_a \) of \( 6.4 \times 10^{-5} \).
- The pKₐ that we have determined for benzoic acid is lower than the value for acetic acid (4.7). Benzoic acid is stronger.
Lewis acids and bases interact by sharing an electron pair

A more generalized description of acid-base interaction in terms of electron sharing was introduced by Lewis. A **Lewis acid** is a species that contains an atom that is at least two electrons short of a closed outer shell. A **Lewis base** contains at least one lone pair of electrons. The symbol X denotes any halogen, while R represents an organic group (Section 2-3).

**Lewis Acids** have unfilled valence shells

- $\text{H}^+ \quad \text{(X)H} \quad \text{B} \quad \text{H(X)}$  
- $\text{AlCl}_3\text{MgX}_2$, many transition metal halide salts

**Lewis Bases** have available electron pairs

- $\text{O} \quad \text{H(R)}$  
- $\text{NCl}$  

A Lewis base shares its lone pair with a Lewis acid to form a new covalent bond. A Lewis base–Lewis acid interaction may therefore be pictured by means of an arrow pointing in the direction that the electron pair moves—from the base to the acid. The Brønsted acid-base reaction between hydroxide ion and a proton is an example of a Lewis acid-base process as well.

**Lewis Acid-Base Reactions**

- $\text{H}^+ + \text{:O} \quad \text{H} \rightarrow \text{H} \quad \text{O} \quad \text{H}$

- $\text{Cl} \quad \text{CH}_3 \quad \text{Cl} \quad \text{CH}_3$
- $\text{Cl} \quad \text{Al} \quad \text{+} \quad \text{:N} \quad \text{CH}_3 \quad \rightarrow \quad \text{Cl} \quad \text{Al} \quad \text{N} \quad \text{CH}_3$

- $\text{F} \quad \text{B} \quad \text{F} \quad \text{+} \quad \text{O} \quad \text{CH}_2\text{CH}_3 \quad \rightarrow \quad \text{F} \quad \text{B} \quad \text{O} \quad \text{CH}_2\text{CH}_3$

**Exercise 2-13**

**Try It Yourself**

How much stronger an acid is acetic acid ($pK_a = 4.7$) compared to water ($pK_a = 15.7$)?

**Chapter 2**

**Structure and Reactivity**
The reaction between boron trifluoride and ethoxyethane (diethyl ether) to give the Lewis acid-base reaction product is shown on the previous page, and also in the form of electrostatic potential maps. As electron density is transferred, the oxygen becomes more positive (blue) and the boron more negative (red).

The dissociation of a Brønsted acid HA is just the reverse of the combination of the Lewis acid H⁺ and the Lewis base A⁻. We write it as follows:

\[
H - A \rightarrow H^+ + :A^-
\]

**Electrophiles and nucleophiles also interact through movement of an electron pair**

Many processes in organic chemistry exhibit characteristics of acid-base reactions. For example, heating an aqueous mixture of sodium hydroxide and chloromethane, CH₃Cl, produces methanol and sodium chloride. This process involves the same kind of movement of two pairs of electrons as does the acid-base reaction between hydroxide ion and HCl, and may be described by the same curved “electron-pushing” arrows:

**Reaction of Sodium Hydroxide and Chloromethane**

\[
\text{CH}_3\text{Cl}^+ + \text{NaOH} \xrightarrow{H_2O, \Delta} \text{CH}_3\text{OH} + \text{NaCl}^-
\]

\text{Methanol}

**Flow of Electrons Using Curved-Arrow Representation**

\[
\text{HO}^- + \text{CH}_3\text{Cl}^+ \rightarrow \text{HO}^-\text{CH}_3 + :\text{Cl}^-
\]

Like the hydrogen atom in HCl, the carbon atom in chloromethane is at the positive end of a polarized bond (Section 1-3). It therefore exhibits a tendency to react with species possessing unshared pairs of electrons. The carbon is said to be **electrophilic** (literally, “electron friendly”; philos, Greek, friend). In turn, atoms bearing lone pairs, such as the oxygen in hydroxide ion, are described as **nucleophilic** (“nucleus friendly”). This reaction is an example of a **nucleophilic substitution**, because a nucleophile substitutes itself for an atom or group in the original starting material.

By definition, the terms **nucleophile** and **Lewis base** are synonymous. **All nucleophiles are Lewis bases.** We commonly use the term **nucleophile** to refer to a Lewis base that is attacking a **nonhydrogen** electrophilic atom, typically carbon. Nucleophiles, often denoted by the abbreviation Nu, may be negatively charged, such as hydroxide, or neutral, such as water, but every nucleophile contains at least one unshared pair of electrons. **All Lewis acids are electrophiles, as shown earlier in the examples of Lewis acid-base reactions. However, species such as HCl and CH₃Cl, whose atoms have closed outer shells and therefore are not Lewis acids, nonetheless may behave as electrophiles because they possess polar bonds.**
Nucleophilic substitution is a general reaction of haloalkanes, organic compounds possessing carbon–halogen bonds. The two following equations are additional examples:

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_3 + \cdot\text{I}^- &\rightarrow \text{CH}_3\text{CH}_2\text{CH}_3 + \cdot\text{Br}^- \\
\text{CH}_3\text{CH}_3\cdot\text{I}^- + \cdot\text{NH}_3 &\rightarrow \text{CH}_3\text{CH}_3\text{NH} + \cdot\text{I}^- 
\end{align*}
\]

Exercise 2-14

**Working with the Concepts: Using Curved Arrows**

Using earlier examples in this section as models, add curved arrows to the first of the two reactions immediately above.

**Strategy**
In the organic substrate, identify the likely reactive bond and its polarization. Classify the other reacting species, and look for reactions in the text between similar types of substances.

**Solution**
- The C–Br bond is the site of reactivity in the substrate and is polarized (δ+)C–Br(δ−). Iodide is a Lewis base and therefore a potential nucleophile (electron-pair donor). Thus the situation resembles that found in the reaction between hydroxide and CH3Cl just above and Example 3 at the beginning of the section.
- Follow the earlier patterns in order to add the appropriate arrows.

Exercise 2-15

**Try It Yourself**
Add curved arrows to the second of the reactions immediately above Exercise 2-14 in the text.

Although the haloalkanes in these examples contain different halogens and varied numbers and arrangements of carbon and hydrogen atoms, they behave very similarly toward nucleophiles. We conclude that it is the presence of the carbon–halogen bond that governs the chemical behavior of haloalkanes: The C–X bond is the structural feature that directs the chemical reactivity—structure determines function. The C–X bond constitutes the functional group, or the center of chemical reactivity, of the haloalkanes. In the next section, we shall introduce the major classes of organic compounds, identify their functional groups, and briefly preview their reactivity.

**In Summary** In Brønsted-Lowry terms, acids are proton donors and bases are proton acceptors. Acid-base interactions are governed by equilibria, which are quantitatively described by an acid dissociation constant \( K_a \). Removal of a proton from an acid generates its conjugate base; attachment of a proton to a base forms its conjugate acid. Lewis bases donate
an electron pair to form a covalent bond with Lewis acids, a process depicted by a curved arrow pointing from the lone pair of the base toward the acid. Electrophiles and nucleophiles are species in organic chemistry that interact very much like acids and bases. The carbon–halogen bond in the haloalkane is its functional group. It contains an electrophilic carbon atom, which reacts with nucleophiles in a process called nucleophilic substitution.

### 2-3 Functional Groups: Centers of Reactivity

Many organic molecules consist predominantly of a backbone of carbons linked by single bonds, with only hydrogen atoms attached. However, they may also contain doubly or triply bonded carbons, as well as other elements. These atoms or groups of atoms tend to be sites of comparatively high chemical reactivity and are referred to as **functional groups** or **functionalities**. Such groups have characteristic properties, and they control the reactivity of the molecule as a whole.

**Hydrocarbons are molecules that contain only hydrogen and carbon**

We begin our study with hydrocarbons, which have the general empirical formula \( \text{C}_x\text{H}_y \). Those containing only single bonds, such as methane, ethane, and propane, are called **alkanes**. Molecules such as cyclohexane, whose carbons form a ring, are called **cycloalkanes**. **Alkanes lack functional groups**; as a result, they are relatively nonpolar and unreactive. The properties and chemistry of the alkanes are described in this chapter and in Chapters 3 and 4.

- Propene
- Ethyne (Acetylene)
- Propyne

A special hydrocarbon is **benzene**, \( \text{C}_6\text{H}_6 \), in which three double bonds are incorporated into a six-membered ring. Benzene and its derivatives are traditionally called **aromatic**, because some substituted benzenes do have a strong fragrance. Aromatic compounds, also called **arenes**, are discussed in Chapters 15, 16, 22, and 25.

### Many functional groups contain polar bonds

Polar bonds determine the behavior of many classes of molecules. Recall that polarity is due to a difference in the electronegativity of two atoms bound to each other (Section 1.3). We have already introduced the [haloalkanes](#), which contain polar carbon–halogen bonds as their functional groups. In Chapters 6 and 7 we shall explore their chemistry in depth. Another functionality is the [hydroxy](#) group, $\text{–O–H}$, characteristic of [alcohols](#). The characteristic functional unit of [ethers](#) is an oxygen bonded to two carbon atoms ($\overset{\text{O}}{\text{C}}\overset{\text{C}}{\text{O}}$). The functional group in alcohols and in some ethers can be converted into a large variety of other functionalities and are therefore important in synthetic transformations. This chemistry is the subject of Chapters 8 and 9.

#### Haloalkanes
- Chloromethane (Methyl chloride) $\text{CH}_{3}\overset{\text{C}}{\text{Cl}}$ (Topical anesthetics)
- Chloroethane (Ethyl chloride) $\text{CH}_{3}\text{CH}_{2}\overset{\text{C}}{\text{Cl}}$ (Wood alcohol)
- Methanol $\text{CH}_{3}\overset{\text{O}}{\text{H}}$ (Wood alcohol)
- Ethanol $\text{CH}_{3}\text{CH}_{2}\overset{\text{O}}{\text{H}}$ (Grain alcohol)
- Methoxymethane (Dimethyl ether) $\text{CH}_{3}\overset{\text{O}}{\text{CH}}_{3}$ (A refrigerant)
- Ethoxyethane (Diethyl ether) $\text{CH}_{3}\overset{\text{O}}{\text{CH}}_{2}\overset{\text{O}}{\text{CH}}_{2}\overset{\text{CH}}_{3}$ (An inhalation anesthetic)

#### Alcohols
- Acetone $\text{CH}_{3}\text{C} = \text{C}\text{H}_{3}$ (Common solvents)
- Butanone (Methyl ethyl ketone) $\text{CH}_{3}\text{CH}_{2}\text{C} = \text{C}\text{H}_{3}$ (Common solvents)
- Formaldehyde $\text{HCHO}$ (A disinfectant)
- Acetaldehyde $\text{CH}_{3}\text{CHO}$ (A hypnotic)

#### Ketones
- Acetone $\text{CH}_{3}\text{C} = \text{C}\text{H}_{3}$ (Common solvents)
- Butanone (Methyl ethyl ketone) $\text{CH}_{3}\text{CH}_{2}\text{C} = \text{C}\text{H}_{3}$ (Common solvents)

#### Carboxylic Acids
- Formic acid $\text{HCO}_{2}\text{H}$ (Strong irritant)
- Acetic acid $\text{CH}_{3}\text{COOH}$ (In vinegar)
Other elements give rise to further characteristic functional groups. For example, alkyl nitrogen compounds are amines. The replacement of oxygen in alcohols by sulfur furnishes thiols.

\(R\) represents a part of an alkane molecule

Table 2-3 depicts a selection of common functional groups, the class of compounds to which they give rise, a general structure, and an example. In the general structures, we commonly use the symbol \(R\) (for radical or residue) to represent an alkyl group, a molecular fragment derived by removal of one hydrogen atom from an alkane (Section 2-5). Therefore, a general formula for a haloalkane is \(R-X\), in which \(R\) stands for any alkyl group and \(X\) for any halogen. Alcohols are similarly represented as \(R-O-H\). In structures that contain multiple alkyl groups, we add a prime (‘) or double prime (‘) to \(R\) to distinguish groups that differ in structure from one another. Thus a general formula for an ether in which both alkyl groups are the same (a symmetrical ether) is \(R-O-R\), whereas an ether with two dissimilar groups (an unsymmetrical ether) is represented by \(R-O-R\).

2-4 Straight-Chain and Branched Alkanes

The functional groups in organic molecules are typically attached to a hydrocarbon scaffold constructed only with single bonds. Substances consisting entirely of single-bonded carbon and hydrogen atoms and lacking functional groups are called alkanes. They are classified into several types according to structure: the linear straight-chain alkanes; the branched alkanes, in which the carbon chain contains one or several branching points; and the cyclic alkanes, or cycloalkanes, which we shall cover in Chapter 4.

A Straight-Chain Alkane  A Branched Alkane  A Cycloalkane

\[
\begin{align*}
\text{CH}_3-\text{CH}_2-\text{CH}_2-\text{CH}_3 & \quad \text{CH}_3-\text{C}-\text{H} \quad \text{CH}_2-\text{CH}_2 \\
\text{Butane, } \text{C}_4\text{H}_{10} & \quad \text{2-Methylpropane, } \text{C}_4\text{H}_{10} (\text{Isobutane}) \quad \text{Cyclobutane, } \text{C}_4\text{H}_8
\end{align*}
\]

Straight-chain alkanes form a homologous series

In the straight-chain alkanes, each carbon is bound to its two neighbors and to two hydrogen atoms. Exceptions are the two terminal carbon nuclei, which are bound to only one carbon atom and three hydrogen atoms. The straight-chain alkane series may be described by the general formula \(\text{H}-(\text{CH}_2)_n-\text{H}\). Each member of this series differs from the next lower one by the addition of a methylene group, \(-\text{CH}_2-\). Molecules that are related in this way are homologs of each other (homos, Greek, same as), and the series is a homologous series. Methane \((n = 1)\) is the first member of the homologous series of the alkanes, ethane \((n = 2)\) the second, and so forth.
Branched alkanes are constitutional isomers of straight-chain alkanes

Branched alkanes are derived from the straight-chain systems by removal of a hydrogen from a methylene (CH₂) group and replacement with an alkyl group. Both branched and straight-chain alkanes have the same general formula, CₙH₂n+2. The smallest branched alkane is 2-methylpropane. It has the same molecular formula as that of butane (C₄H₁₀) but different connectivity; the two compounds therefore form a pair of constitutional isomers (Section 1-9).

For the higher alkane homologs (n > 4), more than two isomers are possible. There are three pentanes, C₅H₁₂, as shown below. There are five hexanes, C₆H₁₄; nine heptanes, C₇H₁₆; and eighteen octanes, C₈H₁₈.

(a) Draw the structures of the five isomeric hexanes. (b) Draw the structures of all the possible next higher and lower homologs of 2-methylbutane.

---

2-5 Naming the Alkanes

The multiple ways of assembling carbon atoms and attaching various substituents accounts for the existence of the very large number of organic molecules. This diversity poses a problem: How can we systematically differentiate all these compounds by name? Is it possible, for example, to name all the C₆H₁₄ isomers so that information on any of them (such as boiling points, melting points, reactions) might easily be found in the index of a handbook? And is there a way to name a compound that we have never seen in such a way as to be able to draw its structure?

This problem of naming organic molecules has been with organic chemistry from its very beginning, but the initial method was far from systematic. Compounds have been named after their discoverers (“Nenitzescu’s hydrocarbon”), after localities (“sydnones”), after their shapes (“cubane,” “basketane”), and after their natural sources (“vanillin”). Many of these common or trivial names are still widely used. However, there now exists a precise system for naming the alkanes. Systematic nomenclature, in which the name of a compound describes its structure, was first introduced by a chemical congress in Geneva, Switzerland, in 1892. It has continually been revised since then, mostly by the International Union of Pure and Applied Chemistry (IUPAC). Table 2-5 gives the systematic names of the first 20 straight-chain alkanes. Their stems, mainly of Greek origin, reveal the number of carbon atoms in the chain. For example, the name heptadecane is composed of the Greek words hepta, seven, and deka, ten. The first four alkanes have special names that have been accepted as part of the systematic

</tbody>
</table>

nomenclature but also all end in -ane. It is important to know these names, because they serve as the basis for naming a large fraction of all organic molecules. A few smaller branched alkanes have common names that still have widespread use. They make use of the prefixes iso- and neo- (margin), as in isobutane, isopentane, and neoheptane.

Exercise 2-17
Draw the structures of isohexane and neopentane.

As mentioned in Section 2-4, an alkyl group is formed by the removal of a hydrogen from an alkane. It is named by replacing the ending -ane in the corresponding alkane by -yl, as in methyl, ethyl, and propyl. Table 2-6 shows a few branched alkyl groups having common names. Note that some have the prefixes sec- (or s-), which stands for secondary, and tert- (or t-), for tertiary. These prefixes are used to classify $sp^3$-hybridized (tetrahedral) carbon atoms in organic molecules. A primary carbon is one attached directly to only one other carbon atom. For example, all carbon atoms at the ends of alkane chains are primary. The hydrogens attached to such carbons are designated primary hydrogens, and an alkyl group created by removing a primary hydrogen also is called primary. A secondary carbon is attached directly to two other carbon atoms, and a tertiary carbon to three others. Their hydrogens are labeled similarly. As shown in Table 2-6, removal of a secondary hydrogen results in a secondary alkyl group, and removal of a tertiary hydrogen in a tertiary alkyl group. Finally, a carbon bearing four alkyl groups is called quaternary.
Exercise 2-18

Label the primary, secondary, and tertiary hydrogens in 2-methylpentane (isohexane).

The information in Table 2-5 enables us to name the first 20 straight-chain alkanes. How do we go about naming branched systems? A set of IUPAC rules makes this a relatively simple task, as long as they are followed carefully and in sequence.

**IUPAC Rule 1.** Find the longest chain in the molecule and name it. This task is not as easy as it seems. The problem is that, in the condensed formula, complex alkanes may be written in ways that mask the identity of the longest chain. Do not assume that it is always depicted horizontally! In the following examples, the longest chain, or stem chain, is clearly marked; the alkane stem gives the molecule its name. Groups other than hydrogen attached to the stem chain are called substituents.
If a molecule has two or more chains of equal length, the chain with the largest number of substituents is the base stem chain.

Here are two more examples, drawn with the use of bond-line notation:

**IUPAC Rule 2.** Name all groups attached to the longest chain as alkyl substituents. For straight-chain substituents, Table 2-5 can be used to derive the alkyl name. However, what if the substituent chain is branched? In this case, the same IUPAC rules apply to such complex substituents: First, find the longest chain in the substituent; next, name all its substituents.

**IUPAC Rule 3.** Number the carbons of the longest chain beginning with the end that is closest to a substituent.

If there are two substituents at equal distance from the two ends of the chain, use the alphabet to decide how to number. The substituent to come first in alphabetical order is attached to the carbon with the lower number.

What if there are three or more substituents? Then number the chain in the direction that gives the lower number at the first difference between the two possible numbering schemes. This procedure follows the first point of difference principle.

Substituent groups are numbered outward from the main chain, with C1 of the group being the carbon attached to the main stem.
IUPAC Rule 4. Write the name of the alkane by first arranging all the substituents in alphabetical order (each preceded by the carbon number to which it is attached and a hyphen) and then adding the name of the stem. Should a molecule contain more than one of a particular substituent, its name is preceded by the prefix di, tri, tetra, penta, and so forth. The positions of attachment to the stem are given collectively before the substituent name and are separated by commas. These prefixes, as well as sec- and tert-, are not considered in the alphabetical ordering, except when they are part of a complex substituent name.

The five common group names in Table 2-6 are permitted by IUPAC: isopropyl, isobutyl, sec-butyl, tert-butyl, and neopentyl. These five are used universally in the course of normal communication between scientists, and it is necessary to know the structures to which they refer. Nonetheless, it is preferable to use systematic names, especially when searching for information about a chemical compound. The online databases containing such information are constructed to recognize the systematic names; therefore, use of a common name as input may not result in retrieval of a complete set of the information being sought.

The systematic name of a complex substituent should be enclosed in parentheses to avoid possible ambiguities. If a particular complex substituent is present more than once, a special set of prefixes is placed in front of the parenthesis: bis, tris, tetrakis, pentakis, and so on, for 2, 3, 4, 5, etc. In the chain of a complex substituent, the carbon numbered one (C1) is always the carbon atom directly attached to the stem chain.
To name haloalkanes, we treat the halogen as a substituent to the alkane framework. As usual, the longest (stem) chain is numbered so that the first substituent from either end receives the lowest number. Substituents are ordered alphabetically, and complex appendages are named according to the rules used for complex alkyl groups.

Common names are based on the older term alkyl halide. For example, the first three structures above have the common names methyl iodide, tert-butyl bromide, and isobutyl fluoride, respectively. Some chlorinated solvents have common names: for example, carbon tetrachloride, CCl₄; chloroform, CHCl₃; and methylene chloride, CH₂Cl₂.

Exercise 2-20

Draw the structure of 5-butyl-3-chloro-2,2,3-trimethyldecane.

Further instructions on nomenclature will be presented when new classes of compounds, such as the cycloalkanes, are introduced.

In Summary Four rules should be applied in sequence when naming a branched alkane: (1) Find the longest chain; (2) find the names of all the alkyl groups attached to the stem; (3) number the chain; (4) name the alkane, with substituent names in alphabetical order and preceded by numbers to indicate their locations. Haloalkanes are named in accord with the rules that apply to naming the alkanes, the halo substituent being treated the same as alkyl groups.

2-6 Structural and Physical Properties of Alkanes

The common structural feature of all alkanes is the carbon chain. This chain influences the physical properties of not only alkanes but also any organic molecules possessing such a backbone. This section will address the properties and physical appearance of such structures.

Alkanes exhibit regular molecular structures and properties

The structural features of the alkanes are remarkably regular. The carbon atoms are tetrahedral, with bond angles close to 109° and with regular C–H (∼1.10 Å) and C–C (∼1.54 Å) bond lengths. Alkane chains often adopt the zigzag patterns used in bond-line notation (Figure 2-3). To depict three-dimensional structures, we shall make use of the hashed-wedged line notation (see Figure 1-23). The main chain and a hydrogen at each end are drawn in the plane of the page (Figure 2-4).

Exercise 2-21

Draw zigzag hashed-wedged line structures for 2-methylbutane and 2,3-dimethylbutane.
The regularity in alkane structures suggests that their physical constants would follow predictable trends. Indeed, inspection of the data presented in Table 2-5 reveals regular incremental increases along the homologous series. For example, at room temperature (25°C), the lower homologs of the alkanes are gases or colorless liquids, the higher homologs are waxy solids. From pentane to pentadecane, each additional CH₂ group causes a 20–30°C increase in boiling point (Figure 2-5).

Attractive forces between molecules govern the physical properties of alkanes

Why are the physical properties of alkanes predictable? Such trends exist because of intermolecular or van der Waals* forces. Molecules exert several types of attractive forces on each other, causing them to aggregate into organized arrangements as solids and liquids. Most solid substances exist as highly ordered crystals. Ionic compounds, such as salts, are rigidly held in a crystal lattice, mainly by strong Coulomb forces. Nonionic but polar molecules, such as chloromethane (CH₃Cl), are attracted by weaker dipole–dipole interactions, also of coulombic origin (Sections 1-2 and 6-1). Finally, the nonpolar alkanes attract each other by London† forces, which are due to electron correlation. When one alkane molecule

*Professor Johannes D. van der Waals (1837–1923), University of Amsterdam, The Netherlands, Nobel Prize 1910 (physics).
†Professor Fritz London (1900–1954), Duke University, North Carolina. Note: In older references the term “van der Waals forces” referred exclusively to what we now call London forces; van der Waals forces now refers collectively to all intermolecular attractions.
Chapter 2  Structure and Reactivity

approaches another, repulsion of the electrons in one molecule by those in the other results
in correlation of their movement. Electron motion causes temporary bond polarization in
one molecule; correlated electron motion in the bonds of the other induces polarization in
the opposite direction, resulting in attraction between the molecules. Figure 2-6 is a simple
picture comparing ionic, dipolar, and London attractions.

London forces are very weak. In contrast to Coulomb forces, which change with the
square of the distance between charges, London forces fall off as the sixth power of the
distance between molecules. There is also a limit to how close these forces can bring
molecules together. At small distances, nucleus–nucleus and electron–electron repulsions
outweigh these attractions.

How do these forces account for the physical constants of elements and compounds? The
answer is that it takes energy, usually in the form of heat, to melt solids and boil liquids. For
example, to cause melting, the attractive forces responsible for the crystalline state must be
overcome. In an ionic compound, such as sodium acetate (Figure 2-6A), the strong interionic
forces require a rather high temperature (324°C) for the compound to melt. In alkanes, melting
points rise with increasing molecular size: Molecules with relatively large surface areas are
subject to greater London attractions. However, these forces are still relatively weak, and even
high-molecular-weight alkanes have rather low melting points. For example, a mixture of straight-
chain alkanes from C_{20}H_{42} to C_{40}H_{82} constitutes paraffin wax, which melts below 64°C.

For a molecule to escape these same attractive forces in the liquid state and enter the
gas phase, more heat has to be applied. When the vapor pressure of a liquid equals atmo-
spheric pressure, boiling occurs. Boiling points of compounds are also relatively high if the
intermolecular forces are relatively large. These effects lead to the smooth increase in boil-
ing points seen in Figure 2-5.

Branched alkanes have smaller surface areas than do their straight-chain isomers. As a
result, they are generally subject to smaller London attractions and are unable to pack as
well in the crystalline state. The weaker attractions result in lower melting and boiling
points. Branched molecules with highly compact shapes are exceptions. For example,
2,2,3,3-tetramethylbutane melts at +101°C because of highly favorable crystal packing
(compare octane, m.p. −57°C). On the other hand, the greater surface area of octane com-
pared with that of the more spherical 2,2,3,3-tetramethylbutane is clearly demonstrated in
their boiling points (126°C and 106°C, respectively). Crystal packing differences also

Figure 2-6  (A) Coulombic attraction in an ionic compound: crystalline sodium acetate, the
sodium salt of acetic acid. (B) Dipole–dipole interactions in solid chloromethane. The polar mole-
cules arrange to allow for favorable coulombic attraction. (C) London forces in crystalline pentane.
In this simplified picture, the electron clouds as a whole mutually interact to produce very small
partial charges of opposite sign. The charge distributions in the two molecules change continually
as the electrons continue to correlate their movements.
account for the slightly lower than expected melting points of odd-membered straight-chain alkanes relative to those of even-membered systems (Figure 2-5).

In Summary Straight-chain alkanes have regular structures. Their melting points, boiling points, and densities increase with molecular size and surface area because of increasing attraction between molecules.

2-7 Rotation about Single Bonds: Conformations

We have considered how intermolecular forces can affect the physical properties of molecules. These forces act between molecules. In this section, we shall examine how the forces present within molecules (i.e., intramolecular forces) make some geometric arrangements of the atoms energetically more favorable than others. Later chapters will show how molecular geometry affects chemical reactivity.

Rotation interconverts the conformations of ethane

If we build a molecular model of ethane, we can see that the two methyl groups are readily rotated with respect to each other. The energy required to move the hydrogen atoms past each other, the barrier to rotation, is only 2.9 kcal mol\(^{-1}\) (12.1 kJ mol\(^{-1}\)). This value turns out to be so low that chemists speak of “free rotation” of the methyl groups. In general, there is free rotation about all single bonds at room temperature.

Figure 2-7 depicts the rotational movement in ethane by the use of hashed-wedged line structures (Section 1-9). There are two extreme ways of drawing ethane: the staggered conformation and the eclipsed one. If the staggered conformation is viewed along the C–C axis, each hydrogen atom on the first carbon is seen to be positioned perfectly between two hydrogen atoms on the second. The second extreme is derived from the first by a 60° turn of one of the methyl groups about the C–C bond. Now, if this eclipsed conformation is viewed along the C–C axis, all hydrogen atoms on the first carbon are directly opposite those on the second—that is, those on the first eclipse those on the second. A further 60° turn converts the eclipsed form into a new but equivalent staggered arrangement. Between these two extremes, rotation of the methyl group results in numerous additional positions, referred to collectively as skew conformations.
The many forms of ethane (and, as we shall see, substituted analogs) created by such rotations are called conformations (also called conformers). All of them rapidly interconvert at room temperature. The study of their thermodynamic and kinetic behavior is conformational analysis.

Newman projections depict the conformations of ethane

A simple alternative to the hashed-wedged line structures for illustrating the conformers of ethane is the Newman projection. We can arrive at a Newman projection from the hashed-wedged line picture by turning the molecule out of the plane of the page toward us and viewing it along the C–C axis (Figure 2-8A and B). In this notation, the front carbon
obscures the back carbon, but the bonds emerging from both are clearly seen. The front carbon is depicted as the point of juncture of the three bonds attached to it, one of them usually drawn vertically and pointing up. The back carbon is represented by a circle (Figure 2-8C). The bonds to this carbon project from the outer edge of the circle. The extreme conformational shapes of ethane are readily drawn in this way (Figure 2-9). To make the three rear hydrogen atoms more visible in eclipsed conformations, they are drawn somewhat rotated out of the perfectly eclipsing position.

The conformers of ethane have different potential energies

The conformers of ethane do not all have the same energy content. The staggered conformer is the most stable and lowest energy state of the molecule. As rotation about the C–C bond axis occurs, the potential energy rises as the structure moves away from the staggered geometry, through skewed shapes, finally reaching the eclipsed conformation. At the point of eclipsing, the molecule has its highest energy content, about 2.9 kcal mol⁻¹ above the staggered conformation. The change in energy resulting from bond rotation from the staggered to the eclipsed conformation is called rotational or torsional energy, or torsional strain.

The origin of the torsional strain in ethane remains controversial. As rotation to the eclipsed geometry brings pairs of C–H bonds on the two carbons closer to each other, repulsion between the electrons in these bonds increases. Rotation also causes subtle changes in molecular orbital interactions, weakening the C–C bond in the eclipsed conformation. The relative importance of these effects has been a matter of debate for decades, with the most recent published theoretical research (2007) favoring electron repulsion as the major contributor to the rotational energy.

A potential-energy diagram (Section 2-1) can be used to picture the energy changes associated with bond rotation. In the diagram for rotation of ethane (Figure 2-10), the x axis denotes degrees of rotation, usually called torsional angle. Figure 2-10 sets 0° at the energy minimum of a staggered conformation, the most stable geometry of the ethane molecule.* Notice that the eclipsed conformer occurs at an energy maximum: Its lifetime is extremely short (less than 10⁻¹² s), and it is in fact only a transition state between rapidly equilibrating staggered

---

*Strictly speaking, the torsional (also called dihedral) angle in a chain of atoms A–B–C–D is defined as the angle between the planes containing A,B,C and B,C,D, respectively. Thus, in Figure 2-10 and subsequent figures in the next section, a torsional angle of 0° would correspond to one of the eclipsed conformations.
arrangements. The 2.9 kcal mol$^{-1}$ energy difference between the staggered and eclipsed conformations therefore corresponds to the activation energy for the rotational process.

All organic molecules with alkanelike backbones exhibit such rotational behavior. The sections that follow will illustrate these principles in more complex alkanes. Later chapters will show how the chemical reactivity of functionalized molecules can depend on their conformational characteristics.

**In Summary** Intramolecular forces control the arrangement of substituents on neighboring and bonded carbon atoms. In ethane, the relatively stable staggered conformations are interconverted by rotation through higher-energy transition states in which the hydrogen atoms are eclipsed. Because the energy barrier to this motion is so small, rotation is extremely rapid at ordinary temperatures. A potential-energy diagram conveniently depicts the energetics of rotation about the C–C bond.

### 2-8 Rotation in Substituted Ethanes

How does the potential-energy diagram change when a substituent is added to ethane? Consider, for example, propane, whose structure is similar to that of ethane, except that a methyl group replaces one of ethane’s hydrogen atoms.

**Steric hindrance raises the energy barrier to rotation**

A potential-energy diagram for the rotation about a C–C bond in propane is shown in Figure 2-11. The Newman projections of propane differ from those of ethane only by the substituted methyl group. Again, the extreme conformations are staggered and eclipsed. However, the activation barrier separating the two is 3.2 kcal mol$^{-1}$ (13.4 kJ mol$^{-1}$), slightly higher than that for ethane. This energy difference is due to unfavorable interference between the methyl substituent and the eclipsing hydrogen in the transition state, a phenomenon called steric hindrance. This effect arises from the fact that two atoms or groups of atoms cannot occupy the same region in space.
Steric hindrance in propane is actually worse than the $E_a$ value for rotation indicates. Methyl substitution raises the energy not only of the eclipsed conformation, but also of the staggered (lowest-energy, or ground state) conformation, the staggered to a lesser extent because of less hindrance. However, because the activation energy is equal to the difference in energy between ground and transition states, the net result is only a small increase in $E_a$.

There can be more than one staggered and one eclipsed conformation: conformational analysis of butane

If we build a model and look at the rotation about the central C–C bond of butane, we find that there are more conformations than one staggered and one eclipsed (Figure 2-12). Consider the staggered conformer in which the two methyl groups are as far away from each other as possible. This arrangement, called anti (i.e., opposed), is the most stable because steric hindrance is minimized. Rotation of the rear carbon in the Newman projections in either direction (in Figure 2-12, the direction is clockwise) produces an eclipsed conformation with two CH$_3$–H interactions. This conformer is 3.6 kcal mol$^{-1}$ (15.1 kJ mol$^{-1}$) higher in energy than the anti precursor. Further rotation furnishes a new staggered structure in which the two methyl groups are closer than they are in the anti conformation. To distinguish this conformer from the others, it is named gauche (gauche, French, in the sense of awkward, clumsy). As a consequence of steric hindrance, the gauche conformer is higher in energy than the anti conformer by about 0.9 kcal mol$^{-1}$ (3.8 kJ mol$^{-1}$).

Further rotation (Figure 2-12) results in a new eclipsed arrangement in which the two methyl groups are superposed. Because the two bulkiest substituents eclipse in this conformer, it is energetically highest, 4.9 kcal mol$^{-1}$ (20.5 kJ mol$^{-1}$) higher than the most stable anti structure. Further rotation produces another gauche conformer. The activation energy for gauche $\rightleftharpoons$ gauche interconversion is 4.0 kcal mol$^{-1}$ (16.7 kJ mol$^{-1}$). A potential-energy diagram summarizes the energetics of the rotation (Figure 2-13). The most stable anti conformer is the most abundant in solution (about 72% at 25°C). Its less stable gauche counterpart is present in lower concentration (28%).
Chapter 2 Structure and Reactivity

Figure 2-12 Clockwise rotation of the rear carbon along the C2–C3 bond in a Newman projection (top) and a ball-and-stick model (bottom) of butane.

Figure 2-13 Potential-energy diagram of the rotation about the C2–C3 bond in butane. There are three processes: \( \text{anti} \rightarrow \text{gauche} \) conversion with \( E_{a1} = 3.6 \text{ kcal mol}^{-1} \); \( \text{gauche} \rightarrow \text{gauche} \) rotation with \( E_{a2} = 4.0 \text{ kcal mol}^{-1} \); and \( \text{gauche} \rightarrow \text{anti} \) transformation with \( E_{a3} = 2.7 \text{ kcal mol}^{-1} \).
We can see from Figure 2-13 that knowing the difference in thermodynamic stability of two conformers (e.g., 0.9 kcal mol\(^{-1}\) between the anti and gauche isomers) and the activation energy for proceeding from the first to the second (e.g., 3.6 kcal mol\(^{-1}\), 15.1 kJ mol\(^{-1}\)) allows us to estimate the activation barrier of the reverse reaction. In this case, \(E_a\) for the gauche-to-anti conversion is \(3.6 - 0.9 = 2.7\) kcal mol\(^{-1}\) (11.3 kJ mol\(^{-1}\)).

**Exercise 2-22**

**Working with the Concepts: Conformations**

Draw a qualitative potential-energy diagram for rotation about the C3–C4 bond in 2-methylpentane. Show Newman projections for all conformations located at the maximum and minimum points on your graph. Describe similarities and differences with other molecules discussed in this section.

**Strategy**

First identify the structure of the molecule in question and the bond to be examined:

![C3–C4 bond with Newman projections](image)

We have been asked to examine rotation about a bond between two CH\(_2\) groups, each of which contains one alkyl substituent. This situation therefore resembles rotation about the C2–C3 bond in butane (see Figures 2-12 and 2-13), and the Newman projections and potential-energy diagram will be similar.

**Solution**

- Using Figures 2-12 and 2-13 as guides, we can produce the following Newman projections and potential-energy diagram:

![Potential-energy diagram with Newman projections](image)

- The single difference is that one of the alkyl groups is a 1-methylethyl (isopropyl) substituent instead of CH\(_3\). Because of its greater size, the energies of all its steric interactions will be larger, especially in conformations that bring the two alkyl groups close together. Therefore, the energy differences between the anti and all other conformations will increase, with the greatest increase at 180°.

**Exercise 2-23**

**Try It Yourself**

Draw the expected potential-energy diagram for the rotation about the C2–C3 bond in 2,3-dimethylbutane. Include the Newman projections of each staggered and eclipsed conformation.
THE BIG PICTURE

The familiar chemistry of acids and bases provides a framework for understanding many of the most important reactions between organic molecules. Much of the chemistry we explore in the upcoming chapters expands on the concept that electrophiles and nucleophiles are mutually attractive species, analogous to acids and bases. By identifying polar sites in molecules, we can develop the ability to understand, and even to predict, what kinds of reactions these molecules will undergo.

The sites of reactivity in organic molecules are called functional groups. Functional groups serve to characterize the main classes of organic compounds. Beginning in Chapter 6 and continuing through to the end of the book, we will discuss these compound classes one by one, examining how their properties and reactivity arise from their structural characteristics.

Most organic molecules consist of hydrocarbon skeletons with functional groups attached. We began a study of these skeletons with a discussion of the names and structures of alkanes, hydrocarbons that lack functional groups. We presented concepts of molecular motion and their associated energy changes. These ideas will underlie the behavior of molecules of all types, and we will return to them frequently.

CHAPTER INTEGRATION PROBLEMS

2-24. Consider the alkane shown in the margin.

a. Name this molecule according to the IUPAC system.

SOLUTION

Step 1. Locate the main, or stem, chain, the longest one in the molecule (shown in black below). Do not be misled: The drawing of the stem chain can have almost any shape. The stem has eight carbons, so the base name is octane.

Step 2. Identify and name all substituents (shown in color): two methyl groups, an ethyl group, and a fourth, branched substituent. The branched substituent is named by first giving the number 1 (italicized in the illustration below) to the carbon that connects it to the main stem. By numbering away from the stem, we reach the number 2; therefore, the substituent is a derivative of the ethyl group (in green), onto which is attached a methyl group (red) at carbon 1. Thus, this substituent is called a 1-methylethyl group.

Step 3. Number the stem chain, starting at the end closest to a carbon bearing a substituent. The numbering shown gives a methyl-substituted carbon the number 3. Numbering the opposite way would have C4 as the lowest numbered substituted carbon.

Step 4. Arrange the names of substituents alphabetically in the final name: ethyl comes first; then methyl comes before methylethyl (the “di” in dimethyl, denoting two methyl groups, is not considered in alphabetization because it is a multiplier of a substituent name and is therefore not considered part of the name). For more practice naming, see Problem 35.

b. Draw structures to represent rotation about the C6–C7 bond. Correlate the structures that you draw with a qualitative potential energy diagram.

SOLUTION

Step 1. Identify the bond in question. Notice that much of the molecule can be treated simply as a large, complicated substituent on C6, the specific structure of which is unimportant. For the purpose
Step 2. Recognize that step 1 simplified the problem: Rotation about the C6–C7 bond will give results very similar to rotation about the C2–C3 bond in butane. The only difference is that a large R group has replaced one of the smaller methyl groups of butane.

Step 3. Draw conformations modeled after those of butane (Section 2-8) and superimpose them on an energy diagram similar to that in Figure 2-13. The only difference between this diagram and that for butane is that we do not know the exact heights of the energy maxima relative to the energy minima. However, we can expect them to be higher, qualitatively, because our R group is larger than a methyl group and thus can be expected to cause greater steric hindrance.

c. Two alcohols derived from this alkane are illustrated in the margin. Alcohols are categorized on the basis of the type of carbon atom that contains the –OH group (primary, secondary, or tertiary). Characterize the alcohols shown in the margin.

SOLUTION
In alcohol 1, the –OH group is located on a carbon atom that is directly attached to one other carbon, a primary carbon. Therefore, alcohol 1 is a primary alcohol. Similarly, the –OH group in alcohol 2 resides on a tertiary carbon (one attached to three other carbon atoms). It is a tertiary alcohol.

d. The –O–H bond in an alcohol is acidic to a similar degree to that in water. Primary alcohols have $K_a \approx 10^{-16}$, tertiary alcohols $K_a \approx 10^{-18}$. What are the approximate $pK_a$ values for alcohols 1 and 2? Which is the stronger acid?

SOLUTION
The $pK_a$ for alcohol 1 is approximately 16 ($-\log K_a$); that for alcohol 2 is about 18. Alcohol 1, with the lower $pK_a$ value, is the stronger acid.

e. In which direction does the following equilibrium lie? Calculate $K$, the equilibrium constant, and $\Delta G^\circ$, the free energy change, associated with the reaction as written in the left-to-right direction.

SOLUTION
The stronger acid (alcohol 1) is on the left; the weaker (alcohol 2) is on the right. Recall the relation between conjugate acids and bases: Stronger acids have weaker conjugate bases, and vice versa. Relatively speaking, therefore, we have

\[
\text{Alcohol 1 (Stronger acid)} \quad \text{Conjugate base of alcohol 2 \quad \rightarrow \quad Conjugate base of alcohol 1} \quad + \quad \text{Alcohol 2 (Weaker base)}
\]

The equilibrium lies to the right, on the side of the weaker acid-base pair. Recall that $K > 1$ and $\Delta G^\circ < 0$ for a reaction that is thermodynamically favorable as written from left to right; use this information to be sure to get the magnitude of $K$ and the sign of $\Delta G^\circ$ correct. The equilibrium constant, $K$, for the process is the ratio of the $K_a$ values, \(10^{-16}/10^{-18} = 10^2\) (not $10^{-2}$). With
reference to Table 2-1, a $K$ value of 100 corresponds to a $\Delta G^\circ$ of $-2.73$ kcal mol$^{-1}$ (not +2.73).

If the reaction were written in the opposite direction, with the equilibrium lying to the left, the correct values would be those in parentheses. For more practice with acids and bases, see Problem 27.

2-25. a. Calculate the equilibrium concentrations of gauche and anti butane at 25°C using the data from Figure 2-13.

**SOLUTION**

We are given the relevant equations in Section 2-1. In particular, at 25°C the relationship between the Gibbs free energy and the equilibrium constant simplifies to $\Delta G^\circ = -1.36 \log K$. The energy difference between the conformations is 0.9 kcal mol$^{-1}$. Substitution of this value into the equation gives $K = 0.219 = [\text{gauche}] / [\text{anti}]$. Conversion to percentages may be achieved by recognizing that $\% \text{ gauche} = 100\% \times [\text{gauche}] / ([\text{anti}] + [\text{gauche}])$. Thus we find $\% \text{ gauche} = 100\% \times (0.219) / (1.0 + 0.219) = 18\%$, and therefore $\% \text{ anti} = 82\%$. The problem is, we are given the answer on page 83: At 25°C, butane consists of 28% gauche and 72% anti. What’s gone wrong?

The error derives from the fact that the energy values given in Sections 2-7 and 2-8 are enthalpies, not free energies, and we have failed to include an entropy contribution to the free energy equation $\Delta G^\circ = \Delta H^\circ - T \Delta S^\circ$. How do we correct this problem? We may look for equations to calculate $\Delta S^\circ$, but let us use another, more intuitive approach. Examine Figure 2-13 again. Note that over a 360° rotation the butane molecule passes from its anti conformation through two distinct gauche conformations before returning to its original anti geometry. The entropy term arises from the availability of two gauche conformers equilibrating with a single anti. Thus we really have three species in equilibrium, not two. Is there a way to solve this problem without going through calculations to determine $\Delta S^\circ$ and $\Delta G^\circ$? The answer is yes, and it is not very difficult.

Returning to Figure 2-13, let us label the two gauche forms A and B to distinguish them from each other. When we calculated $K$ in our original solution, what we actually determined was the value associated with equilibration between the anti and just one of the two gauche conformers, say $\text{gauche}_A$. Of course, the value for $\text{gauche}_B$ is identical, because the two gauche conformations are equal in energy. So, $K = [\text{gauche}_A] / [\text{anti}] = 0.219$, and $K = [\text{gauche}_B] / [\text{anti}] = 0.219$.

Finally, recognizing that total $[\text{gauche}] = [\text{gauche}_A] + [\text{gauche}_B]$, we therefore have $\% \text{ gauche} = 100\% \times ([\text{gauche}_A] + [\text{gauche}_B]) / ([\text{anti}] + [\text{gauche}_A] + [\text{gauche}_B])$, giving us $\% \text{ gauche} = 100\% \times (0.219 + 0.219) / (1.0 + 0.219 + 0.219) = 30\%$, and therefore $\% \text{ anti} = 70\%$, in much better agreement with the values given for the equilibrium percentages in the text.

b. Calculate the equilibrium concentrations of gauche and anti butane at 100°C.

**SOLUTION**

As above, we determine $K$ from the enthalpy difference in Figure 2-13, using this value as to input for $\Delta G^\circ$ in the more general equation $\Delta G^\circ = -2.303 RT \log K$. We follow by correcting for the presence of two gauche conformations in the overall equilibrium. Don’t forget that we must use degrees Kelvin, 373 K for T. Solving, we obtain $K = 0.297 = [\text{gauche}_A] / [\text{anti}] = [\text{gauche}_B] / [\text{anti}]$. Therefore, $\% \text{ gauche} = 100\% \times (0.297 + 0.297) / (1.0 + 0.297 + 0.297) = 37\%$, and therefore $\% \text{ anti} = 63\%$.

The less stable conformations are more prevalent at higher temperatures, a straightforward consequence of the Boltzmann distribution, which states that more molecules have higher energies at higher temperatures (Section 2-1). For more practice with conformations, see Problems 42, 44, and 50.

**Important Concepts**

1. Chemical reactions can be described as equilibria controlled by thermodynamic and kinetic parameters. The change in the Gibbs free energy, $\Delta G^\circ$, is related to the equilibrium constant by $\Delta G^\circ = -RT \ln K = -1.36 \log K$ (at 25°C). The free energy has contributions from changes in enthalpy, $\Delta H^\circ$, and entropy, $\Delta S^\circ$: $\Delta G^\circ = \Delta H^\circ - T \Delta S^\circ$. Changes in enthalpy are due mainly to differences between the strengths of the bonds made and those of the bonds broken. A reaction is exothermic when the former is larger than the latter. It is endothermic when there is a net loss in combined bond strengths. Changes in entropy are controlled by the relative degree of energy dispersal in starting materials compared with that in products. The greater the increase in energy dispersal, the larger a positive $\Delta S^\circ$. 
2. The rate of a chemical reaction depends mainly on the concentrations of starting material(s), the activation energy, and temperature. These correlations are expressed in the Arrhenius equation: rate constant \( k = A e^{-E_a/RT} \).

3. If the rate depends on the concentration of only one starting material, the reaction is said to be of first order. If the rate depends on the concentrations of two reagents, the reaction is of second order.

4. Bronsted acids are proton donors; bases are proton acceptors. Acid strength is measured by the acid dissociation constant \( K_a \); \( pK_a = -\log K_a \). Acids and their deprotonated forms have a conjugate relation. Lewis acids and bases are electron pair acceptors and donors, respectively.

5. Electron-deficient atoms attack electron rich atoms and are called electrophiles. Conversely, electron-rich atoms attack electron-poor atoms and are called nucleophiles. When a nucleophile, which may be either negatively charged or neutral, attacks an electrophile, it donates a lone electron pair to form a new bond with the electrophile.

6. An organic molecule may be viewed as being composed of a carbon skeleton with attached functional groups.

7. Hydrocarbons are made up of carbon and hydrogen only. Hydrocarbons possessing only single bonds are also called alkanes. They do not contain functional groups. An alkane may exist as a single continuous chain or it may be branched or cyclic. The empirical formula for the straight-chain and branched alkanes is \( \text{C}_n\text{H}_{2n+2} \).

8. Molecules that differ only in the number of methylene groups, \( \text{CH}_2 \), in the chain are called homologs and are said to belong to a homologous series.

9. An \( sp^3 \) carbon attached directly to only one other carbon is labeled primary. A secondary carbon is attached to two and a tertiary to three other carbon atoms. The hydrogen atoms bound to such carbon atoms are likewise designated primary, secondary, or tertiary.

10. The IUPAC rules for naming saturated hydrocarbons are (a) find the longest continuous chain in the molecule and name it; (b) name all groups attached to the longest chain as alkyl substituents; (c) number the carbon atoms of the longest chain; (d) write the name of the alkane, citing all substituents as prefixes arranged in alphabetical order and preceded by numbers designating their positions.

11. Alkanes attract each other through weak London forces, polar molecules through stronger dipole–dipole interactions, and salts mainly through very strong ionic interactions.

12. Rotation about carbon–carbon single bonds is relatively easy and gives rise to conformations (conformers). Substituents on adjacent carbon atoms may be staggered or eclipsed. The eclipsed conformation is a transition state between staggered conformers. The energy required to reach the eclipsed state is called the activation energy for rotation. When both carbons bear alkyl or other groups, there may be additional conformers: Those in which the groups are in close proximity (60°) are gauche; those in which the groups are directly opposite (180°) each other are anti. Molecules tend to adopt conformations in which steric hindrance, as in gauche conformations, is minimized.

### Problems

26. The hydrocarbon propene (\( \text{CH}_3\text{CH}═\text{CH}_2 \)) can react in two different ways with bromine (Chapters 12 and 14).

\[
\text{Br} \quad \text{Br} \\
(i) \quad \text{CH}_3\text{CH}═\text{CH}_2 + \text{Br}_2 \rightarrow \text{CH}_3\text{CH}—\text{CH}_2 + \text{HBr} \\
(ii) \quad \text{CH}_3\text{CH}═\text{CH}_2 + \text{Br}_2 \rightarrow \text{CH}_2═\text{CH}═\text{CH}_2 + \text{HBr} \\
\]

(a) Using the bond strengths (kcal mol\(^{-1}\)) given in the margin, calculate \( \Delta H^\circ \) for each of these reactions. (b) \( \Delta S^\circ = 0 \) cal K\(^{-1}\) mol\(^{-1}\) for one of these reactions and \(-35 \) cal K\(^{-1}\) mol\(^{-1}\) for the other. Which reaction has which \( \Delta S^\circ \)? Briefly explain your answer. (c) Calculate \( \Delta G^\circ \) for each reaction at 25°C and at 600°C. Are both of these reactions thermodynamically favorable at 25°C? At 600°C?

27. (i) Determine whether each species in the following equations is acting as a Brønsted acid or base, and label it. (ii) Indicate whether the equilibrium lies to the left or to the right. (iii) Estimate $K$ for each equation if possible. (Hint: Use the data in Table 2-2.)

(a) $\text{H}_2\text{O} + \text{HCN} \rightleftharpoons \text{H}_3\text{O}^+ + \text{CN}^-$
(b) $\text{CH}_3\text{O}^- + \text{NH}_3 \rightleftharpoons \text{CH}_3\text{OH} + \text{NH}_2^-$
(c) $\text{HF} + \text{CH}_3\text{COO}^- \rightleftharpoons \text{F}^- + \text{CH}_3\text{COOH}$
(d) $\text{CH}_3^- + \text{NH}_3 \rightleftharpoons \text{CH}_4 + \text{NH}_2^-$
(e) $\text{H}_2\text{O}^+ + \text{Cl}^- \rightleftharpoons \text{H}_2\text{O} + \text{HCl}$
(f) $\text{CH}_3\text{COOH} + \text{CH}_3\text{S}^- \rightleftharpoons \text{CH}_3\text{COO}^- + \text{CH}_3\text{SH}$

28. Use curved arrows to show electron movement in each acid-base reaction in Problem 27.

29. Identify each of the following species as either a Lewis acid or a Lewis base, and write an equation illustrating a Lewis acid-base reaction for each one. Use curved arrows to depict electron-pair movement. Be sure that the product of each reaction is depicted by a complete, correct Lewis structure.

(a) $\text{CN}^-$
(b) $\text{CH}_3\text{OH}$
(c) $\text{(CH}_3)_2\text{CH}$
(d) $\text{MgBr}_2$
(e) $\text{CH}_3\text{BH}_2$
(f) $\text{CH}_3\text{S}^-$

30. For each example in Table 2-3, identify all polarized covalent bonds and label the appropriate atoms with partial positive or negative charges. (Do not consider carbon–hydrogen bonds.)

31. Characterize each of the following atoms as being either nucleophilic or electrophilic.

(a) Iodide ion, $\Gamma$  
(b) Hydrogen ion, $\text{H}^+$  
(c) Carbon in methyl cation, $\text{CH}_3^+$  
(d) Sulfur in hydrogen sulfide, $\text{H}_2\text{S}$  
(e) Aluminum in aluminum trichloride, $\text{AlCl}_3$  
(f) Magnesium in magnesium oxide, $\text{MgO}$

32. Circle and identify by name each functional group in the compounds pictured.

33. On the basis of electrostatics (Coulomb attraction), predict which atom in each of the following organic molecules is likely to react with the indicated reagent. Write “no reaction” if none seems likely. (See Table 2-3 for the structures of the organic molecules.) (a) Bromoethane, with the oxygen of $\text{HO}^-$; (b) propanal, with the nitrogen of $\text{NH}_3$; (c) methoxyethane, with $\text{H}^+$; (d) 3-hexanone, with the carbon of $\text{CH}_3^-$; (e) ethanenitrile (acetonitrile), with the carbon of $\text{CH}_3^-$; (f) butane, with $\text{HO}^-$.  

34. Use curved arrows to show the electron movement in each reaction in Problem 33.

35. Name the following molecules according to the IUPAC system of nomenclature.

(a) $\text{CH}_3\text{CH}_2\text{CHCH}_3$
(b) $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$

36. Convert the following names into the corresponding molecular structures. After doing so, check to see if the name of each molecule as given here is in accord with the IUPAC system of nomenclature. If not, name the molecule correctly. (a) 2-methyl-3-propylpentane; (b) 5-(1,1-dimethylpropyl)nonane; (c) 2,3,4-trimethyl-4-butylheptane; (d) 4-tert-butyl-5-isopropylhexane; (e) 4-(2-ethylbutyl)decane; (f) 2,4,4-trimethylpentane; (g) 4-sec-butylheptane; (h) isoheptane; (i) neoheptane.

37. Draw the structures that correspond to the following names. Correct any names that are not in accord with the rules of systematic nomenclature.

(a) 4-Chloro-5-methylhexane
(b) 3-Methyl-3-propylpentane
(c) 1,1,1-Trifluoro-2-methylpropane
(d) 4-(3-Bromobutyl)nonane

38. Draw and name all possible isomers of C₇H₁₆ (isomeric heptanes).

39. Identify the primary, secondary, and tertiary carbon atoms and the hydrogen atoms in each of the following molecules: (a) ethane; (b) pentane; (c) 2-methylbutane; (d) 3-ethyl-2,2,3,4-tetramethylpentane.

40. Identify each of the following alkyl groups as being primary, secondary, or tertiary, and give it a systematic IUPAC name.

41. Rank the following molecules in order of increasing boiling point (without looking up the real values!): (a) 3-methylheptane; (b) octane; (c) 2,4-dimethylhexane; (d) 2,2,4-trimethylpentane.

42. Using Newman projections, draw each of the following molecules in its most stable conformation with respect to the bond indicated: (a) 2-methylbutane, C₂–C₃ bond; (b) 2,2-dimethylbutane, C₂–C₃ bond; (c) 2,2-dimethylpentane, C₃–C₄ bond; (d) 2,2,4-trimethylpentane, C₃–C₄ bond.

43. Based on the energy differences for the various conformations of ethane, propane, and butane in Figures 2-10, 2-11, and 2-13, determine the following:

(a) The energy associated with a single hydrogen–hydrogen eclipsing interaction
(b) The energy associated with a single methyl–hydrogen eclipsing interaction
(c) The energy associated with a single methyl–methyl eclipsing interaction
(d) The energy associated with a single methyl–methyl gauche interaction
44. At room temperature, 2-methylbutane exists primarily as two alternating conformations of rotation about the C2–C3 bond. About 90% of the molecules exist in the more favorable conformation and 10% in the less favorable one. (a) Calculate the free energy change ($\Delta G^\circ$, more favorable conformation - less favorable conformation) between these conformations. (b) Draw a potential-energy diagram for rotation about the C2–C3 bond in 2-methylbutane. To the best of your ability, assign relative energy values to all the conformations on your diagram. (c) Draw Newman projections for all staggered and eclipsed conformers in (b) and indicate the two most favorable ones.

45. For each of the following naturally occurring compounds, identify the compound class(es) to which it belongs, and circle all functional groups.

47. **CHALLENGE** Using the Arrhenius equation, calculate the effect on $k$ of increases in temperature of 10, 30, and 50 degrees (Celsius) for the following activation energies. Use 300 K (approximately room temperature) as your initial $T$ value, and assume that $A$ is a constant.
(a) $E_a = 15$ kcal mol$^{-1}$; (b) $E_a = 30$ kcal mol$^{-1}$; (c) $E_a = 45$ kcal mol$^{-1}$.

48. **CHALLENGE** The Arrhenius equation can be reformulated in a way that permits the experimental determination of activation energies. For this purpose, we take the natural logarithm of both sides and convert into the base 10 logarithm.

$$\ln k = \ln (Ae^{-E_a/RT}) = \ln A - E_a/RT$$ becomes

$$\log k = \log A - \frac{E_a}{2.3RT}$$

The rate constant $k$ is measured at several temperatures $T$ and a plot of $\log k$ versus $1/T$ is prepared, a straight line. What is the slope of this line? What is its intercept (i.e., the value of $\log k$ at $1/T = 0$)? How is $E_a$ calculated?

49. Reexamine your answers to Problem 33. Rewrite each one in the form of a complete equation describing a Lewis acid-base process, showing the product and using curved arrows to depict electron-pair movement. **[Hint: For (b) and (d), start with a Lewis structure that represents a second resonance form of the starting organic molecule.]**

50. **CHALLENGE** The equation relating $\Delta G^\circ$ to $K$ contains a temperature term. Refer to your answer to Problem 44(a) to calculate the answers to the questions that follow. You will need to know that $\Delta S^\circ$ for the formation of the more stable conformer of 2-methylbutane from the next most stable conformer is $+1.4$ cal K$^{-1}$ mol$^{-1}$. (a) Calculate the enthalpy difference ($\Delta H^\circ$) between these two conformers from the equation $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$. How well does this agree with the $\Delta H^\circ$ calculated from the number of gauche interactions in each conformer? (b) Assuming that $\Delta H^\circ$ and $\Delta S^\circ$ do not change with temperature, calculate $\Delta G^\circ$ between these two conformations at the following three temperatures: $-250^\circ$C; $-100^\circ$C; $+500^\circ$C. (c) Calculate $K$ for these two conformations at the same three temperatures.

**Team Problem**

51. Consider the difference in the rate between the following two second-order substitution reactions.

Reaction 1: The reaction of bromoethane and iodide ion to produce iodoethane and bromide ion is second order; that is, the rate of the reaction depends on the concentrations of both bromoethane and iodide ion:

$$\text{Rate} = k[\text{CH}_3\text{CH}_2\text{Br}][\text{I}^-] \text{ mol L}^{-1} \text{ s}^{-1}$$

Reaction 2: The reaction of 1-bromo-2,2-dimethylpropane (neopentyl bromide) with iodide ion to produce neopentyl iodide and bromide ion is more than 10,000 times slower than the reaction of bromoethane with iodide ion.

$$\text{Rate} = k[\text{neopentyl bromide}][\text{I}^-] \text{ mol L}^{-1} \text{ s}^{-1}$$

(a) Formulate each reaction by using bond-line structural drawings in your reaction scheme.
(b) Identify the reactive site of the starting haloalkane as primary, secondary, or tertiary.
(c) Discuss how the reaction might take place; that is, how the species would have to interact in order for the reaction to proceed. Remember that, because the reaction is second order, both reagents must be present in the transition state. Use your model kit to help you visualize the trajectory of approach of the iodide ion toward the haloalkane that enables the simultaneous iodide bond making and bromide bond breaking required by the second-order kinetics of these two reactions. Of all the possibilities, which one best explains the experimentally determined difference in rate between the reactions?
(d) Use hashed-wedged line structures to make a three-dimensional drawing of the trajectory on which you agree.
Preprofessional Problems

52. The compound 2-methylbutane has
(a) no secondary H’s   (b) no tertiary H’s   (c) no primary H’s
(d) twice as many secondary H’s as tertiary H’s
(e) twice as many primary H’s as secondary H’s

53. This energy profile diagram represents
(a) an endothermic reaction   (b) an exothermic reaction
(c) a fast reaction   (d) a termolecular reaction

54. In 4-(1-methylethyl)heptane, any H–C–C angle has the value
(a) 120°   (b) 109.5°   (c) 180°
(d) 90°   (e) 360°

55. The structural representation shown in the margin is a Newman projection of the conformer of butane that is
(a) gauche eclipsed   (b) anti gauche   (c) anti staggered   (d) anti eclipsed

56. Genipin (margin) is a Chinese herbal remedy that is effective against diabetes. To which of the compound classes below does genipin not belong?
(a) alcohol   (b) alkene   (c) ester   (d) ether   (e) ketone
Combustion of alkanes releases most of the energy that powers modern industrialized society. We saw in Chapter 2 that alkanes lack functional groups; that being the case, how does combustion occur? We will see in this chapter that alkanes are not very reactive, but that they do undergo several types of transformations. These processes, of which combustion is one example, do not involve acid-base chemistry. Instead, they are called radical reactions. Although we shall not explore radical reactions in great depth in this course, they play significant roles in biochemistry (such as aging and disease processes), the environment (destruction of the Earth’s ozone layer), and industry (manufacture of synthetic fabrics and plastics).

Radical reactions begin with the breaking of a bond, or bond dissociation. We examine the energetics of this process and discuss the conditions under which it occurs. The majority of the chapter will deal with halogenation, a radical reaction in which a hydrogen atom in an alkane is replaced by halogen. The importance of halogenation lies in the fact that it introduces a reactive functional group, turning the alkane into a haloalkane, which is suitable for further chemical change. For each of these processes, we shall discuss the mechanism involved to explain in detail how the reaction occurs. We shall see that different alkanes, and indeed different bonds in the same alkane molecule, may react at different rates, and we shall see why this is so.

A carbon radical

Only a relatively limited number of mechanisms are needed to describe the very large number of reactions in organic chemistry. Mechanisms enable us to understand how and why reactions occur, and what products are likely to form in them. In this chapter we apply mechanistic concepts to explain the effects of halogen-containing chemicals on the stratospheric ozone layer. We conclude with a brief discussion of alkane combustion and show how that process serves as a useful source of thermodynamic information about organic molecules.

NASA’s X-43A hypersonic research aircraft being dropped from under the wing of a B-52B Stratofortress on June 2, 2001. Most supersonic aircraft produce exhaust gases containing molecules such as nitric oxide (NO), whose radical reactions are destructive to the Earth’s stratospheric ozone (O3) layer. In the 1970s the United States abandoned plans to build a fleet of supersonic aircraft (SSTs, or supersonic transports) for just this reason. In contrast, the X-43A is hydrogen fueled, posing no risk to stratospheric ozone, and may represent the first step toward the development of environmentally acceptable high-speed flight. In 2008, Boeing flew successfully the first manned hydrogen-fuel-cell-powered aircraft, another aviation milestone.
**3-1 Strength of Alkane Bonds: Radicals**

In Section 1-2 we explained how bonds are formed and that energy is released on bond formation. For example, bringing two hydrogen atoms into bonding distance produces 104 kcal mol\(^{-1}\) (435 kJ mol\(^{-1}\)) of heat (refer to Figures 1-1 and 1-12).

\[
\begin{align*}
\text{H}^\cdot + \text{H}^\cdot & \xrightarrow{\text{Bond making}} \text{H} - \text{H} \\
\Delta H^\circ & = -104 \text{ kcal mol}^{-1} (-435 \text{ kJ mol}^{-1}) \\
\text{Released heat: exothermic}
\end{align*}
\]

Consequently, breaking such a bond requires heat—in fact, the same amount of heat that was released when the bond was made. This energy is called bond-dissociation energy, \(DH^\circ\), and is a quantitative measure of the bond strength.

\[
\begin{align*}
\text{H} - \text{H} & \xrightarrow{\text{Bond breaking}} \text{H}^\cdot + \text{H}^\cdot \\
\Delta H^\circ & = DH^\circ = 104 \text{ kcal mol}^{-1} (435 \text{ kJ mol}^{-1}) \\
\text{Consumed heat: endothermic}
\end{align*}
\]

**Radicals are formed by homolytic cleavage**

In our example, the bond breaks in such a way that the two bonding electrons divide equally between the two participating atoms or fragments. This process is called homolytic cleavage or bond homolysis. The separation of the two bonding electrons is denoted by two single-barbed or “fishhook” arrows that point from the bond to each of the atoms.

The fragments that form have an unpaired electron, for example, \(\text{H}^\cdot\), \(\text{Cl}^\cdot\), \(\text{CH}_3^\cdot\), and \(\text{CH}_2\text{CH}_3^\cdot\). When these species are composed of more than one atom, they are called radicals. Because of the unpaired electron, radicals and free atoms are very reactive and usually cannot be isolated. However, radicals and free atoms are present in low concentration as unobserved intermediates in many reactions, such as the production of polymers (Chapter 12) and the oxidation of fats that leads to the spoilage of perishable foods (Chapter 22).

In Section 2-2 we introduced an alternative way of breaking a bond, in which the entire bonding electron pair is donated to one of the atoms. This process is heterolytic cleavage and results in the formation of ions.

Homolytic cleavage may be observed in nonpolar solvents or even in the gas phase. In contrast, heterolytic cleavage normally occurs in polar solvents, which are capable of stabilizing ions. Heterolytic cleavage is also restricted to situations where the electronegativities of atoms A and B and the groups attached to them stabilize positive and negative charges, respectively.

Dissociation energies, \(DH^\circ\), refer only to homolytic cleavages. They have characteristic values for the various bonds that can be formed between the elements. Table 3-1 lists dissociation energies of some common bonds. The larger the value for \(DH^\circ\), the stronger the corresponding bond. Note the relatively strong bonds to hydrogen, as in \(\text{H–F}\) and \(\text{H–OH}\). However, even though these bonds have high \(DH^\circ\) values, they readily undergo heterolytic cleavage in water to \(\text{H}^+\) and \(\text{F}^-\) or \(\text{HO}^-\); do not confuse homolytic with heterolytic processes.
Bonds are strongest when made by overlapping orbitals that are closely matched in energy and size (Section 1-7). For example, the strength of the bonds between hydrogen and the halogens decreases in the order F > Cl > Br > I, because the $p$ orbital of the halogen contributing to the bonding becomes larger and more diffuse along the series. Thus, the efficiency of its overlap with the relatively small $1s$ orbital on hydrogen diminishes. A similar trend holds for bonding between the halogens and carbon.

**Note:** (a) $DH^\circ$ for the process A–B $\rightarrow$ A· + ·B. (b) These numbers are being revised continually because of improved methods for their measurement. (c) The trends observed for A–H bonds are significantly altered for polar A–B bonds because of dipolar contributions to $DH^\circ$.

Bonds are strongest when made by overlapping orbitals that are closely matched in energy and size (Section 1-7). For example, the strength of the bonds between hydrogen and the halogens decreases in the order F > Cl > Br > I, because the $p$ orbital of the halogen contributing to the bonding becomes larger and more diffuse along the series. Thus, the efficiency of its overlap with the relatively small $1s$ orbital on hydrogen diminishes. A similar trend holds for bonding between the halogens and carbon.

### Exercise 3-1

**Working with the Concepts: Understanding Bond Strengths**

Compare the bond-dissociation energies of CH$_3$–F, CH$_3$–OH, and CH$_3$–NH$_2$. Why do the bonds get weaker along this series even though the orbitals participating in overlap become better matched in size and energy?

**Strategy**

What factors contribute to the strength of a bond? As mentioned above, the sizes and energies of the orbitals are very important. However, coulombic contributions may enhance covalent bond strength. Let’s look at each factor separately to see if one outweighs the other in these three bonds.

**Solution**

- The better the match in size and energy of orbitals between two atoms in a bond, the better the bonding overlap will be (note Figure 1-2). However, the decrease in orbital size in the series C, N, O, F is slight, and therefore the overlap changes by only a very small amount going from C–F to C–O to C–N.
- In the progression from N to O to F, nuclear charge increases, giving rise to stronger attraction between the nucleus and the electrons. The increasing electronegativity in this series confirms this effect (Table 1-2). As the electronegativity of the element attached to carbon increases, so does its attraction for the shared electron pair in the covalent bond. Thus the polarity and the charge separation in the bond both increase, giving rise to a partial positive charge ($\delta^+$) on carbon and a partial negative charge ($\delta^-$) on the more electronegative atom.
- Coulombic attraction between these opposite charges supplements the bonding resulting from covalent overlap and makes the bond stronger. In this series of bonds, increasing coulombic attraction outweighs decreasing overlap going from N to O to F, giving the observed result.
The stability of radicals determines the C–H bond strengths

How strong are the C–H and C–C bonds in alkanes? The bond-dissociation energies of various alkane bonds are given in Table 3-2. Note that bond energies generally decrease with the progression from methane to primary, secondary, and tertiary carbon. For example, the C–H bond in methane is strong and has a high $\Delta H^\circ$ value of 105 kcal mol$^{-1}$. In ethane, this bond energy is less: $\Delta H^\circ = 101$ kcal mol$^{-1}$. The latter number is typical for primary C–H bonds, as can be seen for the bond in propane. The secondary C–H bond is even weaker, with a $\Delta H^\circ$ of 98.5 kcal mol$^{-1}$, and a tertiary carbon atom bound to hydrogen has a $\Delta H^\circ$ of only 96.5 kcal mol$^{-1}$.

### Exercise 3-2

**Try It Yourself**

In the series C–C (in ethane, H$_3$C–CH$_3$), N–N (in hydrazine, H$_2$N–NH$_2$), O–O (in hydrogen peroxide, HO–OH), the bonds decrease in strength from 90 to 60 to 50 kcal mol$^{-1}$. Explain. (Hint: Lone pairs on adjacent atoms repel each other.)

The stability of radicals determines the C–H bond strengths

A similar trend is seen for C–C bonds (Table 3-2). The extremes are the bonds in H$_3$C–CH$_3$ ($\Delta H^\circ = 90$ kcal mol$^{-1}$) and (CH$_3$)$_3$C–CH$_3$ ($\Delta H^\circ = 87$ kcal mol$^{-1}$).

Why do all of these dissociations exhibit different $\Delta H^\circ$ values? The radicals formed have different energies. For reasons we will address in the next section, radical stability increases along the series from primary to secondary to tertiary; consequently, the energy required to create them decreases.

### Radical Stabilities

$\cdot$CH$_3$ < $\cdot$R$_{\text{primary}}$ < $\cdot$R$_{\text{secondary}}$ < $\cdot$R$_{\text{tertiary}}$
Chapter 3

99

In Summary Bond homolysis in alkanes yields radicals and free atoms. The heat required to do so is called the bond-dissociation energy, $DH^\ddagger$. Its value is characteristic only for the bond between the two participating elements. Bond breaking that results in tertiary radicals demands less energy than that furnishing secondary radicals; in turn, secondary radicals are formed more readily than primary radicals. The methyl radical is the most difficult to obtain in this way.

3-2 Structure of Alkyl Radicals: Hyperconjugation

What is the reason for the ordering in stability of alkyl radicals? To answer this question, we need to inspect the alkyl radical structure more closely. Consider the structure of the methyl radical, formed by removal of a hydrogen atom from methane. Spectroscopic measurements have shown that the methyl radical, and probably other alkyl radicals, adopts a nearly planar configuration, best described by $sp^3$ hybridization (Figure 3-2). The unpaired electron occupies the remaining $p$ orbital perpendicular to the molecular plane.

Figure 3-1 The different energies needed to form radicals from an alkane $\text{CH}_3\text{CH}_2\text{CHR}_2$. Radical stability increases from primary to secondary to tertiary.

Figure 3-2 The hybridization change upon formation of a methyl radical from methane. The nearly planar arrangement is reminiscent of the hybridization in $\text{BH}_3$ (Figure 1-17).
Let us see how the planar structures of alkyl radicals help explain their relative stabilities. Figure 3-3A shows that there is a conformer in the ethyl radical in which a C–H bond of the CH₃ group is aligned with and overlaps one of the lobes of the singly occupied p orbital on the radical center. This arrangement allows the bonding pair of electrons in the s orbital to delocalize into the partly empty p lobe, a phenomenon called hyperconjugation.

The interaction between a filled orbital and a singly occupied orbital has a net stabilizing effect (recall Exercise 1-14). Both hyperconjugation and resonance (Section 1-5) are forms of electron delocalization. They are distinguished by type of orbital: Resonance normally refers to π-type overlap of p orbitals, whereas hyperconjugation incorporates overlap with the orbitals of s bonds. Radicals are stabilized by hyperconjugation.

What if we replace the remaining hydrogens on the radical carbon with alkyl groups? Each additional alkyl group increases the hyperconjugation interactions further (Figure 3-3B). The order of stability of the radicals is a consequence of this effect. Notice in Figure 3-1 that the degree of stabilization arising from each hyperconjugative interaction is relatively small [2.0–2.5 kcal mol⁻¹ (8.4–10.5 kJ mol⁻¹)]: We shall see later that stabilization of radicals by resonance is considerably greater (Chapter 14). Another contribution to the relative stability of secondary and tertiary radicals is the greater relief of steric crowding between the substituent groups as the geometry changes from tetrahedral in the alkane to planar in the radical.

Even a cursory glance at the bond-dissociation energies between carbon and the more electronegative atoms in Table 3-1 suggests that hyperconjugation and radical stabilities alone do not provide a complete picture. For example, bonds between carbon and any of the halogens all display essentially identical ΔH° regardless of the type of carbon. Several interpretations have been proposed to explain these observations. Polar effects are likely involved (as mentioned in the table footnote). In addition, the longer bonds between carbon and large atoms reduce the steric repulsion between atoms around that carbon, diminishing its influence on bond-dissociation energies.

### 3-3 Conversion of Petroleum: Pyrolysis

Alkanes are produced naturally by the slow decomposition of animal and vegetable matter in the presence of water but in the absence of oxygen, a process lasting millions of years. The smaller alkanes—methane, ethane, propane, and butane—are present in natural gas, methane being by far its major component. Many liquid and solid alkanes are obtained from crude petroleum, but distillation alone does not meet the enormous demand for the lower-molecular-weight hydrocarbons needed for gasoline, kerosene, and other hydrocarbon-based fuels. Additional heating is required to break up longer-chain petroleum components into smaller molecules. How does this occur? Let us first look into the effect of strong heating on simple alkanes and then move on to petroleum.
High temperatures cause bond homolysis

When alkanes are heated to a high temperature, both C–H bonds and C–C bonds rupture, a process called **pyrolysis**. In the absence of oxygen, the resulting radicals can combine to form new higher- or lower-molecular-weight alkanes. Radicals can also remove hydrogen atoms from the carbon atom adjacent to another radical center to give alkenes, a process called **hydrogen abstraction**. Indeed, very complicated mixtures of alkanes and alkenes form in pyrolyses. Under special conditions, however, these transformations can be controlled to obtain a large proportion of hydrocarbons of a defined chain length.

**Pyrolysis of Hexane**

Examples of cleavage into radicals:

\[
\begin{align*}
\text{Hexane} & \xrightarrow{C1-C2 cleavage} \text{CH}_3 \cdot + \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \\
& \xrightarrow{C2-C3 cleavage} \text{CH}_3\text{CH}_2 \cdot + \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \\
& \xrightarrow{C3-C4 cleavage} \text{CH}_3\text{CH}_2\text{CH}_2 \cdot + \text{CH}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

Examples of radical combination reactions:

\[
\begin{align*}
\text{CH}_3 \cdot \text{CH}_3 & \rightarrow \text{CH}_3\text{CH}_3 \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2 \cdot \text{CH}_2\text{CH}_2\text{CH}_3 & \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

Examples of hydrogen abstraction reactions:

\[
\begin{align*}
\text{CH}_3\text{CH}_2 \cdot \text{H} & \rightarrow \text{CH}_3\text{CH}_2 + \text{CH}_2=\text{CH}_2 \\
\text{CH}_3\text{CH}_2\text{CH}_2 \cdot \text{H} & \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2 + \text{CH}_2=\text{CH}_2
\end{align*}
\]

Note how we used single-barbed (fishhook) arrows in these examples to show the formation of a new covalent bond by the combination of two electrons. In the hydrogen abstraction reactions, electrons from a bond being broken combine with unshared electrons to form new bonds.

Control of such processes frequently requires the use of special **catalysts**, such as crystalline sodium aluminosilicates, also called zeolites. For example, zeolite-catalyzed pyrolysis of dodecane yields a mixture in which hydrocarbons containing from three to six carbons predominate.

\[
\begin{array}{c}
\text{Dodecane} \xrightarrow{\text{Zeolite, 482°C, 2 min}} C_3 + C_4 + C_5 + C_6 + \text{other products} \\
\text{17%} & \text{31%} & \text{23%} & \text{18%} & \text{11%}
\end{array}
\]

**The Function of a Catalyst**

What is the function of the zeolite catalyst? It speeds up the pyrolysis, so that the process occurs at a lower temperature than otherwise would be the case. The catalyst also causes certain products to form preferentially. Such enhanced reaction **selectivity** is a feature frequently observed in catalyzed reactions. How does this happen?

In general, catalysts are additives that accelerate reactions. They enable new pathways through which reactants and products are interconverted, pathways that have lower activation energies, \(E_{\text{act}}\), than those available in the absence of the catalyst, \(E_a\). In Figure 3-4, both uncatalyzed and catalyzed processes are shown in a simplified manner to consist of only a single step with one activation barrier. We shall see that most reactions involve more than one step. However, regardless of the number of steps, the catalyzed version of a reaction
always has greatly reduced activation energies. While a catalyst is not consumed during the reaction it facilitates, it actively participates in it through the formation of intermediate reactive species from which it is ultimately regenerated. Therefore, only a small amount of a catalyst is needed to effect the conversion of a large amount of reactants. Catalysts modify the *kinetics* of reactions; that is, they change the rate at which equilibrium is established. However, catalysts do not affect the position of the equilibrium. The overall $\Delta H^\circ$, $\Delta S^\circ$, and hence $\Delta G^\circ$ values for catalyzed and uncatalyzed processes are identical: A catalyst does *not* affect the overall *thermodynamics* of a reaction.

Many organic reactions occur at a useful rate only because of the presence of a catalyst. The catalyst may be an acid (a proton), a base (hydroxide), a metal surface or metal compound, or a complex organic molecule. In nature, *enzymes* usually fulfill this function. The degree of reaction acceleration induced by a catalyst can amount to many orders of magnitude. Enzyme-catalyzed reactions are known to take place $10^{19}$ times faster than the uncatalyzed processes. The use of catalysts allows many transformations to take place at lower temperatures and under much milder reaction conditions than would otherwise be possible.

**Petroleum is an important source of alkanes**

Breaking an alkane down into smaller fragments is also known as *cracking*. Such processes are important in the oil-refining industry for the production of gasoline and other liquid fuels from petroleum.

As mentioned in the introduction to this chapter, petroleum, or crude oil, is believed to be the product of microbial degradation of living organic matter that existed several hundred million years ago. Crude oil, a dark viscous liquid, is primarily a mixture of several hundred different hydrocarbons, particularly straight-chain alkanes, some branched alkanes, and varying quantities of aromatic hydrocarbons. Distillation yields several fractions with a typical product distribution, as shown in Table 3-3. The composition of petroleum varies widely, depending on the origin of the oil.

$^a$This refers to gasoline straight from petroleum, without having been treated in any way.
To increase the quantity of the much-needed gasoline fraction, the oils with higher boiling points are cracked by pyrolysis. Cracking the residual oil from crude petroleum distillation gives approximately 30% gas, 50% gasoline, and 20% higher-molecular-weight oils and a residue called coke.

**CHEMICAL HIGHLIGHT 3-1**

**Sustainability and the Needs of the 21st Century: “Green” Chemistry**

Oil and natural gas supply much of the energy requirement of both the United States and most of the rest of the industrialized nations of the world. In 2007, U.S. energy sources included gas (23%), oil (40%), coal (22%), nuclear (8%), hydroelectric and hydrothermal (3%), and other renewable (4%). Significantly, these percentages have not changed appreciably in over a decade. Much of this requirement is met by imported petroleum products, the rapidly rising cost of which has had a significant impact on the domestic economy. These substances also constitute the raw materials of much of U.S. chemical industry, via their conversion into simpler hydrocarbons such as alkenes, the starting points for countless manufacturing processes. However, this petroleum-based economy is plagued by significant problems: It is energy intensive, suffers from the frequent necessity for toxic discharge, and generates waste in the form of by-products, solvents, and inorganic salts. It is also not sustainable in the future, because the earth’s supply of petroleum is limited.

Chemists in academia and industry have responded by actively exploring alternative sources of raw materials. Less exploited fossil fuels such as methane are under investigation, as are renewable starting materials, typically derived from agricultural sources. The latter, consisting of wood, grain, plant parts and plant oils, and carbohydrates, are by far the most abundant. Plant growth consumes CO₂ via photosynthesis, a desirable feature in a time of concern over the increasing concentration of CO₂ in the atmosphere and its long-term effect on global climate. Conversion of these raw materials into useful products presents a significant challenge, however. Ideally, processes developed for these conversions should be both efficient and environmentally acceptable. What does this mean?

Over the past decade the term green chemistry has been used increasingly to describe processes that meet a number of environmental requirements. The term was coined in 1994 by Dr. Paul T. Anastas of the U.S. Environmental Protection Agency (EPA) to denote chemical activities that strive to achieve the goals of environmental protection and sustainable development. Specifically, this means pollution prevention by reducing or eliminating the use or generation of hazardous materials in design, manufacture, and application of chemical products, and switching from oil-based chemicals to those generated by nature. Some of the principles of green chemistry are (in abbreviated form):

1. It is better to prevent waste than to have to clean it up.
2. Synthetic methods should maximize the incorporation of all starting materials into the final products (“atom economy”).
3. Reactions should use and generate substances that possess efficacy of function but little or no toxicity.
4. Energy requirements should be minimized by conducting reactions at ambient temperature and pressure.
5. Feedstocks should be renewable.
6. Catalytic processes are superior to stoichiometric ones.

A case of a green approach to the cracking of petroleum is the recent discovery of a catalytic process that converts linear alkanes into their higher and lower homologs with good selectivity. For example, when butane is passed over a Ta catalyst deposited on silica at 150°C, it undergoes metathesis (metatithenai, Greek, to transpose) to mainly propane and pentane:

\[
\begin{align*}
\text{Butane} & \to \text{H}_2 + \text{C}_2\text{H}_4 + \text{C}_5\text{H}_{12} \\
\text{Ta on SiO}_2, \text{150°C} & \to \\
\text{H}_2\text{C}_2\text{H}_4 & \to \text{H}_2\text{C}_2\text{H}_4 + \text{H}_2\text{C}_2\text{H}_6
\end{align*}
\]

This process has no waste, complete atom economy, is nontoxic, occurs at a much lower temperature than conventional cracking, and is catalytic, fulfilling all the requirements of a green reaction. Methods such as these are forming a new paradigm for the practice of chemistry in the 21st century.
3-4 Chlorination of Methane: The Radical Chain Mechanism

We have seen that alkanes undergo chemical transformations when subjected to pyrolysis, and that these processes include the formation of radical intermediates. Do alkanes participate in other reactions? In this section, we consider the effect of exposing an alkane (methane) to a halogen (chlorine). A chlorination reaction, in which radicals again play a key role, takes place, producing chloromethane and hydrogen chloride. We shall analyze each step in this transformation to establish the mechanism of the reaction.

Chlorine converts methane into chloromethane

When methane and chlorine gas are mixed in the dark at room temperature, no reaction occurs. The mixture must be heated to a temperature above 300°C (denoted by Δ) or irradiated with ultraviolet light (denoted by hν) before a reaction takes place. One of the two initial products is chloromethane, derived from methane in which a hydrogen atom is removed and replaced by chlorine. The other product of this transformation is hydrogen chloride. Further substitution leads to dichloromethane (methylene chloride), CH₂Cl₂; trichloromethane (chloroform), CHCl₃; and tetrachloromethane (carbon tetrachloride), CCl₄.

Why should this reaction proceed? Consider its ΔH°. Note that a C–H bond in methane (ΔH° = 105 kcal mol⁻¹) and a Cl–Cl bond (ΔH° = 58 kcal mol⁻¹) are broken, whereas the C–Cl bond of chloromethane (ΔH° = 85 kcal mol⁻¹) and an H–Cl linkage (ΔH° = 103 kcal mol⁻¹) are formed. The net result is the release of 25 kcal mol⁻¹ in forming stronger bonds: The reaction is exothermic (heat releasing).

Why, then, does the thermal chlorination of methane not occur at room temperature? The fact that a reaction is exothermic does not necessarily mean that it proceeds rapidly and spontaneously. Remember (Section 2-1) that the rate of a chemical transformation depends on its activation energy, which in this case is evidently high. Why is this so? What is the function of irradiation when the reaction does proceed at room temperature? Answering these questions requires an investigation of the mechanism of the reaction.

The mechanism explains the experimental conditions required for reaction

A mechanism is a detailed, step-by-step description of all the changes in bonding that occur in a reaction (Section 1-1). Even simple reactions may consist of several separate steps. The mechanism shows the sequence in which bonds are broken and formed, as well as the energy changes associated with each step. This information is of great value in both analyzing possible transformations of complex molecules and understanding the experimental conditions required for reactions to occur.

The mechanism for the chlorination of methane, in common with the mechanisms of most radical reactions, consists of three stages: initiation, propagation, and termination. Let us look at these stages and the experimental evidence for each of them in more detail.

The chlorination of methane can be studied step by step

Experimental observation. Chlorination occurs when a mixture of CH₄ and Cl₂ is either heated to 300°C or irradiated with light, as mentioned earlier. Under such conditions, methane by itself is completely stable, but Cl₂ undergoes homolysis to two atoms of chlorine.

Interpretation. The first step in the mechanism of chlorination of methane is the heat- or light-induced homolytic cleavage of the Cl–Cl bond (which happens to be the weakest bond
in the starting mixture, with $\Delta H^\circ = 58$ kcal mol$^{-1}$). This event is required to start the chlorination process and is therefore called the initiation step. As implied by its name, the initiation step generates reactive species (in this case, chlorine atoms) that permit the subsequent steps in the overall reaction to take place.

**Initiation:** Homolytic cleavage of the Cl–Cl bond

$$\Delta H^\circ = \Delta H^\circ(\text{Cl}_2) = +58 \text{ kcal mol}^{-1} (+243 \text{ kJ mol}^{-1})$$

**Experimental observation.** Only a relatively small number of initiation events (e.g., photons of light) are necessary to enable a great many methane and chlorine molecules to undergo conversion into products.

**Interpretation.** After initiation has taken place, the subsequent steps in the mechanism are self-sustaining, or self-propagating; that is, they can occur many times without the addition of further chlorine atoms from the homolysis of Cl$_2$. Two propagation steps fulfill this requirement. In the first step, a chlorine atom attacks methane by abstracting a hydrogen atom. The products are hydrogen chloride and a methyl radical.

**Propagation step 1: Abstraction of an H atom by :Cl.**

The $\Delta H^\circ$ for this transformation is positive; it is endothermic (heat absorbing), and its equilibrium is slightly unfavorable. What is its activation energy, $E_a$? Is there enough heat to overcome this barrier? In this case, the answer is yes. An orbital description of the transition state (Section 2-1) of hydrogen removal from methane (Figure 3-5) reveals the details

**Figure 3-5** Approximate orbital description of the abstraction of a hydrogen atom by a chlorine atom to give a methyl radical and hydrogen chloride. Notice the rehybridization at carbon in the planar methyl radical. The additional three nonbonded electron pairs on chlorine have been omitted. The orbitals are not drawn to scale. The symbol ‡ identifies the transition state.
of the process. The reacting hydrogen is positioned between the carbon and the chlorine, partly bound to both: H–Cl bond formation has occurred to about the same extent as C–H bond-breaking. The transition state, which is labeled by the symbol ‡, is located only about 4 kcal mol\(^{-1}\) above the starting materials. A potential-energy diagram describing this step is shown in Figure 3-6.

Propagation step 1 gives one of the products of the chlorination reaction: HCl. What about the organic product, CH\(_3\)Cl? Chloromethane is formed in the second propagation step. Here the methyl radical abstracts a chlorine atom from one of the starting Cl\(_2\) molecules, thereby furnishing chloromethane and a new chlorine atom. The latter reenters propagation step 1 to react with a new molecule of methane. Thus, one propagation cycle is closed, and a new one begins, without the need for another initiation step to take place. Note how exothermic propagation step 2 is, \(-27\) kcal mol\(^{-1}\). It supplies the overall driving force for the reaction of methane with chlorine.

**Propagation step 2: Abstraction of a Cl atom by \(\cdot\)CH\(_3\)**

\[
\text{H} + \text{Cl} 
\quad \rightarrow \quad \text{H} + \text{Cl} 
\]

\[
\Delta H^\circ = \Delta H^\circ(\text{Cl}_2) - \Delta H^\circ(\text{CH}_3\text{Cl}) 
\]

\[
= -27 \text{ kcal mol}^{-1} (-113 \text{ kJ mol}^{-1}) 
\]

Because propagation step 2 is exothermic, the unfavorable equilibrium in the first propagation step is pushed toward the product side by the rapid depletion of its methyl radical product in the subsequent reaction.

\[
\text{CH}_4 + \text{Cl}\cdot \rightleftharpoons \text{CH}_3\cdot + \text{HCl} 
\quad \rightarrow \quad \text{CH}_3\cdot + \text{HCl} 
\rightarrow \text{CH}_3\text{Cl} + \text{Cl}\cdot + \text{HCl} 
\]

Slightly unfavorable; Very favorable; “drives” first equilibrium

The potential-energy diagram in Figure 3-7 illustrates this point by continuing the progress of the reaction begun in Figure 3-6. Propagation step 1 has the higher activation energy and is therefore slower than step 2. The diagram also shows that the overall \(\Delta H^\circ\) of the reaction is made up of the \(\Delta H^\circ\) values of the propagation steps: \(+2 - 27 = -25\) kcal mol\(^{-1}\). You can see that this is so by adding the equations for the two propagation steps.

\[
\Delta H^\circ [\text{kcal mol}^{-1} (\text{kJ mol}^{-1})] 
\]

\[
\begin{align*}
\text{Cl}\cdot + \text{CH}_4 & \rightarrow \text{CH}_3\cdot + \text{HCl} \\
\text{CH}_3\cdot + \text{Cl}_2 & \rightarrow \text{CH}_3\text{Cl} + \text{Cl}\cdot \\
\text{CH}_4 + \text{Cl}_2 & \rightarrow \text{CH}_3\text{Cl} + \text{Cl}\cdot 
\end{align*}
\]

\[
\begin{align*}
\Delta H^\circ &= +2 (+8) \\
\Delta H^\circ &= -27 (-113) \\
\Delta H^\circ &= -25 (-105) 
\end{align*}
\]
Experimental observation. Small amounts of ethane are identified among the products of chlorination of methane.

Interpretation. Radicals and free atoms are capable of undergoing direct covalent bonding with one another. In the methane chlorination process, three such combination processes are possible, one of which—the reaction of two methyl groups—furnishes ethane. The concentrations of radicals and free atoms in the reaction mixture are very low, however, and hence the chance of one radical or free atom finding another is small. Such combinations are therefore relatively infrequent. When such an event does take place, the propagation of the chains giving rise to the radicals or atoms is terminated. We thus describe these combination processes as termination steps.

Chain termination: Radical–radical combination

\[
\cdot\ddot{\text{Cl}} + \ddot{\text{Cl}} \rightarrow \text{Cl} + \text{Cl} \\
\cdot\ddot{\text{Cl}} + \cdot\ddot{\text{CH}} \rightarrow \text{CH}_3 + \ddot{\text{Cl}} \\
\text{CH}_3 + \cdot\ddot{\text{CH}} \rightarrow \text{CH}_3 + \text{CH}_3
\]

The mechanism for the chlorination of methane is an example of a radical chain mechanism.
Only a few halogen atoms are necessary for initiating the reaction, because the propagation steps are self-sufficient in $\dot{X}$-. The first propagation step consumes a halogen atom, the second produces one. The newly generated halogen atom then reenters the propagation cycle in the first propagation step. In this way, a radical chain is set in motion that can drive the reaction for many thousands of cycles.

**Exercise 3-4**

**Working with the Concepts: Radical Chain Mechanisms**

Write a detailed mechanism for the light-initiated monochlorination of ethane, which furnishes chloroethane. Calculate $\Delta H^o$ for each step.

**Strategy**

Begin by writing the overall equation for the reaction and calculating its $\Delta H^o$, using data in Tables 3-1 and 3-2 and the formula $\Delta H^o = \sum \Delta H^o_{\text{bonds broken}} - \sum \Delta H^o_{\text{bonds formed}}$. Then write the initiation, propagation, and termination steps for a typical radical chain mechanism.

**Solution**

• The reaction equation is

$$\text{CH}_3\text{CH}_2\text{H} + \dot{\text{Cl}} \rightarrow \text{CH}_3\text{CH}_2\dot{\text{Cl}} + \text{H}$$

$$\Delta H^o = 101 + 58 - 84 - 103 = -28 \text{ kcal mol}^{-1}$$

The reaction is more exothermic than chlorination of methane, mainly because breaking the C–H bond in ethane requires less energy than breaking the C–H bond in methane.

• The initiation step in the mechanism is light-induced dissociation of Cl₂:

$$\text{Cl}_2 \rightarrow 2\dot{\text{Cl}}. \quad \Delta H^o = +58 \text{ kcal mol}^{-1}$$

• Using the propagation steps for chlorination of methane as a model, write analogous steps for ethane. In step 1, a chlorine atom abstracts a hydrogen:

$$\text{CH}_3\text{CH}_2\text{H} + \dot{\text{Cl}} \rightarrow \text{CH}_3\text{CH}_2\text{Cl} + \text{H}$$

$$\Delta H^o = 101 - 103 = -2 \text{ kcal mol}^{-1}$$

• In step 2, the ethyl radical formed in step 1 abstracts a chlorine atom from Cl₂:

$$\text{CH}_3\text{CH}_2\dot{\text{Cl}} + \text{Cl}_2 \rightarrow \text{CH}_3\text{CH}_2\text{Cl} + \text{Cl}_2$$

$$\Delta H^o = 58 - 84 = -26 \text{ kcal mol}^{-1}$$

Note that the sum of the $\Delta H^o$ values for the two propagation steps gives us $\Delta H^o$ for the overall reaction. This is because summing the species present in the two propagation steps cancels both ethyl radicals and chlorine atoms, leaving just the overall stoichiometry.

• Finally, we formulate the termination steps as follows:

$$\text{Cl}_2 + \dot{\text{Cl}} \rightarrow \text{Cl}_2$$

$$\Delta H^o = -58 \text{ kcal mol}^{-1}$$

$$\text{CH}_3\text{CH}_2\dot{\text{Cl}} + \text{Cl}_2 \rightarrow \text{CH}_3\text{CH}_2\text{Cl}$$

$$\Delta H^o = -84 \text{ kcal mol}^{-1}$$

$$\text{CH}_3\text{CH}_2\dot{\text{Cl}} + \text{CH}_3\text{CH}_3 \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3$$

$$\Delta H^o = -88 \text{ kcal mol}^{-1}$$

One of the practical problems in chlorinating methane is the control of product selectivity. As mentioned earlier, the reaction does not stop at the formation of chloromethane but continues to form di-, tri-, and tetrachloromethane by further substitution. A practical solution to this problem is the use of a large excess of methane in the reaction. Under
such conditions, the reactive intermediate chlorine atom is at any given moment surrounded by many more methane molecules than product CH₃Cl. Thus, the chance of Cl· finding CH₃Cl to eventually make CH₂Cl₂ is greatly diminished, and product selectivity is achieved.

**Exercise 3-5**

**Try It Yourself**

Write out the overall equation and the propagation steps of the mechanism for the chlorination of chloromethane to furnish dichloromethane, CH₂Cl₂. (Caution: Write out each step of the mechanism separately and completely. Be sure to include full Lewis structures of all species and all appropriate arrows to show electron movement.)

**In Summary** Chlorine transforms methane into chloromethane. The reaction proceeds through a mechanism in which heat or light causes a small number of Cl₂ molecules to undergo homolysis to chlorine atoms (initiation). The chlorine atoms induce and maintain a radical chain sequence consisting of two (propagation) steps: (1) hydrogen abstraction to generate the methyl radical and HCl and (2) conversion of CH₃· by Cl₂ into CH₃Cl and regenerated Cl·. The chain is terminated by various combinations of radicals and free atoms. The heats of the individual steps are calculated by comparing the strengths of the bonds that are being broken with those of the bonds being formed.

### 3-5 Other Radical Halogenations of Methane

Fluorine and bromine, but not iodine, also react with methane by similar radical mechanisms to furnish the corresponding halomethanes. The dissociation energies of X₂ (X = F, Br, I) are lower than that of Cl₂, thus ensuring ready initiation of the radical chain (Table 3-4).

#### Fluorine is most reactive, iodine least reactive

Let us compare the enthalpies of the first propagation step in the different halogenations of methane (Table 3-5). For fluorine, this step is exothermic by −31 kcal mol⁻¹. We have already seen that, for chlorine, the same step is slightly endothermic; for bromine, it is substantially so, and for iodine even more so. This trend has its origin in the decreasing bond strengths of the hydrogen halides in the progression from fluorine to iodine (Table 3-1). The strong hydrogen–fluorine bond is the cause of the high reactivity of fluorine atoms in hydrogen abstraction reactions. Fluorine is more reactive than chlorine, chlorine is more reactive than bromine, and the least reactive halogen atom is iodine.

The contrast between fluorine and iodine is illustrated by comparing potential-energy diagrams for their respective hydrogen abstractions from methane (Figure 3-8). The highly exothermic reaction of fluorine has a negligible activation barrier. Moreover, in its transition state, the fluorine atom is relatively far from the hydrogen that is being

transferred, and the H–CH₃ distance is only slightly greater than that in CH₄ itself. Why should this be so? The H–CH₃ bond is about 30 kcal mol⁻¹ (125 kJ mol⁻¹) weaker than that of H–F (Table 3-1). Only a small shift of the H toward the F is necessary for bonding between the two to overcome the bonding between hydrogen and carbon. If we view the reaction coordinate as a measure of the degree of hydrogen shift from C to F, the transition state is reached early and is much closer in appearance to the starting materials than to the products. Early transition states are frequently characteristic of fast, exothermic processes.

On the other hand, reaction of I· with CH₄ has a very high Eₐ [at least as large as its endothermicity, +34 kcal mol⁻¹ (+142 kJ mol⁻¹); Table 3-5]. Thus, the transition state is not reached until the H–C bond is nearly completely broken and the H–I bond is almost fully formed. The transition state is said to occur late in the reaction pathway. It is substantially further along the reaction coordinate and is much closer in structure to the products of this process, CH₃· and HI. Late transition states are frequently typical of relatively slow, endothermic reactions. Together these rules concerning early and late transition states are known as the Hammond* postulate.

The second propagation step is exothermic

Let us now consider the second propagation step for each halogenation in Table 3-5. This process is exothermic for all the halogens. Again, the reaction is fastest and most exothermic for fluorine. The combined enthalpies of the two steps for the fluorination of methane result in a ΔH° of -103 kcal mol⁻¹ (-431 kJ mol⁻¹). The formation of chloromethane is less exothermic and that of bromomethane even less so. In the latter case, the appreciably endothermic nature of the first step [ΔH° = +18 kcal mol⁻¹ (+75 kJ mol⁻¹)] is barely overcome by the enthalpy of the second [ΔH° = -24 kcal mol⁻¹ (-100 kJ mol⁻¹)], resulting in an energy change of only -6 kcal mol⁻¹ (-25 kJ mol⁻¹) for the overall substitution. Finally, iodine does not react with methane to furnish methyl iodide and hydrogen iodide: The first step costs so much energy that the second step, although exothermic, cannot drive the reaction.

*Professor George S. Hammond (1921–2005), Georgetown University, Washington, D.C.
In Summary  Fluorine, chlorine, and bromine react with methane to give halomethanes. All three reactions follow the radical chain mechanism described for chlorination. In these processes, the first propagation step is always the slower of the two. It becomes more exothermic and its activation energy decreases in the progression from bromine to chlorine to fluorine. This trend explains the relative reactivity of the halogens, fluorine being the most reactive. Iodination of methane is endothermic and does not occur. Strongly exothermic reaction steps are often characterized by early transition states. Conversely, endothermic steps typically have late transition states.

3-6 Chlorination of Higher Alkanes: Relative Reactivity and Selectivity

What happens in the radical halogenation of other alkanes? Will the different types of R–H bonds—namely, primary, secondary, and tertiary—react in the same way as those in methane? As we saw in Exercise 3-4, the monochlorination of ethane gives chloroethane as the product.

\[
\text{Chlorination of Ethane} \\
\text{CH}_3\text{CH}_3 + \text{Cl}_2 \xrightarrow{\Delta \text{ or } h\nu} \text{CH}_3\text{CH}_2\text{Cl} + \text{HCl} \\
\text{Δ}H^\circ = -28 \text{ kcal mol}^{-1} \quad (-117 \text{ kJ mol}^{-1})
\]

This reaction proceeds by a radical chain mechanism analogous to the one observed for methane. As in methane, all of the hydrogen atoms in ethane are indistinguishable from one another. Therefore, we observe only one monochlorination product, chloroethane, regardless of which hydrogen is initially abstracted by chlorine in the first propagation step.

**Propogation Steps in the Mechanism of the Chlorination of Ethane**

\[
\text{CH}_3\text{CH}_3 + :\text{Cl} \rightarrow \text{CH}_3\text{CH}_2\cdot + \text{HCl} : \quad \text{Δ}H^\circ = -2 \text{ kcal mol}^{-1} \quad (-8 \text{ kJ mol}^{-1})
\]

\[
\text{CH}_3\text{CH}_2\cdot + \text{Cl}_2 \rightarrow \text{CH}_3\text{CH}_2\text{Cl} : + :\text{Cl} \cdot \quad \text{Δ}H^\circ = -26 \text{ kcal mol}^{-1} \quad (-109 \text{ kJ mol}^{-1})
\]

What can be expected for the next homolog, propane?

**Secondary C–H bonds are more reactive than primary ones**

The eight hydrogen atoms in propane fall into two groups: six primary and two secondary hydrogens. If chlorine atoms were to abstract and replace primary and secondary hydrogens at equal rates, we should expect to find a product mixture containing three times as much 1-chloropropane as 2-chloropropane. We call this outcome a *statistical product ratio*, because it derives from the statistical fact that in propane there are three times as many primary sites for reaction as secondary sites. In other words, it is three times as likely for a chlorine atom to collide with a primary hydrogen in propane, of which there are six, as with a secondary hydrogen atom, of which there are only two.

However, secondary C–H bonds are weaker than primary ones (\(\Delta H^\circ = 98.5\) versus 101 kcal mol\(^{-1}\)). Abstraction of a secondary hydrogen is therefore more exothermic and
proceeds with a smaller activation barrier (Figure 3-9). We might thus expect secondary hydrogens to react faster, leading to more 2-chloro- than 1-chloropropane. What is actually observed? At 25°C, the experimental ratio of 1-chloropropane:2-chloropropane is found to be 43:57. This result indicates that both statistical and bond-energy factors determine the product formed.

**Chlorination of Propane**

\[
\text{Cl}_2 + \text{CH}_3\text{CH}_2\text{CH}_3 \xrightarrow{\text{hv}} \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} + \text{CH}_3\text{CHCH}_3 + \text{HCl}
\]

Expected statistical ratio: 3 : 1
Expected C–H bond reactivity ratio: Less : More
Experimental ratio (25°C): 43 : 57

It would be good to know the **relative reactivity of secondary and primary hydrogens** in the chlorination of propane and, by extrapolation, the alkanes in general. For this purpose, we need to factor out the statistical contribution of the hydrogens in propane to the product ratio. In other words, what we want to know is: How much does one primary hydrogen contribute to the “43” in the product ratio, and how much does one secondary hydrogen do so to the “57” part? To find out, we simply divide these values by the respective numbers of hydrogens giving rise to them: 43 is divided by 6 (=7) and 57 by 2 (=28).

\[
\frac{\text{Reactivity of } H_{\text{sec}}}{\text{Reactivity of } H_{\text{prim}}} = \frac{\text{yield of 2-chloropropane/number of } H_{\text{sec}}}{\text{yield of 1-chloropropane/number of } H_{\text{prim}}} = \frac{57}{43/6} = \frac{57/7}{28/7} = \frac{28}{4} = 7
\]

Thus, the relative reactivity of a secondary versus primary H in propane is about 28/7 = 4. We say that chlorine exhibits a **selectivity** of 4:1 in the removal of secondary versus primary hydrogens at 25°C.

We could predict from this analysis that **all** secondary hydrogens are four times as reactive as all primary hydrogens in **all** radical chain reactions. Is this prediction true? Unfortunately, no. Although secondary C–H bonds generally undergo dissociation faster than do their primary counterparts, their relative reactivity very much depends on the nature of the attacking species, X·, the strength of the resulting H–X bond, and the temperature. For example, at 600°C, the chlorination of propane results in the statistical distribution of products: roughly three times as much 1-chloropropane as 2-chloropropane. At such a high
Tertiary C–H bonds are more reactive than secondary ones

Let us now find the relative reactivity of a tertiary hydrogen in the chlorination of alkanes. For this purpose, we expose 2-methylpropane, a molecule containing one tertiary and nine primary hydrogens, to chlorination conditions at 25°C. The resulting two products, 2-chloro-2-methylpropane (tert-butyl chloride) and 1-chloro-2-methylpropane (isobutyl chloride), are formed in the relative yields of 36 and 64%, respectively.

Chlorination of 2-Methylpropane

\[
\text{Cl}_2 + \text{CH}_3\text{C} - \text{H} \xrightarrow{hv} \text{ClCH}_2\text{C} - \text{H} + \text{CH}_3\text{C} - \text{Cl} + \text{HCl}
\]

<table>

<td>64%</td>
</tr>
<tr>
<td>(tert-Butyl chloride)</td>
<td></td>
</tr>
</tbody>
</table>

We determine the reactivity of tertiary relative to primary hydrogens in the same manner as that employed above for secondary relative to primary hydrogens. We combine the experimental result of 64% primary chlorination and 36% tertiary chlorination in 2-methylpropane with the statistical presence of nine primary hydrogens and one tertiary hydrogen atom in the starting alkane. Dividing the proportionate amount observed of each product by the number of hydrogens that contribute to its formation gives a measure of reactivity per hydrogen atom:

\[
\text{Reactivity of } H_{\text{tert}} = \frac{\text{yield of 2-chloro-2-methylpropane}}{\text{number of } H_{\text{tert}}} = \frac{36}{9} = 4
\]

\[
\text{Reactivity of } H_{\text{prim}} = \frac{\text{yield of 1-chloro-2-methylpropane}}{\text{number of } H_{\text{prim}}} = \frac{36}{7} = 5
\]

Thus, tertiary hydrogen atoms are about five times as reactive as primary ones. This selectivity, again, decreases at higher temperatures. However, we can say that, at 25°C, the relative reactivities of the various C–H bonds in chlorinations are roughly

\[
\text{Tertiary : secondary : primary} = 5 : 4 : 1
\]

The result agrees qualitatively quite well with the relative reactivity expected from consideration of bond strength: The tertiary C–H bond is weaker than the secondary, and the secondary in turn is weaker than the primary.
Exercise 3-8

Working with the Concepts: Determining Product Ratios from Selectivity Data

Consider the monochlorination of 2-methylbutane. How many different products do you expect? Estimate their yields.

Strategy
The first step is to identify all non-equivalent groups of hydrogens in the starting alkane and count how many hydrogens are in each group. This will tell you how many different products to expect from the reaction. To calculate the relative yield of each product, multiply the number of hydrogens in the starting alkane that give rise to that product by the relative reactivity corresponding to that type of hydrogen (primary, secondary, or tertiary). To find the absolute percentage yield, normalize to 100% by dividing each relative yield by the sum of the yields of all the products.

Solution
• 2-Methylbutane contains nine primary hydrogens, two secondary hydrogens, and one tertiary hydrogen. However, the nine primary hydrogens are not all equivalent; that is, they are not all indistinguishable from one another. Instead, we can discern two distinct groups of primary hydrogens. How do we know these groups are distinct from each other? Chlorination of any one of the six hydrogens in group A gives 1-chloro-2-methylbutane, whereas reaction of any one of the three in group B gives 1-chloro-3-methylbutane. These products are constitutional isomers of each other and have different names—this is the clue that tells us that they arise from replacement of hydrogens in distinct, non-equivalent groups. Thus, we can obtain four structurally different products instead of three:

Chlorination of 2-Methylbutane

- Chlorination at A
- Chlorination at B
- Chlorination at C
- Chlorination at D

Substitution at the primary carbon
Substitution at the secondary carbon
Substitution at the tertiary carbon

• Carrying out the calculations as described in the strategy above gives us the following table:

<table>
<thead>
<tr>
<th>Product</th>

</tbody>
</table>

Exercise 3-9

Try It Yourself

Give products and the ratio in which they are expected to form for the monochlorination of 3-methylpentane at 25°C. (Caution: Be sure to take into account the number of hydrogens in each distinct group in the starting alkane.)
In Summary  The relative reactivity of primary, secondary, and tertiary hydrogens follows the trend expected on the basis of their relative C–H bond strengths. Relative reactivity ratios can be calculated by factoring out statistical considerations. These ratios are temperature dependent, with greater selectivity at lower temperatures.

3-7 Selectivity in Radical Halogenation with Fluorine and Bromine

How selectively do halogens other than chlorine halogenate the alkanes? Table 3-5 and Figure 3-8 show that fluorine is the most reactive halogen: Hydrogen abstraction is highly exothermic and has negligible activation energy. Conversely, bromine is much less reactive, because the same step has a large positive $\Delta H^\circ$ and a high activation barrier. Does this difference affect their selectivity in halogenation of alkanes?

To answer this question, consider the reactions of fluorine and bromine with 2-methylpropane. Single fluorination at 25°C furnishes two possible products, in a ratio very close to that expected statistically.

Fluorination of 2-Methylpropane

\[
F_2 + (CH_3)_2CH \xrightarrow{hv} FCH_2\overset{\text{F}}{\text{C}} \overset{\text{H}}{\text{H}} + (CH_3)_2CF + HF
\]

<table>
<thead>
<tr>
<th>Expected statistical ratio</th>
<th>9 : 1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Expected C–H bond reactivity ratio</td>
<td>Less : More</td>
</tr>
<tr>
<td>Experimental ratio (25°C)</td>
<td>86 : 14</td>
</tr>
</tbody>
</table>

Fluorine thus displays very little selectivity. Why? Because the transition states for the two competing processes are reached very early, their energies and structures are similar to each other, as well as similar to those of the starting material (Figure 3-10).

Conversely, bromination of the same compound is highly selective, giving the tertiary bromide almost exclusively. Hydrogen abstractions by bromine have late transition states in which extensive C–H bond breaking and H–Br bond making have occurred. Thus, their respective structures and energies resemble those of the corresponding radical products. As a result, the activation barriers for the reaction of bromine with primary and tertiary hydrogens, respectively, will differ by almost as much as the difference in stability between

Figure 3-10 Potential-energy diagram for the abstraction of a primary or a tertiary hydrogen by a fluorine atom from 2-methylpropane. The energies of the respective early transition states are almost the same and barely higher than that of starting material (i.e., both $E_a$ values are close to zero), resulting in little selectivity.
primary and tertiary radicals (Figure 3-11), a difference leading to the observed high selectivity (more than 1700:1).

**Bromination of 2-Methylpropane**

\[
\text{Br}_2 + (\text{CH}_3)_2\text{CH} \xrightarrow{hv} (\text{CH}_3)_2\text{CBr} + \text{BrCH}_2\text{C} - \text{H} + \text{HBr}
\]

\[
\begin{align*}
&\text{CH}_3 \\
&\text{CH}_3\text{CH}_3 + :\text{Br} \\
&\text{CH}_3\text{CH}_3\text{CH}_3 + \text{Br} \\
&\text{CH}_3\text{CH}_3\text{CH}_2 + \text{HBr}
\end{align*}
\]

In Summary Increased reactivity goes hand in hand with reduced selectivity in radical substitution reactions. Fluorine and chlorine, the more reactive halogens, discriminate between the various types of C–H bonds much less than does the less reactive bromine (Table 3-6).

### 3-8 Synthetic Radical Halogenation

Halogenation converts nonfunctional alkanes into functionalized haloalkanes, which (as we shall soon see) are useful starting materials for a variety of subsequent transformations. Thus, devising successful and cost-effective halogenations is of practical value. To do so, we must take into account safety, convenience, selectivity, efficiency, and cost of starting materials and reagents—considerations of green chemistry (see Chemical Highlight 3-1).

Fluorinations are unattractive, because fluorine is relatively expensive and corrosive. Even worse, its reactions are often violently uncontrollable. Radical iodinations, at the other extreme, fail because of unfavorable thermodynamics.

⁠For each halogen, reactivities with four types of alkane C–H bonds are normalized to the reactivity of the primary C–H bond.
Chlorinations are important, particularly in industry, simply because chlorine is inexpensive. (It is prepared by electrolysis of sodium chloride, ordinary table salt.) The drawback to chlorination is low selectivity, so the process results in mixtures of isomers that are difficult to separate. To circumvent the problem, an alkane that contains a single type of hydrogen can be used as a substrate, thus giving (at least initially) a single product. Cyclopentane is one such alkane. We depict it using the bond-line notation (Section 1-9).

**Chlorination of a Molecule with Only One Type of Hydrogen**

\[
\text{Cyclopentane} + \text{Cl}_2 \xrightarrow{hv} \text{Chlorocyclopentane} + \text{HCl}
\]

To minimize production of compounds with more than one chlorine atom, chlorine is used as the limiting reagent (Section 3-4). Even then, multiple substitution can complicate the reaction. Conveniently, the more highly chlorinated products have higher boiling points and can be separated by distillation.

### Exercise 3-10

**Working with the Concepts: Evaluating Synthetic Utility**

Would you consider the monochlorination of methylcyclopentane (margin) to be a synthetically useful reaction?

**Strategy**

Synthetically useful reactions are ones that produce a single product with high selectivity and in good yield. Does this one? The starting compound contains 12 hydrogen atoms. Consider the product of replacement of each of these hydrogens by chlorine. Are they all the same, or are they structurally different? If more than one can form, we must estimate their relative amounts.

**Solution**

The molecule’s 12 hydrogens divide into three primary (on the CH₃ group), one tertiary (on C1), and eight secondary (on C2–C5). In addition, the eight secondary hydrogens are divided into two groups, four on C2 and C5, and four on C3 and C4. Thus several isomeric products must result from monochlorination. The only way this reaction can still be synthetically useful is if one of these isomers forms in much higher yield than all of the others.

Recalling the relative reactivities of hydrogens toward chlorination (tertiary = 5, secondary = 4, and primary = 1), it is evident that all of the above products will form in significant amounts. By multiplying the number of hydrogens in each group in the starting structure by the relative reactivity corresponding to its type, we find that the actual ratios for A, B, C, and D will be 5 (1 × 5) : 3 (3 × 1) : 16 (4 × 4) : 16 (4 × 4). This process will *not* be synthetically useful!
Chapter 3
Reactions of Alkanes

Exercise 3-11

Chlorination, Chloral, and DDT

1,1,1-Trichloro-2,2-bis(4-chlorophenyl)ethane
(DDT, for “dichlorodiphenyltrichloroethane”)

Chlorination of ethanol to produce trichloroacetaldehyde, 
CCl₃CHO, was first described in 1832. Its hydrated form is 
called chloral and is a powerful hypnotic with the nickname “knockout drops.” Chloral is a key reagent in the synthesis 
of DDT, which was first prepared in 1874 and was demonstrated by Paul Mueller* in 1939 to be a powerful insecticide. 
The use of DDT in the suppression of insect-borne diseases was perhaps best described in a 1970 report by the 
U.S. National Academy of Sciences: “To only a few chemicals does man owe as great a debt as to DDT . . . . In little 
more than two decades, DDT has prevented 500 million human deaths, due to malaria, that otherwise would have 
been inevitable.” DDT effectively kills the Anopheles mosquito, the main carrier of the malaria parasite. Malaria 
afflicts hundreds of millions of people worldwide and claims over 2 million lives each year, mostly children under the age 
of five.

Although its toxicity to mammals is low, DDT is rather 
resistant to biodegradation. Its accumulation in the food 
chain makes it a hazard to birds and fish; in particular, DDT interferes with proper eggshell development in many species. 
DDT was banned by the U.S. Environmental Protection 
Agency in 1972. However, because of its remarkable efficacy 
in controlling malaria, 13 countries in which the disease is a 
major health problem are still using DDT, albeit in a highly 
controlled manner.

*Dr. Paul Mueller (1899–1965), J. R. Geigy Co., Basel, Switzerland, 
Nobel Prize 1948 (physiology or medicine).

Because bromination is selective (and bromine is a liquid), it is frequently the method 
of choice for halogenating an alkane on a relatively small scale in the research laboratory. 
Reaction occurs at the more substituted carbon, even in statistically unfavorable situations. 
Typical solvents are chlorinated methanes (CCl₄, CHCl₃, CH₂Cl₂), which are comparatively 
unreactive with bromine.

In Summary
Even though it is more expensive, bromine is the reagent of choice for selective radical halogenations. Chlorinations furnish product mixtures, a problem that can be minimized by choosing alkanes with only one type of hydrogen and treating them with a deficiency of chlorine.

Exercise 3-11

Try It Yourself

Would you expect either monochlorination or monobromination of 2,3-dimethylbutane to be a synthetically useful process?

Eggshells damaged by high concentrations of environmental pollutants.
3-9 Synthetic Chlorine Compounds and the Stratospheric Ozone Layer

We have seen that bond homolysis can be caused by heat and light. Such chemical events can occur on a grand scale in nature and may have serious environmental consequences. This section explores an example of radical chemistry that has had a significant effect on our lives and will continue to do so for at least the next 50 years.

The ozone layer shields Earth’s surface from high-energy ultraviolet light

Earth’s atmosphere consists of several distinct layers. The lowest layer, extending to about 15 km in altitude, is the troposphere, the region where weather occurs. Above the troposphere, the stratosphere extends upward to an altitude of some 50 km. Although the density of the stratosphere is too low to sustain terrestrial life, the stratosphere is the home of the ozone layer, which plays a critical role in the ability of life to survive on Earth (Figure 3-12). Ozone (O₃) and ordinary molecular oxygen (O₂) interconvert in the stratosphere by the action of ultraviolet light from the sun:

\[
\text{O}_2 + \cdot \text{O} \rightarrow \text{O}_3 \\
\text{O}_3 + \cdot \text{O} \rightarrow \text{O}_2 + \cdot \text{O} \\
\]

In the first two reactions, high-energy solar radiation splits O₂ into oxygen atoms, which may combine with other molecules of O₂ to produce ozone, a bluish gas with a characteristic sharp and penetrating odor. Occasionally, ozone may be detected in the vicinity of high-voltage equipment, in which electrical discharges cause the conversion of O₂ into O₃.

In urban areas, nitrogen dioxide (NO₂) is produced through oxidation of nitric oxide (NO), a product of high-temperature combustion. Nitrogen dioxide, in turn, is split by sunlight to release oxygen atoms, which produce O₃ in the lower atmosphere.

A color-enhanced view of the upper atmosphere above Antarctica shows that region in which the concentration of ozone has dropped below 35% of normal (violet and gray areas). The ozone hole has shown considerable variation in size and shape, reaching its greatest extent — 12 million square miles (30 million square km) — in both 2003 and 2006. In 2008 the hole peaked at 11 million square miles (27 million square km), still twice the size of Antarctica and large enough to pose a hazard to people in South America.
The presence of ozone as an air pollutant near Earth’s surface causes severe irritation of the respiratory membranes and the eyes. However, in the upper atmosphere, the third reaction in the interconversion of ozone and molecular oxygen shown above occurs, in which ozone absorbs UV light in the 200- to 300-nm wavelength range. Irradiation at these wavelengths is capable of destroying the complex molecules that make up biochemical systems. Ozone serves as a natural atmospheric filter, preventing up to 99% of this light from reaching the surface and thereby protecting Earth’s life from damage.

**CFCs release chlorine atoms upon ultraviolet irradiation**

Chlorofluorocarbons (CFCs), or freons, are alkanes in which all of the hydrogens have been replaced by fluorine and chlorine. In general, chlorofluorocarbons are thermally stable, essentially odorless, and nontoxic gases. Among their many commercial applications, their use as refrigerants predominates, because they absorb large quantities of heat upon vaporization. Compression liquefies gaseous CFC, which flows through the cooling coils in refrigerators, freezers, and air conditioners. The liquid absorbs heat from the environment outside the coils and evaporates. The gas then reenters the compressor to be liquefied again, and the cycle continues.

CFCs are among the most effective and until recently the most widely used synthetic organic compounds in modern society. Why, then, have the nations of the world, with almost unprecedented unanimity, agreed to phase them completely out of use? This remarkable event dates its origins to the late 1960s and early 1970s, when chemists Johnston, Crutzen, Rowland, and Molina* pointed to the existence of radical mechanisms that could convert several kinds of compounds, including CFCs, into reactive species capable of destroying ozone in the Earth’s stratosphere (Figure 3-12).

Upon irradiation by UV light, the weaker C–Cl bonds in the CFC molecules undergo homolysis, giving rise to atomic chlorine.

**Initiation step:** Freon 11 is dissociated by sunlight

$$\text{F}_3\text{C} \rightarrow \text{Cl} \rightleftharpoons \text{F}_3\text{C} \cdot + \cdot \text{Cl}$$

Chlorine atoms, in turn, react efficiently with ozone in a radical chain sequence.

**Propagation steps:** Ozone is decomposed by a radical chain reaction

$$\cdot \text{Cl} \cdot + \text{O}_3 \rightarrow \cdot \text{Cl} \cdot \cdot \text{O}_2 \cdot + \cdot \text{O}_2$$

$$\cdot \text{Cl} \cdot \cdot \text{O}_2 \cdot + \cdot \text{O} \rightarrow \cdot \text{O}_3 \cdot + \cdot \text{Cl} \cdot$$

The net result of these two steps is the conversion of a molecule of ozone and an oxygen atom into two molecules of ordinary oxygen. As in the other radical chain processes that we have examined in this chapter, however, the reactive species consumed in one propagation step ($\cdot \text{Cl} \cdot$) is regenerated in the other. As a consequence, a small concentration of chlorine atoms is capable of destroying many molecules of ozone. Does such a process actually occur in the atmosphere?

*Professor Harold S. Johnston (b. 1920), University of California at Berkeley; Professor Paul Crutzen (b. 1933), Max Planck Institute, Mainz, Germany, Nobel Prize 1995 (chemistry); Professor F. Sherwood Rowland (b. 1927), University of California at Irvine, Nobel Prize 1995 (chemistry); Professor Mario Molina (b. 1943), Massachusetts Institute of Technology, Nobel Prize 1995 (chemistry).
Stratospheric ozone has decreased by about 6% since 1978

Since measurements of atmospheric composition were first made, significant decreases in stratospheric ozone have been recorded. These decreases are seasonal, being most severe in the winter. They show extreme variations with latitude, with large reductions in the ozone layer over the Antarctic being noticeable as early as 1978. Satellite measurements in 1987 confirmed that total ozone content in this portion of the atmosphere was less than half of its usual value, and each year since 1995 more than 85% of the ozone in the lower stratosphere over Antarctica is destroyed each spring. Localized regions of the Antarctic had no ozone layer above them at all. In October 2000, an “ozone hole” 2.5 times the area of Europe stretched as far north as southern South America. This finding prompted an alert by the government of Chile to its citizens in Punta Arenas city and Tierra del Fuego that unprotected skin would burn from as little as 7 minutes of exposure to the sun. In November 2001, a 40% depletion of the ozone above Northern Europe was observed. Stratospheric clouds, which can form only in the extreme cold of the polar regions, have been shown to participate in a complex chain of processes that enable halogen atoms to cause ozone hole formation.

Reduction in total ozone above the temperate regions of the Northern Hemisphere currently averages 6%. Epidemiological studies suggest that a reduction in stratospheric ozone density of 1% might be expected to give rise to a 1–3% increase in skin cancers. As a consequence, considerable effort has been made to identify the causes of ozone depletion. Are CFCs responsible? Or could natural sources of atmospheric chlorine or other substances be contributing significantly?

The answers to these questions were obtained in systematic studies carried out from 1987 to 1994: Chlorine monoxide (ClO), a critical component in the ozone-destroying chain reaction illustrated earlier, rises to more than 500 times normal levels in regions of the Antarctic ozone hole, where O₃ concentration is the lowest. Furthermore, this chlorine monoxide and at least 75% of stratospheric chlorine come from CFCs. This connection has been proven by the observation of corresponding concentrations of gaseous hydrogen fluoride (HF) in the stratosphere as well. Neither HF nor any other gaseous fluorine compound occurs naturally or is produced by natural chemical processes anywhere on (or in) this planet. However, CFC decomposition in the presence of hydrocarbons in the atmosphere is known to produce HF. The observations demonstrate that natural sources such as volcanic eruptions or sea spray are not major contributors to stratospheric chlorine, relative to CFCs. Volcanic aerosols do, however, contribute to depletion of the ozone layer indirectly, by interfering with chemical processes that convert stratospheric chlorine atoms into less reactive compounds.

The world is searching for CFC substitutes

The Montreal Protocol on Substances That Deplete the Ozone Layer was signed in 1987 and called for a 50% reduction in output of CFCs by 1998. Increasingly alarming evidence regarding ozone depletion led to amendments in 1990 and again in 1992, finally setting an advanced deadline for complete rather than partial phaseout of CFC production: December 31, 1995, marked the end of production of virtually all CFCs in the industrialized world. Meanwhile, hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs) have been developed as replacements for CFCs in commercial applications. HCFCs are more chemically reactive than CFCs and are much more prone to decomposition at lower atmospheric altitudes. Their threat to stratospheric ozone is therefore less, because a smaller proportion survives the time necessary to get to the upper atmosphere. Currently, HFC-134a is replacing CFC-12 in refrigerator and motor vehicle air conditioner compressors. HCFCs-22 and -141b have replaced CFC-11 in the manufacture of foam insulation.

Hydrochlorofluorocarbons are potential ozone-destroying agents and are themselves scheduled for total phaseout in the United States by 2030. Efforts to replace all HCFCs with HFCs are actively underway. It is hoped that this worldwide effort will finally bring the depletion of the ozone layer to a halt in the near future. Recovery to nearly normal levels is anticipated by the middle of this century.
3-10 Combustion and the Relative Stabilities of Alkanes

Let us review what we have learned in this chapter so far. We started by defining bond strength as the energy required to cleave a molecule homolytically. Some typical values were then presented in Tables 3-1 and 3-2 and explained through a discussion of relative radical stabilities, a major factor being the varying extent of hyperconjugation. We then used this information to calculate the $\Delta H^\circ$ values of the steps making up the mechanism of radical halogenation, a discussion leading to an understanding of reactivity and selectivity. It is clear that knowing bond-dissociation energies is a great aid in the thermochemical analysis of organic transformations, an idea that we shall explore on numerous occasions later on. How are these numbers found experimentally?

Chemists determine bond strengths by first establishing the relative energy contents of entire molecules, or their relative positions along the energy axis in our potential-energy diagrams. The reaction chosen for this purpose is complete oxidation (literally, “burning”), or combustion, a process common to almost all organic structures, in which all carbon atoms are converted into CO$_2$ (gas) and all of the hydrogens into H$_2$O (liquid).

Both products in the combustion of alkanes have a very low energy content, and hence their formation is associated with a large negative $\Delta H^\circ$, released as heat.

$$2 \text{C}_n\text{H}_{2n+2} + (3n + 1) \text{O}_2 \rightarrow 2n \text{CO}_2 + (2n + 2) \text{H}_2\text{O} + \text{heat of combustion}$$

The heat released in the burning of a molecule is called its heat of combustion, $\Delta H^\circ_{\text{comb}}$. Many heats of combustion have been measured with high precision, thus allowing comparisons of the relative energy content of the alkanes (Table 3-7) and other compounds. Such comparisons have to take into account the physical state of the compound undergoing combustion (gas, liquid, solid). For example, the difference between the heats of combustion of liquid and gaseous ethanol corresponds to its heat of vaporization, $\Delta H^\circ_{\text{vap}} = 9.7 \text{ kcal mol}^{-1}$ ($40.6 \text{ kJ mol}^{-1}$).

It is not surprising that the $\Delta H^\circ_{\text{comb}}$ of alkanes increases with chain length, simply because there is more carbon and hydrogen to burn along the homologous series. Conversely, isomeric alkanes contain the same number of carbons and hydrogens, and one might expect that their respective combustions would be equally exothermic. However, that is not the case.

</table>

Note: Combustion products are CO$_2$ (gas) and H$_2$O (liquid).
A comparison of the heats of combustion of isomeric alkanes reveals that their values are usually not the same. Consider butane and 2-methylpropane. The combustion of butane has a $\Delta H_{\text{comb}}$ of $-687.4$ kcal mol$^{-1}$, whereas its isomer releases $\Delta H_{\text{comb}} = -685.4$ kcal mol$^{-1}$, 2 kcal mol$^{-1}$ less (Table 3-7). This finding shows that 2-methylpropane has a smaller energy content than does butane, because combustion yielding the identical kind and number of products produces less energy (Figure 3-13). Butane is said to be thermodynamically less stable than its isomer. Exercise 3-12 reveals the origin of this energy difference.

**Exercise 3-12**

The hypothetical thermal conversion of butane into 2-methylpropane should have a $\Delta H^\circ = -2.0$ kcal mol$^{-1}$. What value do you obtain by using the bond-dissociation data in Table 3-2? (Use $\Delta H^\circ = 89$ kcal mol$^{-1}$ for the methyl–propyl bond in butane.)

**In Summary** The heats of combustion values of alkanes and other organic molecules give quantitative estimates of their energy content and, therefore, their relative stabilities.

**THE BIG PICTURE**

Alkanes lack functional groups, so they do not undergo the kinds of electrophile–nucleophile reactions typical of functionalized molecules. In fact, alkanes are pretty unreactive. However, under appropriate conditions, they undergo homolytic bond cleavage to form radicals, which are reactive species containing odd numbers of electrons. This is another situation in which the structure of a class of compounds determines their function. Unlike heterolytic processes, which normally proceed via movement of pairs of electrons to form or break bonds, homolytic chemistry utilizes the splitting of covalent bonds to give unpaired single electrons, as well as their combination to give new bonds.

In organic chemistry, radical reactions are not encountered as frequently as those of polar functional groups. However, radicals play prominent roles in biological, environmental, and industrial chemistry.

The halogenation of alkanes, a radical process in which hydrogen is replaced by halogen, forms the haloalkane functional group. Examination of halogenation allows us to learn about several features common to most transformations, including the way information about a reaction mechanism may be obtained from experimental observations, the relationship between thermodynamics and kinetics, and notions of reactivity and selectivity. The products of halogenation, the haloalkanes, are the starting compounds for a wide variety of reactions, as we will see in Chapters 6 through 9.
Before we examine other classes of compounds and their properties, we need to learn more about the structures and, in particular, the geometric shapes of organic molecules. In Chapter 4 we discuss compounds that contain atoms in rings and in Chapter 5 we study additional forms of isomerism. The ideas we introduce are a necessary background as we begin a systematic study in the chapters that follow of polar reactions of haloalkanes and alcohols.

**CHAPTER INTEGRATION PROBLEMS**

3-13. Iodomethane reacts with hydrogen iodide under free radical conditions \((hv)\) to give methane and iodine. The overall equation of the reaction is

\[
\text{CH}_3\text{I} + \text{HI} \xrightarrow{hv} \text{CH}_4 + \text{I}_2
\]

a. Write a mechanism for this process, including initiation, propagation, and at least one termination step. Use bond strength data from Tables 3-1 and 3-4.

**SOLUTION**

**Step 1.** Begin by proposing a likely **initiation** step. Recall—from Section 3-4, for example—that initiation steps of radical reactions include cleavage of the **weakest** bond in the starting compounds. According to Tables 3-1 and 3-4, that is the carbon–iodine bond in \(\text{CH}_3\text{I}\), with \(DH^o = 57\) kcal mol\(^{-1}\). Therefore

**Initiation step**

\[
\text{H}_3\text{C} - \text{I} \xrightarrow{hv} \text{H}_3\text{C} \cdot + \cdot \text{I}
\]

**Step 2.** Again following the model in Section 3-4, propose a **propagation** step in which one of the species produced in the initiation step reacts with one of the molecules shown in the overall equation of the reaction. Try to design the step so that one of its products corresponds to a molecule formed in the overall reaction and the other is a species that can give rise to a second propagation step. The possibilities are

(i) \(\text{H}_3\text{C} \cdot + \text{HI} \rightarrow \text{CH}_4 + \cdot \text{I}
\)

(ii) \(\text{H}_3\text{C} \cdot + \text{CH}_3\text{I} \rightarrow \text{CH}_4 + \cdot \text{CH}_3\text{I}
\)

(iii) \(\cdot \text{I} + \text{HI} \rightarrow \text{I}_2 + \cdot \text{H}
\)

(iv) \(\cdot \text{I} + \text{CH}_3\text{I} \rightarrow \text{I}_2 + \cdot \text{CH}_3\text{I}
\)

Propagation steps (i) and (ii) both convert methyl radical into methane by removing a hydrogen atom from HI and CH\(_3\)I, respectively. Processes (iii) and (iv) show the removal of an iodine atom by another iodine atom from either HI or CH\(_3\)I, giving I\(_2\). All four propagation steps convert a molecule of starting material in the overall equation of the reaction into a molecule of product. How do we choose the correct steps? **Look at the radical products of each hypothetical propagation step. The two correct steps are those whose product radicals are each other’s reactants.** Propagation step (i) consumes a methyl radical and produces an iodine atom. Step (iv) consumes iodine and produces methyl. Therefore, steps (i) and (iv) are the correct steps of a propagation cycle.

**Propagation steps**

\[
\text{H}_3\text{C} \cdot + \text{HI} \rightarrow \text{CH}_4 + \cdot \text{I}
\]

\[
\cdot \text{I} + \text{CH}_3\text{I} \rightarrow \text{I}_2 + \cdot \text{CH}_3\text{I}
\]

You can check this answer by adding up all species on the left and right sides of these equations, respectively, to see if they correspond to the reactants and products of the overall reaction. They do: The radicals cancel on both sides of the equations, leaving only the correct molecules.

**Step 3.** Finally, combination of **any pair of radicals** to give a single molecule constitutes a legitimate **termination** step. There are three:

\[
2 \cdot \text{I} \quad \rightarrow \quad \text{I}_2
\]

\[
2 \cdot \text{H}_3\text{C} \cdot \rightarrow \text{H}_3\text{C} - \text{CH}_3 \quad \text{(ethane)}
\]

\[
\cdot \text{H}_3\text{C} + \cdot \text{I} \quad \rightarrow \quad \text{CH}_3\text{I}
\]
b. Calculate the enthalpy changes, $\Delta H^\circ$, associated with the overall reaction and all of the mechanistic steps. Use Tables 3-1, 3-2, and 3-4, as appropriate.

**SOLUTION**

Breaking a bond requires energy *input*, forming a bond gives rise to energy *output*, and $\Delta H^\circ = (\text{energy in}) - (\text{energy out})$. For the overall reaction, we have the following bond strength values to consider:

$$
\text{CH}_3 - I + H - I \xrightarrow{hv} \text{CH}_3 - H + I - I
$$

$\Delta H^\circ$: \[57 \quad 71 \quad 105 \quad 36\]

The answer is $\Delta H^\circ = (57 + 71) - (105 + 36) = -13 \text{ kcal mol}^{-1}$ (see also Table 3-5).

For the mechanistic steps, the same principle applies. With one exception, the same four $\Delta H^\circ$ values just shown are all that you need, because they correspond to the only four bonds that are either made or broken in any of the steps in the mechanism.

- **Initiation step:** $\Delta H^\circ = \Delta H^\circ (\text{CH}_3 - I) = +57 \text{ kcal mol}^{-1}$
- **Propagation step (i):** $\Delta H^\circ = \Delta H^\circ (H - I) - \Delta H^\circ (\text{CH}_3 - H) = -34 \text{ kcal mol}^{-1}$
- **Propagation step (iv):** $\Delta H^\circ = \Delta H^\circ (\text{CH}_3 - I) - \Delta H^\circ (I - I) = +21 \text{ kcal mol}^{-1}$

Notice that the sum of the $\Delta H^\circ$ values for the two propagation steps equals $\Delta H^\circ$ for the overall reaction. *This is always true.*

- **Termination steps:** $\Delta H^\circ = -\Delta H^\circ$ for the bond formed; $-36 \text{ kcal mol}^{-1}$ for $I_2$, $-57 \text{ kcal mol}^{-1}$ for $\text{CH}_3I$, and $-90 \text{ kcal mol}^{-1}$ for the $C-C$ bond in ethane.

**3-14.** Consider the process described in Exercise 3-6, the reaction between methane and equimolar amounts of Cl$_2$ and Br$_2$. Analyze the full process mechanistically and predict what products you expect to form.

Before presenting the solution to this problem, we shall introduce a problem solving strategy that may be of value to you: the “WHIP” approach. We will develop this approach in detail in an Interlude section that follows Chapter 11, but we introduce it here to illustrate its features. “WHIP” stands for four steps to take in organizing your thinking to solve a problem:

- **What is the problem asking?** — Do you understand the question?
- **How to begin?** — What is the first step to take?
- **Information needed?** — Do you need to look up data or review previously-covered material?
- **Proceed logically, step-by-step.** — Do *not* skip any steps!

Let us apply this strategy to the problem at hand.

**SOLUTION**

What is the problem asking? Two things: You are to write out the mechanism steps that are involved in the reaction system and decide what organic product or products you expect to form.

**How to begin?** Begin with the propagation steps, because they *describe the formation of the products*.

**Information needed?** Refer back to Exercise 3-6 (and its solution in Appendix A): The problem relates to radical halogenation of methane, which is depicted in Sections 3-4 and 3-5. Enthalpy data from Tables 3-1 and 3-3 and from the text are also likely to be useful.

**Proceed, step-by-step:**

**Initiation**

Both Cl$_2$ and Br$_2$ undergo dissociation to atoms under the influence of heat or light. So, both chlorine and bromine atoms are present.

**Propagation step 1**

Although both chlorine and bromine atoms are *capable* of reacting with methane, we note that the reaction of chlorine proceeds with $\Delta H^\circ = +2 \text{ kcal mol}^{-1}$ and $E_a = 4 \text{ kcal mol}^{-1}$ (Section 3-4), whereas the reaction of bromine has $\Delta H^\circ = +18 \text{ kcal mol}^{-1}$ and $E_a = 19-20 \text{ kcal mol}^{-1}$ (Section 3-5). The large difference in $E_a$ means that chlorine will abstract a hydrogen atom from methane very much
faster than will bromine. Thus for all practical purposes the only first propagation step we need to consider is

\[ \text{CH}_3 - \text{H} + \cdot \text{Cl} \rightarrow \text{CH}_3\cdot + \cdot \text{Cl} \]

Does this mean that only CH\(_3\)Cl will form as a final product? If you jumped to this conclusion, you failed to “Proceed logically, step-by-step. — Do not skip any steps!” You also got the problem wrong. Why? Ask yourself the following question: Does propagation step 1 include the formation of the final product? No! The products of this step are HCl and methyl radical, not CH\(_3\)Cl. At this point we are not yet ready to answer the question of the final product. We \textit{must} look at propagation step 2 first. And here, things get interesting.

\textbf{Propagation step 2}

Propagation step 1 forms methyl radicals. Propagation step 2 is the reaction of methyl radical with the halogen X\(_2\) (X\(_2\) = either Cl\(_2\) or Br\(_2\)) to give a halogen atom and the final product, CH\(_3\)X (X = either Cl or Br). What have we learned in this chapter about the reactions of methyl radical with these halogens? From Sections 3-4 and 3-5 we find

\[ \text{CH}_3\cdot + \cdot \text{Cl} \rightarrow \text{CH}_3\cdot + \cdot \text{Cl} : \quad \Delta H^\circ = -27 \text{ kcal mol}^{-1} \]

\[ E_a = 0 \text{ kcal mol}^{-1} \]

\[ \text{CH}_3\cdot + \cdot \text{Br} \rightarrow \text{CH}_3\cdot + \cdot \text{Br} : \quad \Delta H^\circ = -24 \text{ kcal mol}^{-1} \]

\[ E_a = 0 \text{ kcal mol}^{-1} \]

Look carefully! Methyl radicals, once formed, have the option to attack \textit{either} Cl\(_2\) or Br\(_2\) in reactions that are almost equally exothermic and, more importantly, because of their very low activation energies, \textit{almost equally fast!} It is here, in propagation step 2, where the choice of forming \textit{either} CH\(_3\)Cl or CH\(_3\)Br as the final product is made. We find that this propagation step proceeds at about the same rate regardless of whether methyl radical reacts with bromine or chlorine. Thus, we arrive at the observed experimental result, namely that CH\(_3\)Cl or CH\(_3\)Br are formed in \textit{almost equal amounts}.

This quite counterintuitive outcome would be impossible to predict (or understand, after the experimental fact) without analyzing the mechanistic details as we have done. Notice that both CH\(_3\)Cl and CH\(_3\)Br are derived from methyl radicals that arose from the reaction of methane with \textit{only} chlorine atoms in propagation step 1. For more practice with radical reactions, see Problems 24, 39, and 40.

\textbf{Important Concepts}

1. The \(\Delta H^\circ\) of bond homolysis is defined as the \textbf{bond-dissociation energy}, \(\Delta H^\circ\). Bond homolysis gives radicals or free atoms.

2. The C–H bond strengths in the alkanes decrease in the order

\[ \text{CH}_3\cdot > \text{RCH}_2\cdot > \text{RCH}(\text{Methyl (strongest)}) \]

\[ \text{RCH}_2\cdot > \text{RCH}\cdot > \text{C} = \text{H} \]

\[ \text{Methyl (least stable)} \]

because the order of stability of the corresponding alkyl radicals is

\[ \text{CH}_3\cdot < \text{RCH}_2\cdot < \text{RCH}\cdot < \text{C} = \text{H} \]

\[ \text{Methyl (least stable)} \]

This is the order of increasing stabilization due to \textit{hyperconjugation}. 
3. **Catalysts** speed up the establishment of an equilibrium between starting materials and products.

4. Alkanes react with halogens (except iodine) by a **radical chain mechanism** to give haloalkanes. The mechanism consists of **initiation** to create a halogen atom, two **propagation steps**, and various **termination steps**.

5. In the first propagation step, the slower of the two, a hydrogen atom is abstracted from the alkane chain, a reaction resulting in an alkyl radical and HX. Hence, **reactivity** increases from I₂ to F₂. **Selectivity** decreases along the same series, as well as with increasing temperature.

6. The **Hammond postulate** states that fast, exothermic reactions are typically characterized by **early transition states**, which are similar in structure to the starting materials. On the other hand, slow, endothermic processes usually have **late** (productlike) **transition states**.

7. The ΔH° for a reaction may be calculated from the ΔH° values of the bonds affected in the process as follows:

\[ ΔH° = \sum \Delta H°_{\text{bonds broken}} - \sum \Delta H°_{\text{bonds formed}} \]

8. The ΔH° for a radical halogenation process equals the sum of the ΔH° values for the propagation steps.

9. The relative reactivities of the various types of alkane C–H bonds in halogenations can be estimated by factoring out statistical contributions. They are roughly constant under identical conditions and follow the order

\[ CH_4 < Primary < CH < Secondary < Tertiary \]

The reactivity differences between these types of CH bonds are greatest for bromination, making it the most **selective** radical halogenation process. Chlorination is much less selective, and fluorination shows very little selectivity.

10. The ΔH° of the combustion of an alkane is called the **heat of combustion**, ΔH°_comb. The heats of combustion of isomeric compounds provide an experimental measure of their relative stabilities.

### Problems

15. Label the primary, secondary, and tertiary hydrogens in each of the following compounds.

   (a) CH₃CH₂CH₂CH₃  
   (b) CH₃CH₂CH₂CH₃  
   (c) CH₃  
   (d) 

16. Within each of the following sets of alkyl radicals, name each radical; identify each as either primary, secondary, or tertiary; rank in order of decreasing stability; and sketch an orbital picture of the most stable radical, showing the hyperconjugative interaction(s).

   (a) CH₃CH₂CH₂CH₃ and CH₃CH₂CH₂CH₂⁺  
   (b) (CH₃)₂CHCH₂⁺ and (CH₃)₂CHCH₂⁺  
   (c) (CH₃)₂CHCH₂CH₃, (CH₃)₂CHCH₂CH₃, and (CH₃)₂CHCH₂CH₃  

17. Write as many products as you can think of that might result from the pyrolytic cracking of propane. Assume that the only initial process is C–C bond cleavage.

18. Answer the question posed in Problem 17 for (a) butane and (b) 2-methylpropane. Use the data in Table 3-2 to determine the bond most likely to cleave homolytically, and use that bond cleavage as your first step.

19. Calculate ΔH° values for the following reactions. (a) H₂ + F₂ → 2 HF;  
   (b) H₂ + Cl₂ → 2 HCl;  
   (c) H₂ + Br₂ → 2 HBr;  
   (d) H₂ + I₂ → 2 HI;  
   (e) (CH₃)₂CH + F₂ → (CH₃)₂CF + HF;  
   (f) (CH₃)₂CH + Cl₂ → (CH₃)₂CCl + HCl;  
   (g) (CH₃)₂CH + Br₂ → (CH₃)₂CBr + HBr;  
   (h) (CH₃)₂CH + I₂ → (CH₃)₂ICl + HI.

20. For each compound in Problem 15, determine how many constitutional isomers can form upon monohalogenation. (Hint: Identify all groups of hydrogens that reside in distinct structural environments in each molecule.)
21. (a) Using the information given in Sections 3-6 and 3-7, write the products of the radical monochlorination of (i) pentane and (ii) 3-methylpentane. (b) For each, estimate the ratio of the isomeric monochlorination products that would form at 25°C. (c) Using the bond strength data from Table 3-1, determine the $\Delta H^\circ$ values of the propagation steps for the chlorination of 3-methylpentane at C3. What is the overall $\Delta H^\circ$ value for this reaction?

22. Write in full the mechanism for monobromination of methane. Be sure to include initiation, propagation, and termination steps.

23. Sketch potential-energy/reaction-coordinate diagrams for the two propagation steps of the monobromination of methane (Problem 22).

24. Write a mechanism for the radical bromination of the hydrocarbon benzene, C$_6$H$_6$ (for structure, see Section 2-3). Use propagation steps similar to those in the halogenation of alkanes, as presented in Sections 3-4 through 3-6. Calculate $\Delta H^\circ$ values for each step and for the reaction as a whole. How does this reaction compare thermodynamically with the bromination of other hydrocarbons? Data: $\Delta H^\circ$ (C$_6$H$_5$ – H) = 112 kcal mol$^{-1}$; $\Delta H^\circ$ (C$_6$H$_5$ – Br) = 81 kcal mol$^{-1}$. Note the Caution in Exercise 3-5.

25. Sketch potential-energy/reaction-coordinate diagrams for the two propagation steps of the monobromination of benzene (Problem 24).

26. Identify each of the diagrams you drew in Problem 25 as showing an early or a late transition state.

27. Write the major organic product(s), if any, of each of the following reactions.

(a) CH$_3$CH$_3$ + I$_2$ $\xrightarrow{\Delta}$
(b) CH$_3$CH$_2$CH$_3$ + F$_2$ $\rightarrow$
(c) + Br$_2$ $\xrightarrow{\Delta}$

28. Calculate product ratios in each of the reactions in Problem 27. Use relative reactivity data for F$_2$ and Cl$_2$ at 25°C and for Br$_2$ at 150°C (Table 3-6).

29. Which, if any, of the reactions in Problem 27 give the major product with reasonable selectivity (i.e., are useful “synthetic methods”)?

30. (a) What would be the major organic product of monobromination of pentane at 125°C? (b) Draw Newman projections of all possible staggered conformations arising from rotation about the C2–C3 bond for this product molecule. (c) Draw a qualitative graph of potential energy versus torsional angle for C2–C3 rotation in this molecule. (Note: A bromine atom is considerably smaller, sterically, than is a methyl group.)

31. (a) Sketch a potential energy/reaction coordinate graph showing the two propagation steps for the monobromination of pentane to give the major product (Problem 30). Use $\Delta H^\circ$ information from this chapter (Tables 3-1, 3-2, and 3-4, as appropriate). (b) Indicate the locations of the transition states and whether each is early or late. (c) Sketch a similar graph for reaction of pentane with I$_2$. How does it differ from the graph for bromination?

32. At room temperature, 1,2-dibromoethane exists as an equilibrium mixture in which 89% of the molecules are in an anti conformation and 11% are gauche. The comparable ratio for butane under the same circumstances is 72% anti and 28% gauche. Suggest an explanation for the difference, bearing in mind that Br is sterically smaller than CH$_3$ (see Problem 30). (Hint: Consider the polarity of a C–Br bond and consequent electrostatic effects.)

33. Write balanced equations for the combustion of each of the following substances (molecular formulas may be obtained from Table 3-7): (a) methane; (b) propane; (c) cyclohexane; (d) ethanol; (e) sucrose.

34. Propanal (CH$_3$CH$_2$CH$_2$CO) and acetone (CH$_3$C(=O)CH$_3$) are isomers with the formula C$_3$H$_6$O. The heat of combustion of propanal is −434.1 kcal mol$^{-1}$, that of acetone −427.9 kcal mol$^{-1}$. (a) Write a
balanced equation for the combustion of either compound. (b) What is the energy difference between propional and acetone? Which has the lower energy content? (c) Which substance is more thermodynamically stable, propional or acetone? (Hint: Draw a diagram similar to that in Figure 3-13.)

35. Sulfuryl chloride (SO₂Cl₂, see margin for structure) is a liquid reagent that may be used for chlorinations of alkanes as a substitute for gaseous elemental chlorine. Propose a mechanism for chlorination of CH₄ using sulfuryl chloride. (Hint: Follow the usual model for a radical chain process, substituting SO₂Cl₂ for Cl₂ where appropriate.)

36. Use the Arrhenius equation (Section 2-1) to estimate the ratio of the rate constants k for the reactions of a C–H bond in methane with a chlorine atom and with a bromine atom at 25°C. Assume that the A values for the two processes are equal, and use E_a = 19 kcal mol⁻¹ for the reaction between Br⁻ and CH₄.

37. When an alkane with different types of C–H bonds, such as propane, reacts with an equimolar mixture of Br₂ and Cl₂, the selectivity in the formation of the brominated products is much worse than that observed when reaction is carried out with Br₂ alone. (In fact, it is very similar to the selectivity for chlorination.) Explain.

38. Bromination of 1-bromopropane gives the following results:

\[
\text{CH₃CH₂CH₂Br} \xrightarrow{\text{Br₂, 200°C}} \text{CH₃CH₂CHBr₂} + \text{CH₃CHBrCH₂Br} + \text{BrCH₂CH₂CH₂Br}
\]

<table>

</tbody>
</table>

Calculate the relative reactivities of the hydrogens on each of the three carbons toward bromine atoms. Compare these results with those from a simple alkane such as propane, and suggest explanations for any differences.

39. A hypothetical alternative mechanism for the halogenation of methane has the following propagation steps.

(i) \(X^- + CH_4 \rightarrow CH_3X + H^+\)
(ii) \(H^- + X_2 \rightarrow HX + X^-\)

(a) Using \(\Delta H^0\) values from appropriate tables, calculate \(\Delta H^0\) for these steps for any one of the halogens. (b) Compare your \(\Delta H^0\) values with those for the accepted mechanism (Table 3-5). Do you expect this alternative mechanism to compete successfully with the accepted one? (Hint: Consider activation energies.)

40. (Challenge) The addition of certain materials called radical inhibitors to halogenation reactions causes the reactions to come to a virtually complete stop. An example is the inhibition by I₂ of the chlorination of methane. Explain how this inhibition might come about. (Hint: Calculate \(\Delta H^0\) values for possible reactions of the various species present in the system with I₂, and evaluate the possible further reactivity of the products of these I₂ reactions.)

41. Typical hydrocarbon fuels (e.g., 2,2,4-trimethylpentane, a common component of gasoline) have very similar heats of combustion when calculated in kilocalories per gram. (a) Calculate heats of combustion per gram for several representative hydrocarbons in Table 3-7. (b) Make the same calculation for ethanol (Table 3-7). (c) In evaluating the feasibility of “gasohol” (90% gasoline and 10% ethanol) as a motor fuel, it has been estimated that an automobile running on pure ethanol would get approximately 40% fewer miles per gallon than would an identical automobile running on standard gasoline. Is this estimate consistent with the results in (a) and (b)? What can you say in general about the fuel capabilities of oxygen-containing molecules relative to hydrocarbons?

42. Two simple organic molecules that have been used as fuel additives are methanol (CH₃OH) and 2-methoxy-2-methylpropane [tert-butyl methyl ether, (CH₃)₂COCH₃]. The \(\Delta H_{\text{comb}}\) values for these compounds in the gas phase are \(-182.6\) kcal mol⁻¹ for methanol and \(-809.7\) kcal mol⁻¹ for 2-methoxy-2-methylpropane. (a) Write balanced equations for the complete combustion of each of these molecules to CO₂ and H₂O. (b) Using Table 3-7, compare the \(\Delta H_{\text{comb}}\) values for these compounds with those for alkanes with similar molecular weights.

43. (Challenge) Figure 3-9 compares the reactions of Cl⁻ with the primary and secondary hydrogens of propane. (a) Draw a similar diagram comparing the reactions of Br⁻ with the primary and secondary hydrogens of propane. (Hint: First obtain the necessary \(\Delta H^0\) values from Table 3-1 and calculate \(\Delta H^0\) for both the primary and the secondary hydrogen abstraction reactions. Other data: \(E_a = 15\) kcal mol⁻¹ for Br⁻ reacting with a primary C–H bond and \(E_a = 13\) kcal mol⁻¹...
for Br· reacting with a secondary C–H bond.) (b) Which among the transition states of these reactions would you call “early,” and which “late”? (c) Judging from the locations of the transition states of these reactions along the reaction coordinate, should they show greater or lesser radical character than do the corresponding transition states for chlorination (Figure 3-9)? (d) Is your answer to (c) consistent with the selectivity differences between Cl· reacting with propane and Br· reacting with propane? Explain.

44. Two of the propagation steps in the Cl+/O3 system consume ozone and oxygen atoms (which are necessary for the production of ozone), respectively (Section 3-9).

\[
\text{Cl + O}_3 \rightarrow \text{ClO} + \text{O}_2
\]

\[
\text{ClO} + \text{O} \rightarrow \text{Cl} + \text{O}_2
\]

Calculate \(\Delta H^\circ\) for each of these propagation steps. Use the following data: \(\Delta H^\circ\) for ClO = 64 kcal mol\(^{-1}\); \(\Delta H^\circ\) for O\(_2\) = 120 kcal mol\(^{-1}\); \(\Delta H^\circ\) for an O–O\(_2\) bond in O\(_3\) = 26 kcal mol\(^{-1}\). Write the overall equation described by the combination of these steps and calculate its \(\Delta H^\circ\). Comment on the thermodynamic favorability of the process.

Team Problem

45. (a) Provide an IUPAC name for each of the isomers that you drew in Exercise 2-16 (a). (b) For each isomer that you drew and named here, give all the free radical monochlorination and monobromination products that are structurally isomeric. (c) Referring to Table 3-6, discuss which starting alkane and which halogen will yield the least number of isomeric products.

Preprofessional Problems

46. The reaction \(\text{CH}_4 + \text{Cl}_2 \rightarrow \text{CH}_3\text{Cl} + \text{HCl}\) is an example of

(a) neutralization
(b) an acidic reaction
(c) an isomerization
(d) an ionic reaction
(e) a radical chain reaction

47. 
\[
\begin{array}{c}
\text{CH}_3\text{Cl} \\
\text{CH}_2-\text{CHCH}_3
\end{array}
\]

\[
\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3
\]

The sum of all the digits that appear in the (IUPAC) name for this compound is which of the following?

(a) Five  (b) Six  (c) Seven  (d) Eight  (e) Nine

48. In a competition reaction, equimolar amounts of the four alkanes shown were allowed to react with a limited amount of Cl\(_2\) at 300°C. Which one of these alkanes would be depleted most from the mixture?

(a) Pentane  (b) 2-Methylpropane  (c) Butane  (d) Propane

49. The reaction of CH\(_4\) with Cl\(_2\) to yield CH\(_3\)Cl and HCl is well known. On the basis of the values in the short table below, the enthalpy \(\Delta H^\circ\) (kcal mol\(^{-1}\)) of this reaction is

(a) +135  (b) −135  (c) +25  (d) −25

| Bond-Dissociation Energies \(\Delta H^\circ\) (kcal mol\(^{-1}\)) |
|-----------------|-----------------|
| H–Cl            | 103             |
| Cl–Cl           | 58              |
| H\(_3\)C–Cl      | 85              |
| H\(_3\)C–H       | 105             |
When you hear or read the word steroids, two things probably come to mind immediately: athletes who “take steroids” illegally to develop their muscles, and “the pill” used for birth control. But what do you know about steroids aside from this general association? What is their structure and function? How does one steroid differ from another? Where are they found in nature?

An example of a naturally occurring steroid is diosgenin, obtained from root extracts of the Mexican yam and used as a starting material for the synthesis of several commercial steroids. Most striking is the number of rings in the compound.

Hydrocarbons containing single-bonded carbon atoms arranged in rings are known as cyclic alkanes, carbocycles (in contrast to heterocycles, Chapter 25), or cycloalkanes. The majority of organic compounds occurring in nature contain rings. Indeed, so many fundamental biological
functions depend on the chemistry of ring-containing compounds that life as we know it could not exist in their absence.

This chapter deals with the names, physical properties, structural features, and conformational characteristics of the cycloalkanes. Because of their cyclic nature, members of this class of compounds can exhibit new types of strain, such as ring strain and transannular interactions. We end with the biochemical significance of selected carbocycles and their derivatives, including steroids.

4-1 Names and Physical Properties of Cycloalkanes

Cycloalkanes have their own names under IUPAC rules, and their properties are generally different from those of their noncyclic (also called acyclic) analogs with the same number of carbons. We will see that they also exhibit a kind of isomerism unique to cyclic molecules.

The names of the cycloalkanes follow IUPAC rules

We can construct a molecular model of a cycloalkane by removing a hydrogen atom from each terminal carbon of a model of a straight-chain alkane and allowing these carbons to form a bond. The empirical formula of a cycloalkane is \( \text{C}_n\text{H}_{2n} \) or \( (\text{CH}_2)_n \). The system for naming members of this class of compounds is straightforward: Alkane names are preceded by the prefix cyclo-. Three members in the homologous series—starting with the smallest, cyclopropane—are shown in the margin, written both in condensed form and in bond-line notation.

Exercise 4-1

Make molecular models of cyclopropane through cyclododecane. Compare the relative conformational flexibility of each ring with that of others within the series and with that of the corresponding straight-chain alkanes.

Naming a substituted cyclic alkane requires numbering the individual ring carbons only if more than one substituent is attached to the ring. In monosubstituted systems, the carbon of attachment is defined as carbon 1 of the ring. For polysubstituted compounds, take care to provide the lowest possible numbering sequence. When two such sequences are possible, the alphabetical order of the substituent names takes precedence. Radicals derived from cycloalkanes by abstraction of a hydrogen atom are cycloalkyl radicals. Substituted cycloalkanes are therefore sometimes named as cycloalkyl derivatives. In general, the smaller unit is treated as a substituent to the larger one—for example, methylcyclopropane (not cyclopropylmethane) and cyclobutylcyclohexane (not cyclohexylcyclobutane).
Disubstituted cycloalkanes can be stereoisomers

Inspection of molecular models of disubstituted cycloalkanes in which the two substituents are located on different carbons shows that two isomers are possible in each case. In one isomer, the two substituents are positioned on the same face, or side, of the ring; in the other isomer, they are on opposite faces. Substituents on the same face are called cis (cis, Latin, on the same side); those on opposite faces, trans (trans, Latin, across).

We can use hashed-wedged line structures to depict the three-dimensional arrangement of substituted cycloalkanes. The positions of any remaining hydrogens are not always shown.

Cis and trans isomers are stereoisomers—compounds that have identical connectivities (i.e., their atoms are attached in the same sequence) but differ in the arrangement of their atoms in space. They are distinct from constitutional or structural isomers (Sections 1-9 and 2-4), which are compounds with differing connectivities among atoms. Conformations (Sections 2-7 and 2-8) also are stereoisomers by this definition. However, unlike cis and trans isomers, which can be interconverted only by breaking bonds (try it on your models), conformers are readily equilibrated by rotation about bonds. Stereoisomerism will be discussed in more detail in Chapter 5.

Because of the possibility of structural and cis-trans isomerism, a variety of structural possibilities exist in substituted cycloalkanes. For example, there are eight isomeric bromomethylcyclohexanes (three of which are shown below), all with different and distinct physical and chemical properties.
The properties of the cycloalkanes differ from those of their straight-chain analogs

The physical properties of a few cycloalkanes are recorded in Table 4-1. Note that, compared with the corresponding straight-chain alkanes (Table 2-5), the cycloalkanes have higher boiling and melting points as well as higher densities. These differences are due in large part to increased London interactions of the relatively more rigid and more symmetric cyclic systems. In comparing lower cycloalkanes possessing an odd number of carbons with those having an even number, we find a pronounced alternation in their melting points. This phenomenon has been ascribed to differences in crystal packing forces between the two series.
In Summary Names of the cycloalkanes are derived in a straightforward manner from those of the straight-chain alkanes. In addition, the position of a single substituent is defined to be C1. Disubstituted cycloalkanes can give rise to cis and trans isomers, depending on the relative spatial orientation of the substituents. Physical properties parallel those of the straight-chain alkanes, but individual values for boiling and melting points and for densities are higher for the cyclic compounds of equal carbon number.

4-2 Ring Strain and the Structure of Cycloalkanes

The molecular models made for Exercise 4-1 reveal obvious differences between cyclopropane, cyclobutane, cyclopentane, and so forth, and the corresponding straight-chain alkanes. One notable feature of the first two members in the series is how difficult it is to close the ring without breaking the plastic tubes used to represent bonds. This problem is called ring strain. The reason for it lies in the tetrahedral carbon model. The C–C–C bond angles in, for example, cyclopropane (60°) and cyclobutane (90°) differ considerably from the tetrahedral value of 109.5°. As the ring size increases, strain diminishes. Thus, cyclohexane can be assembled without distortion or strain.

Does this observation tell us anything about the relative stability of the cycloalkanes—for example, as measured by their heats of combustion, $\Delta H^\circ_{\text{comb}}$? How does strain affect structure and function? This section and Section 4-3 address these questions.

The heats of combustion of the cycloalkanes reveal the presence of ring strain

Section 3-10 introduced one measure of the stability of a molecule: its heat content. We also learned that the heat content of an alkane can be estimated by measuring its heat of combustion, $\Delta H^\circ_{\text{comb}}$ (Table 3-7). To find out whether there is something special about the stability of cycloalkanes, we could compare their heats of combustion with those of the analogous straight-chain alkanes. Such a direct comparison is flawed, however, because the empirical formula of cycloalkanes, $C_nH_{2n}$, differs from that of normal alkanes, $C_nH_{2n+2}$, by two hydrogens. To solve this problem, we take a roundabout approach, based on the recognition that we can rewrite the formula for cycloalkanes as $(CH_2)_n$. Thus, if we had an experimental number for the contribution of a “strain-free” CH$_2$ fragment to the $\Delta H^\circ_{\text{comb}}$ of straight-chain alkanes, then the corresponding $\Delta H^\circ_{\text{comb}}$ of a cycloalkane should simply be multiples of this number. If it is not, it might signal the presence of strain.

The $\Delta H^\circ_{\text{comb}}$ of a Strain-Free Cycloalkane Should Be Multiples of $\Delta H^\circ_{\text{comb}}(CH_2)$

$$\Delta H^\circ_{\text{comb}}(C_nH_{2n}) = n \times \Delta H^\circ_{\text{comb}}(CH_2)$$

How do we obtain a $\Delta H^\circ_{\text{comb}}$ value of CH$_2$? Let us turn to Table 3-7 and the combustion data for the straight-chain alkanes. We note that $\Delta H^\circ_{\text{comb}}$ increases by about the same amount.
with each successive member of the homologous series: about 157 kcal mol\(^{-1}\) for each additional CH\(_2\) moiety.

When averaged over a large number of alkanes, this value approaches 157.4 kcal mol\(^{-1}\) (658.6 kJ mol\(^{-1}\)), our requisite value for \( \Delta H^\circ_{\text{comb}} \) (CH\(_2\))!

Armed with this number, we can calculate the expected \( \Delta H^\circ_{\text{comb}} \) of the cycloalkanes, \((\text{CH}_2)_n\), namely, \(-n \times 157.4\) kcal mol\(^{-1}\). For example, for cyclopropane, \(n = 3\), hence its \( \Delta H^\circ_{\text{comb}} \) should be \(-472.2\) kcal mol\(^{-1}\); for cyclobutane, it should be \(-629.6\) kcal mol\(^{-1}\); and so on (Table 4-2, column 2). However, when we measure the actual heats of combustion of these molecules, they turn out to be generally larger in magnitude (Table 4-2, column 3). Thus, for cyclopropane, the experimental value is \(-499.8\) kcal mol\(^{-1}\), a discrepancy between the expected and observed values of 27.6 kcal mol\(^{-1}\). Therefore, cyclopropane is more energetic than expected for a strainless molecule. The extra energy is attributed to a property of cyclopropane of which we are already aware because of the model we built: ring strain. The strain per CH\(_2\) group in this molecule is 9.2 kcal mol\(^{-1}\).

**Ring Strain in Cyclopropane**

Calculated for strainless molecule:

\[
\Delta H^\circ_{\text{comb}} = -(3 \times 157.4) = -472.2 \text{ kcal mol}^{-1}
\]

Measured: \( \Delta H^\circ_{\text{comb}} = -499.8 \text{ kcal mol}^{-1}\)

Strain: \(499.8 - 472.2 = 27.6 \text{ kcal mol}^{-1}\)

A similar calculation for cyclobutane (Table 4-2) reveals a ring strain of 26.3 kcal mol\(^{-1}\), or about 6.6 kcal mol\(^{-1}\) per CH\(_2\) group. In cyclopentane, this effect is much smaller, the total strain amounting to only 6.5 kcal mol\(^{-1}\), and cyclohexane is virtually strain free. However, succeeding members of the series again show considerable strain until we reach very large rings (see Section 4-5). Because of these trends, organic chemists have loosely defined four groups of cycloalkanes:

1. Small rings (cyclopropane, cyclobutane)
2. Common rings (cyclopentane, cyclohexane, cycloheptane)

**Table 4-2 Calculated and Experimental Heats of Combustion in kcal mol\(^{-1}\) (kJ mol\(^{-1}\)) of Various Cycloalkanes**

*Note:* The calculated numbers are based on the value of \(-157.4\) kcal mol\(^{-1}\) (658.6 kJ mol\(^{-1}\)) for a CH\(_2\) group.
3. **Medium rings** (from 8- to 12-membered)

4. **Large rings** (13-membered and larger)

What kinds of effects contribute to the ring strain in cycloalkanes? We answer this question by exploring the detailed structures of several of these compounds.

**Strain affects the structures and conformational function of the smaller cycloalkanes**

As we have just seen, the smallest cycloalkane, cyclopropane, is much less stable than expected for three methylene groups. Why should this be? The reason is twofold: torsional strain and bond-angle strain.

The structure of the cyclopropane molecule is represented in Figure 4-1. We notice first that all methylene hydrogens are eclipsed, much like the hydrogens in the eclipsed conformation of ethane (Section 2-7). We know that the energy of the eclipsed form of ethane is higher than that of the more stable staggered conformation because of **eclipsing (torsional) strain**. This effect is also present in cyclopropane. Moreover, the carbon skeleton in cyclopropane is by necessity flat and quite rigid, and bond rotation that might relieve eclipsing strain is very difficult.

Second, we notice that cyclopropane has C–C–C bond angles of 60°, a significant deviation from the “natural” tetrahedral bond angle of 109.5°. How is it possible for three supposedly tetrahedral carbon atoms to maintain a bonding relation at such highly distorted angles? The problem is perhaps best illustrated in Figure 4-2, in which the bonding in the strain-free “open cyclopropane,” the trimethylene diradical \( \text{CH}_2\text{CH}_2\text{CH}_2 \), is compared with that in the closed form. We can see that the two ends of the trimethylene diradical cannot “reach” far enough to close the ring without “bending” the two C–C bonds already present. However, if all three C–C bonds in cyclopropane adopt a bent configuration (interorbital angle 104°, see Figure 4-2B), overlap is sufficient for bond formation. The energy needed to distort the tetrahedral carbons enough to close the ring is called **bond-angle strain**. The ring strain in cyclopropane is derived from a combination of eclipsing and bond-angle contributions.

As a consequence of its structure, cyclopropane has relatively weak C–C bonds \( \Delta H^\circ = 65 \text{ kcal mol}^{-1} (272 \text{ kJ mol}^{-1}) \). This value is low [recall that the C–C strength in ethane is 90 kcal mol\(^{-1} \) (377 kJ mol\(^{-1} \))] because breaking the bond opens the ring and relieves ring strain. For example, reaction with hydrogen in the presence of a palladium catalyst opens the ring to give propane.

\[
\text{H}_3\text{C} + \text{H}_2 \xrightarrow{\text{Pd catalyst}} \text{CH}_3\text{CH}_2\text{CH}_3 \quad \Delta H^\circ = -37.6 \text{ kcal mol}^{-1} (-157 \text{ kJ mol}^{-1})
\]

**Figure 4-1** Cyclopropane: (A) molecular model; (B) bond lengths and angles.

**Figure 4-2** Orbital picture of (A) the trimethylene diradical and (B) the bent bonds in cyclopropane. Only the hybrid orbitals forming C–C bonds are shown. Note the interorbital angle of 104° in cyclopropane.
Chapter 4  Cycloalkanes

Exercise 4-4

trans-1,2-Dimethylcyclopropane is more stable than cis-1,2-dimethylcyclopropane. Why? Draw a picture to illustrate your answer. Which isomer liberates more heat on combustion?

What about higher cycloalkanes? The structure of cyclobutane (Figure 4-3) reveals that this molecule is not planar but puckered, with an approximate bending angle of 26°. The nonplanar structure of the ring, however, is not very rigid. The molecule “flips” rapidly from one puckered conformation to the other. Construction of a molecular model shows why distorting the four-membered ring from planarity is favorable: It partly relieves the strain introduced by the eight eclipsing hydrogens. Moreover, bond-angle strain is considerably reduced relative to that in cyclopropane, although maximum overlap is, again, only possible with the use of bent bonds. The C–C bond strength in cyclobutane also is low [about 63 kcal mol⁻¹ (264 kJ mol⁻¹)] because of the release of ring strain on ring opening and the consequences of relatively poor overlap in bent bonds. Cyclobutane is less reactive than cyclopropane but undergoes similar ring-opening processes.

\[ \text{Cyclobutane: (A) molecular model; (B) bond lengths and angles. The nonplanar molecule “flips” rapidly from one conformation to another.} \]

\[ D_H^* = 63 \text{ kcal mol}^{-1} \]

\[ D_H^* = 88 \text{ kcal mol}^{-1} \]

Cyclopentane might be expected to be planar because the angles in a regular pentagon are 108°, close to tetrahedral. However, such a planar arrangement would have ten H–H eclipsing interactions. The puckering of the ring reduces this effect, as indicated in the structure of the molecule (Figure 4-4). Although puckering relieves eclipsing, it also increases bond-angle strain. The conformation of lowest energy is a compromise in which the energy of the system is minimized.

There are two puckered conformations possible for cyclopentane: the envelope and the half chair. There is little difference in energy between them, and the activation barriers for rapid interconversion are extremely low, averaging the positions of all carbons and hydrogens (as in cyclobutane). Overall, cyclopentane has relatively little ring strain, and its C–C bond

Figure 4-4 Cyclopentane: (A) molecular model of the half-chair conformation; (B) bond lengths and angles. The molecule is flexible, with little strain.
strength \( DH^\circ = 81 \text{ kcal mol}^{-1} \) approaches that in acyclic alkanes (Table 3-2). As a consequence, it does not show the unusual reactivity of three- or four-membered rings.

### Exercise 4-5

**Working with the Concepts: Estimating Strain**

The heat of reaction of hydrogen with the exotic-looking hydrocarbon bicyclo[2.1.0]pentane (A), a strained bicyclic alkane (see Section 4-6), to give cyclopentane has been measured to be \(-56 \text{ kcal mol}^{-1}\). This reaction is considerably more exothermic than that for cyclopropane on p. 137 \((-37.6 \text{ kcal mol}^{-1})\), indicating relatively more strain. How would you estimate the strain energy in A? (Hint: To tackle this problem, it is useful to review Section 2-1 and consult Tables 3-1, 3-2, and 4-2.)

\[
\text{A} + \text{H}_2 \xrightarrow{\text{Catalyst}} \text{Cyclopentane} \quad \Delta H^\circ = -56 \text{ kcal mol}^{-1}
\]

**Strategy 1**

A possibly quickest way to estimate the strain in A is to check Table 4-2 and simply add the strains of the component rings cyclopropane \((27.6 \text{ kcal mol}^{-1})\) and cyclobutane \((26.3 \text{ kcal mol}^{-1})\): \(53.9 \text{ kcal mol}^{-1}\). (Caution: This approach ignores the likely effect that the two rings will have on their respective strains when sharing a bond. You can verify this effect by building a model of cyclobutane and then converting it to a model of A. The four-membered ring flattens completely, and the bond angles of the cyclopropane CH\(_2\) bridge are considerably more distorted than those to the corresponding two hydrogens in cyclobutane.)

**Strategy 2**

Another way to approach this problem is to estimate the strain in the shared bond in A and equate this value to the overall strain in the molecule. To do so, we need to determine the corresponding bond strength and compare it to that of a presumed unstrained model, for example, the central bond in 2,3-dimethylbutane, \( DH^\circ = 85.5 \text{ kcal mol}^{-1} \) (Table 3-2). How do we do this? We can use the heat of the reaction given in the problem and apply the equation given in Section 2-1, in which the enthalpy change of a reaction was related to the changes in bond strengths.

**Solution**

- Rewrite the reaction of A with hydrogen and label the relevant bonds with the available data (in kcal mol\(^{-1}\)) from Tables 3-1 and 3-2.

\[
\text{A} + \text{H}_2 \xrightarrow{\text{Catalyst}} \text{Cyclopentane} \quad \Delta H^\circ = -56 \text{ kcal mol}^{-1}
\]

- Apply the equation from Section 2-1:

\[
\Delta H^\circ = \Sigma \text{(strengths of bonds broken)} - \Sigma \text{(strengths of bonds made)}
\]

\[
-56 = (104 + x) - 197
\]

\[
x = 37 \text{ kcal mol}^{-1}
\]

This is a very weak bond indeed! Compared to the central C–C bond in 2,3-dimethylbutane \((85.5 \text{ kcal mol}^{-1})\), its strain is 48.5 kcal mol\(^{-1}\).

- Does this number reflect the strain in A completely? (Caution: Not quite, because the product cyclopentane has some residual strain of 6.5 kcal mol\(^{-1}\) that is not released in the reaction of A.) Here, a reasonable estimate of the ring strain in A is 48.5 + 6.5 = 55 kcal mol\(^{-1}\), which is pretty close to our “quick solution,” the sum of the ring strains of the component rings \((53.9 \text{ kcal mol}^{-1})\). Gratifyingly, it is also close to the experimental value, based on the heat of combustion: 57.3 kcal mol\(^{-1}\).
Chapter 4

Cycloalkanes

Exercise 4-6

Try It Yourself

The strain energy in the hydrocarbon A shown in the margin is 50.7 kcal mol\(^{-1}\). Estimate its heat of reaction with hydrogen to give cyclohexane.

4-3  Cyclohexane: A Strain-Free Cycloalkane

The cyclohexane ring is one of the most common and important structural units in organic chemistry. Its substituted derivatives exist in many natural products (see Section 4-7), and an understanding of its conformational mobility is an important aspect of organic chemistry. Table 4-2 reveals that, within experimental error, cyclohexane is unusual in that it is free of bond-angle or eclipsing strain. Why?

The chair conformation of cyclohexane is strain free

A hypothetical planar cyclohexane would suffer from 12 H–H eclipsing interactions and sixfold bond-angle strain (a regular hexagon requires 120° bond angles). However, one conformation of cyclohexane, obtained by moving carbons 1 and 4 out of planarity in opposite directions, is in fact strain free (Figure 4-5). This structure is called the chair conformation of cyclohexane (because it resembles a chair), in which eclipsing is completely absent, and the bond angles are very nearly tetrahedral. As seen in Table 4-2, the calculated \( \Delta H^\circ \text{comb} \) of cyclohexane (−944.4 kcal mol\(^{-1}\)) based on a strain-free \((\text{CH}_2)_6\) model is very close to the experimentally determined value (−944.5 kcal mol\(^{-1}\)). Indeed, the C–C bond strength, \( \Delta H^\circ = 88 \text{ kcal mol}^{-1} \) (368 kJ mol\(^{-1}\)), is normal (Table 3-2).

Looking at the molecular model of cyclohexane enables us to recognize the conformational stability of the molecule. If we view it along (any) one C–C bond, we can see the staggered arrangement of all substituent groups along it. We can visualize this arrangement by drawing a Newman projection of that view (Figure 4-6). Because of its lack of strain, cyclohexane is as inert as a straight-chain alkane.

Exercise 4-7

Draw Newman projections of the carbon–carbon bonds in cyclopropane, cyclobutane, and cyclopentane in their most stable conformations. Use the models that you prepared for Exercise 4-1 to assist you and refer to Figure 4-6. What are the approximate torsional angles between the C–H bonds in each?

Figure 4-5 Conversion of the (A) hypothetical planar cyclohexane into the (B) chair conformation, showing bond lengths and angles; (C) molecular model. The chair conformation is strain free.
Cyclohexane also has several less stable conformations

Cyclohexane also adopts other, less stable conformations. One is the **boat form**, in which carbons 1 and 4 are out of the plane in the same direction (Figure 4-7). The boat is less stable than the chair form by 6.9 kcal mol\(^{-1}\). One reason for this difference is the eclipsing of eight hydrogen atoms at the base of the boat. Another is steric hindrance (Section 2-8) due to the close proximity of the two inside hydrogens in the boat framework. The distance between these two hydrogens is only 1.83 Å, small enough to create an energy of repulsion of about 3 kcal mol\(^{-1}\) (13 kJ mol\(^{-1}\)). This effect is an example of **transannular strain**, that is, strain resulting from steric crowding of two groups across a ring (trans, Latin, across; anulus, Latin, ring).

![Figure 4-7](image_url) Conversion of the hypothetical planar cyclohexane into the boat form. In the boat form, the hydrogens on carbons 2, 3, 5, and 6 are eclipsed, thereby giving rise to torsional strain. The “inside” hydrogens on carbons 1 and 4 interfere with each other sterically in a transannular interaction. The space-filling size of these two hydrogens, reflecting the actual size of their respective electron clouds, is depicted in the ball-and-stick model on the right.

Boat cyclohexane is fairly flexible. If one of the C–C bonds is twisted relative to another, this form can be somewhat stabilized by partial removal of the transannular interaction. The new conformation obtained is called the **twist-boat** (or skew-boat) **conformation** of cyclohexane (Figure 4-8). The stabilization relative to the boat form amounts to about 1.4 kcal mol\(^{-1}\). As shown in Figure 4-8, two twist-boat forms are possible. They interconvert rapidly, with the boat conformer acting as a **transition state** (verify this with your model). Thus, the boat cyclohexane is not a normally isolable species, the twist-boat form is present in very small amounts, and the chair form is the major conformer (Figure 4-9). The activation barrier separating the most stable chair from the boat forms is 10.8 kcal mol\(^{-1}\). We shall see that the equilibration depicted in Figure 4-9 has important structural consequences with respect to the positions of substituents on the cyclohexene ring.

Cyclohexane has axial and equatorial hydrogen atoms

The chair-conformation model of cyclohexane reveals that the molecule has two types of hydrogens. Six carbon–hydrogen bonds are nearly parallel to the principal molecular axis
Chapter 4  Cycloalkanes

(Figure 4-10) and hence are referred to as axial; the other six are nearly perpendicular to the axis and close to the equatorial plane and are therefore called equatorial.*

Being able to draw cyclohexane chair conformations will help you learn the chemistry of six-membered rings. Several rules are useful.

How to Draw Chair Cyclohexanes

1. Draw the chair so as to place the C2 and C3 atoms below and slightly to the right of C5 and C6, with apex 1 pointing downward on the left and apex 4 pointing upward on the

*An equatorial plane is defined as being perpendicular to the axis of rotation of a rotating body and equidistant from its poles, such as the equator of the planet Earth.
right. Ideally, bonds straight across the ring (namely, bonds 1–6 and 3–4; 2–3 and 5–6; 1–2 and 4–5) should appear parallel to one another.

2. Add all the axial bonds as vertical lines, pointing downward at C1, C3, and C5 and upward at C2, C4, and C6. In other words, the axial bonds alternate up-down around the ring.

3. Draw the two equatorial bonds at C1 and C4 at a slight angle from horizontal, pointing upward at C1 and downward at C4, parallel to the bond between C2 and C3 (or between C5 and C6).

4. This rule is the most difficult to follow: Add the remaining equatorial bonds at C2, C3, C5, and C6 by aligning them parallel to the C–C bond “once removed,” as shown below.

Figure 4-10 The axial and equatorial positions of hydrogens in the chair form of cyclohexane. The blue shading represents the equatorial plane encompassing the (blue) equatorial hydrogens. The yellow and green shaded areas are located above and below that plane, respectively.
Conformational flipping interconverts axial and equatorial hydrogens

What happens to the identity of the equatorial and axial hydrogens when we let chair cyclohexane equilibrate with its boat forms? You can follow the progress of conformational interconversion in Figure 4-9 with the help of molecular models. Starting with the chair structure on the left, you simply “flip” the CH₂ group farthest to the left (C1 in the preceding section) upward through the equatorial plane to generate the boat conformers. If you now return the molecule to the chair form not by a reversal of the movement but by the equally probable alternative—namely, the flipping downward of the opposite CH₂ group (C4)—the original sets of axial and equatorial positions have traded places. In other words, cyclohexane undergoes chair—chair interconversions (“flipping”) in which all axial hydrogens in one chair become equatorial in the other and vice versa (Figure 4-11). The activation energy for this process is 10.8 kcal mol⁻¹ (Figure 4-9). As suggested in Sections 2-7 and 2-8, this value is so low that, at room temperature, the two chair forms interconvert rapidly (approximately 200,000 times per second).

![Figure 4-11](https://example.com/fig4_11.png)

Figure 4-11 Chair—chair interconversion (“ring flipping”) in cyclohexane. In the process, which is rapid at room temperature, a (green) carbon at one end of the molecule moves up while its counterpart (also green) at the other end moves down. All groups originally in axial positions (red in the structure at the left) become equatorial, and those that start in equatorial positions (blue) become axial.

The two chair forms shown in Figure 4-11 are, except for the color coding, identical. We can lift this degeneracy by introducing substituents: Now the chair with a substituent in the equatorial position is different from its conformer, in which the substituent is axial. The preference for one orientation over the other strongly affects the stereochemistry and reactivity of cyclohexanes. We will describe the consequences of such substitution in the next section.

In Summary The discrepancy between calculated and measured heats of combustion in the cycloalkanes can be largely attributed to three forms of strain: bond angle (deformation of tetrahedral carbon), eclipsing (torsional), and transannular (across the ring). Because of strain, the small cycloalkanes are chemically reactive, undergoing ring-opening reactions. Cyclohexane is strain free. It has a lowest-energy chair as well as additional higher-energy conformations, particularly the boat and twist-boat structures. Chair—chair interconversion is rapid at room temperature; it is a process in which equatorial and axial hydrogen atoms interchange their positions.

4-4 Substituted Cyclohexanes

We can now apply our knowledge of conformational analysis to substituted cyclohexanes. Let us look at the simplest alkylcyclohexane, methylcyclohexane.

Axial and equatorial methylcyclohexanes are not equivalent in energy

In methylcyclohexane, the methyl group occupies either an equatorial or an axial position.
Are the two forms equivalent? Clearly not. In the equatorial conformer, the methyl group extends into space away from the remainder of the molecule. In contrast, in the axial conformer, the methyl substituent is close to the other two axial hydrogens on the same side of the molecule. The distance to these hydrogens is small enough (about 2.7 Å) to result in steric repulsion, another example of transannular strain. Because this effect is due to axial substituents on carbon atoms that have a 1,3-relation (in the drawing, 1,3 and 1,3′), it is called a 1,3-diaxial interaction. This interaction is the same as that resulting in the gauche conformation of butane (Section 2-8). Thus, the axial methyl group is gauche to two of the ring carbons (C3 and C3′); when it is in the equatorial position, it is anti to the same nuclei.

The two forms of chair methylcyclohexane are in equilibrium. The equatorial conformer is more stable by 1.7 kcal mol\(^{-1}\) (7.1 kJ mol\(^{-1}\)) and is favored by a ratio of 95:5 at 25°C (Section 2-1). The activation energy for chair–chair interconversion is similar to that in cyclohexane itself [about 11 kcal mol\(^{-1}\) (46 kJ mol\(^{-1}\))], and equilibrium between the two conformers is established rapidly at room temperature.

The unfavorable 1,3-diaxial interactions to which an axial substituent is exposed are readily seen in Newman projections of the ring C–C bond bearing that substituent. In contrast with that in the axial form (gauche to two ring bonds), the substituent in the equatorial conformer (anti to the two ring bonds) is away from the axial hydrogens (Figure 4-12).

**Figure 4-12** A Newman projection of a substituted cyclohexane. The conformation with an axial Y substituent is less stable because of 1,3-diaxial interactions, only one of which is shown (see the “eye” for the choice of the Newman projection). Axial Y is gauche to the ring bonds shown in green; equatorial Y is anti.
The energy differences between the axial and the equatorial forms of many monosubstituted cyclohexanes have been measured; several are given in Table 4-3. In many cases (but not all), particularly for alkyl substituents, the energy difference between the two forms increases with the size of the substituent, a direct consequence of increasing unfavorable 1,3-diaxial interactions. This effect is particularly pronounced in (1,1-dimethylethyl)cyclohexane (tert-butylcyclohexane). The energy difference here is so large (about 5 kcal mol\(^{-1}\)) that very little (about 0.01%) of the axial conformer is present at equilibrium.

*Note: In all examples, the more stable conformer is the one in which the substituent is equatorial.*

**Exercise 4-8**

Calculate \(K\) for equatorial versus axial methylcyclohexane from the \(\Delta G^\circ\) value of 1.7 kcal mol\(^{-1}\). Use the expression \(\Delta G^\circ\) (in kcal mol\(^{-1}\)) = \(-1.36 \log K\). (**Hint:** If \(\log K = x\), then \(K = 10^x\).) How well does your result agree with the 95:5 conformer ratio stated in the text?

The energy differences between the axial and the equatorial forms of many monosubstituted cyclohexanes have been measured; several are given in Table 4-3. In many cases (but not all), particularly for alkyl substituents, the energy difference between the two forms increases with the size of the substituent, a direct consequence of increasing unfavorable 1,3-diaxial interactions. This effect is particularly pronounced in (1,1-dimethylethyl)cyclohexane (tert-butylcyclohexane). The energy difference here is so large (about 5 kcal mol\(^{-1}\)) that very little (about 0.01%) of the axial conformer is present at equilibrium.

**Exercise 4-9**

**Working with the Concepts: Building Models to Visualize Sterics**

The \(\Delta G^\circ\) value for the equatorial to axial flip of cyclohexylcyclohexane is the same as that for (1-methylethyl)cyclohexane, 2.20 kcal mol\(^{-1}\). Is this reasonable? Explain.

**Strategy**

When trying to deal with conformational problems, a good strategy is to build molecular models.

**Solution**

- Molecular models reveal that cyclohexylcyclohexane may be viewed as a cyclic analog of (1-methylethyl)cyclohexane, in which the two methyl groups have been connected by a (CH\(_2\))\(_3\) chain (Section 4-1).
- Both structures are floppy and have several conformers, but you will find that the seemingly more bulky (chair) cyclohexyl substituent in (cyclohexyl)cyclohexane can rotate away from the cyclohexane core in such a way as to avoid 1,3-diaxial contact beyond that encountered by its (1-methylethyl) counterpart. Thus, the equivalence of the free energy changes is reasonable.

**Exercise 4-10**

**Try It Yourself**

The isomeric hydrocarbons A and B (see margin) both exhibit preferred conformations in which the methyl groups are equatorial, yet B is more stable than A by 2.3 kcal mol\(^{-1}\). What is the origin of this difference? (**Caution:** Are A and B ring flip isomers? **Hint:** Build models and look at the nature of the conformations of the methyl substituted cyclohexane ring.)
Substituents compete for equatorial positions

To predict the more stable conformer of a more highly substituted cyclohexane, the cumulative effect of placing substituents either axially or equatorially must be considered, in addition to their potential mutual 1,3-diaxial or 1,2-gauche (Section 2-8) interactions. For many cases, we can ignore the last two and simply apply the values of Table 4-3 for a prediction.

Let us look at some isomers of dimethylcyclohexane to illustrate this point. In 1,1-dimethylcyclohexane, one methyl group is always equatorial and the other axial. The two chair forms are identical, and hence their energies are equal.

![1,1-Dimethylcyclohexane](diagram)

**1,1-Dimethylcyclohexane**  
(Conformations equal in energy, equally stable)

Similarly, in *cis*-1,4-dimethylcyclohexane, both chairs have one axial and one equatorial substituent and are of equal energy.

![cis-1,4-Dimethylcyclohexane](diagram)

**cis-1,4-Dimethylcyclohexane**

On the other hand, the trans isomer can exist in two different chair conformations: one having two axial methyl groups (diaxial) and the other having two equatorial groups (diequatorial).

![trans-1,4-Dimethylcyclohexane](diagram)

**trans-1,4-Dimethylcyclohexane**

Experimentally, the diequatorial form is preferred over the diaxial form by 3.4 kcal mol$^{-1}$, exactly twice the $\Delta G^\circ$ value for monomethylcyclohexane. Indeed, this additive behavior of the data given in Table 4-3 applies to many other substituted cyclohexanes. For example, the $\Delta G^\circ$ (diaxial $\Rightarrow$ diequatorial) for *trans*-1-fluoro-4-methylcyclohexane is $-1.95$ kcal mol$^{-1}$ [$-1.70$ kcal mol$^{-1}$ for CH$_3$ plus 0.25 kcal mol$^{-1}$ for F]. Conversely, in *cis*-1-fluoro-4-methylcyclohexane, the two groups compete for the equatorial positions
Chapter 4  Cycloalkanes

Exercise 4-11

Calculate $\Delta G^\circ$ for the equilibrium between the two chair conformers of (a) 1-ethyl-1-methylcyclohexane; (b) cis-1-ethyl-4-methylcyclohexane; (c) trans-1-ethyl-4-methylcyclohexane.

Exercise 4-12

Draw both chair conformations for each of the following isomers: (a) cis-1,2-dimethylcyclohexane; (b) trans-1,2-dimethylcyclohexane; (c) cis-1,3-dimethylcyclohexane; (d) trans-1,3-dimethylcyclohexane. Which of these isomers always have equal numbers of axial and equatorial substituents? Which exist as equilibrium mixtures of diaxial and diequatorial forms?

Exercise 4-13

Working with the Concepts: Perturbations to Additivity in the Cyclohexane Conformational Flip

Although the substituent values in Table 4-3 are additive and may be used to indicate the position of the equilibrium between two substituted cyclohexane conformers, the observed $\Delta G^\circ$ values can be perturbed by additional 1,3-diaxial or 1,2-gauche interactions between groups. For example, like trans-1,4-dimethylcyclohexane, its isomer cis-1,3-dimethylcyclohexane exists in a diequatorial–diaxial equilibrium and hence should exhibit the same $\Delta G^\circ$ value of 3.4 kcal mol$^{-1}$. However, the measured value is larger (5.4 kcal mol$^{-1}$). Explain. (Hint: For cis-1,3-dimethylcyclohexane, look closely at all 1,3-diaxial interactions and compare them with those of diaxial trans-1,4-dimethylcyclohexane.)

Strategy

Again, a good strategy for addressing conformational issues is to build models. First construct a model for cis-1,3-dimethylcyclohexane and perform the ring flip from diequatorial to diaxial. What is different in this system compared with methylcyclohexane “taken twice”?

Solution

• In the diequatorial conformer, the two methyl groups are each located in an area of space that is the same as that in methylcyclohexane.

• Is this true also for the diaxial conformer? The answer is no. The $\Delta G^\circ = 1.7$ kcal mol$^{-1}$ for ring flip in axial methylcyclohexane arises from two CH$_3$/H-1,3-diaxial interactions [one CH$_3$ with two hydrogens, as in the picture for (1,1-dimethylethyl)cyclohexane shown on p. 145; see also Figure 4-12], 0.85 kcal mol$^{-1}$ each. In cis-1,3-dimethylcyclohexane, the diaxial conformation suffers also from two CH$_3$/H interactions (two CH$_3$ groups with a single H) for the same total of 1.7 kcal mol$^{-1}$. The extra strain originates from the proximity of the two axial methyls, amounting to 3.7 kcal mol$^{-1}$.
In Summary

The conformational analysis of cyclohexane enables us to predict the relative stability of its various conformers and even to approximate the energy differences between two chair conformations. Bulky substituents, particularly a 1,1-dimethylethyl group, tend to shift the chair–chair equilibrium toward the side in which the large substituent is equatorial.

4-5 Larger Cycloalkanes

Do similar relations hold for the larger cycloalkanes? Table 4-2 shows that cyclolkanes with rings larger than that of cyclohexane also have more strain. This strain is due to a combination of bond-angle distortion, partial eclipsing of hydrogens, and transannular steric repulsions. It is not possible for medium-sized rings to relieve all of these strain-producing interactions in a single conformation. Instead, a compromise solution is found in which the molecule equilibrates among several geometries that are very close in energy. One such conformation of cyclodecane, which has a strain energy of 14 kcal mol\(^{-1}\) (59 kJ mol\(^{-1}\)), is shown in the margin.

Essentially strain-free conformations are attainable only for large-sized cycloalkanes, such as cyclotetradecane (Table 4-2). In such rings, the carbon chain adopts a structure very similar to that of the straight-chain alkanes (Section 2-6), having staggered hydrogens and an all-anti configuration. However, even in these systems, the attachment of substituents usually introduces various amounts of strain. Most cyclic molecules described in this book are not strain free.

4-6 Polycyclic Alkanes

The cycloalkanes discussed so far contain only one ring and therefore may be referred to as monocyclic alkanes. In more complex structures—the bi-, tri-, tetra-, and higher polycyclic hydrocarbons—two or more rings share carbon atoms. Many of these compounds exist in nature with various alkyl or functional groups attached. Let us look at some of the wide variety of possible structures.

**Polycyclic alkanes may contain fused or bridged rings**

Molecular models of polycyclic alkanes can be readily constructed by linking the carbon atoms of two alkyl substituents in a monocyclic alkane. For example, if you remove two hydrogen atoms from the methyl groups in 1,2-diethylcyclohexane and link the resulting two CH\(_2\) groups, the result is a new molecule with the common name decalin. In decalin, two cyclohexanes share two adjacent carbon atoms, and the two rings are said to be **fused**. Compounds constructed in this way are called **fused bicyclic** ring systems and the shared carbon atoms are called the **ring-fusion carbons**. Groups attached to ring-fusion carbons are called **ring-fusion substituents**.

**Exercise 4-14**

**Try It Yourself**

Like *cis*-1,3-dimethylcyclohexane in Exercise 4-13, its isomer *trans*-1,2-dimethylcyclohexane exists in a diequatorial–diaxial equilibrium and hence would be expected to exhibit the same \( \Delta G^\circ \) value as *trans*-1,4-dimethylcyclohexane, namely, 3.4 kcal mol\(^{-1}\). However, the measured value is smaller (2.5 kcal mol\(^{-1}\)). Explain. (Hint: Take into consideration the proximity of the two methyl groups; see gauche–anti butane, Section 2-8.)
If we treat a molecular model of cis-1,3-dimethylcyclopentane in the same way, we obtain another carbon skeleton, that of norbornane. Norbornane is an example of a bridged bicyclic ring system. In bridged bicyclic systems, two nonadjacent carbon atoms, the bridgehead carbons, belong to both rings.

If we think of one of the rings as a substituent on the other, we can identify stereochemical relations at ring fusions. In particular, bicyclic ring systems can be cis or trans fused. The stereochemistry of the ring fusion is most easily determined by inspecting the ring-fusion substituents. For example, the ring-fusion hydrogens of trans-decalin are trans with respect to each other, whereas those of cis-decalin have a cis relation (Figure 4-13).

---

**Exercise 4-15**

Construct molecular models of both cis- and trans-decalin. What can you say about their conformational mobility?

---

**Do hydrocarbons have strain limits?**

Seeking the limits of strain in hydrocarbon bonds is a fascinating area of research that has resulted in the synthesis of many exotic molecules. What is surprising is how much bond-angle distortion a carbon atom is able to tolerate. A case in point in the bicyclic series is bicyclobutane, whose strain energy is 66.5 kcal mol\(^{-1}\) (278 kJ mol\(^{-1}\)), making it remarkable that the molecule exists at all. Yet it can be isolated and stored.

A series of strained compounds attracting the attention of synthetic chemists possess a carbon framework geometrically equivalent to the Platonic solids: the tetrahedron (tetrahe-drane), the hexahedron (cubane), and the pentagonal dodecahedron (dodecahedrane; see margin, page 152). In these polyhedra, all faces are composed of equally sized rings—namely, cyclopropane, cyclobutane, and cyclopentane, respectively. The hexahedron was synthesized first in 1964, a C\(_8\)H\(_8\) hydrocarbon shaped like a cube and accordingly named cubane. The experimental strain energy [166 kcal mol\(^{-1}\) (695 kJ mol\(^{-1}\))] is more than the total strain of six
Cyclohexane, Adamantane, and Diamandoids: Diamond “Molecules”

The brief glimpse into the world of polycyclic hydrocarbons in Section 4-6 provides further examples of the diversity of the carbon frame in organic chemistry (see Table 2-4 for the number of possible isomeric acyclic alkanes). Whenever possible, such molecules adopt structures in which cyclohexane rings exist in the chair configuration, for example, trans-decalin. We constructed this molecule by fusing one cyclohexane ring to another at the equatorial positions. Another way of building all-chair cyclohexane polycycles is via the axial positions. Thus, if we add three axial CH₂ groups to cyclohexane and connect them by a single CH unit, we arrive at an all-chair tetracyclic cage, C₁₀H₁₆, called adamantane (adamantinos, Greek, diamond, read on why). Build a model and you will recognize its simple symmetry: All four faces are identical.

Adamantane is the most stable of the family of C₁₀H₁₆ isomers. Its tight shape allows it to pack unusually well in the solid, as reflected in the high melting point of 270°C (see Section 2-6). For comparison, its acyclic counterpart nonane melts at -53.5°C (Table 2-5). Adamantane was discovered in crude oil in 1933, can be readily synthesized, and is now commercially available in kilogram quantities.

If we apply the capping process described above to three axial positions of any of the rings in adamantane, we get diamantane, a polycycle composed of seven chair cyclohexanes and endowed with six equivalent faces. Continued capping gives triamantane, the first in this series to contain a quaternary carbon. From triamantane, we can construct three tetramantanes in this way, only one of which is shown, bearing two quaternary carbons. The number of possible isomers increases rapidly for the higher “oligomantanes”; there are 7 pentamantanes, 24 hexamantanes, and 88 heptamantanes. Decamantane, C₃₅H₃₆, is a unique isomer dubbed “superadamantane” because of its compact symmetry. It exhibits a quaternary carbon surrounded by four other quaternary carbons. Its structure illustrates how one can envisage building a three-dimensional array of layers of linked chair cyclohexanes (highlighted in color) made up of pure carbon. Such a polymer is known: It is the crystalline form of carbon named diamond (see also Chemical Highlight 15-1)!

Because the oligomantanes represent “microdiamonds” in which all peripheral carbons are saturated by hydrogen (so-called hydrogen-terminated diamond), they have been given the name diamandoids. The higher diamandoids have only been known since 2003 (see Chapter 1 Opening), when a group at Chevron in California identified members of the series up to undeca-mantane in high-boiling petroleum distillates. Interest in these molecules stems from not only their relationship to diamond and their potential to act as seed crystals in industrial diamond production, but also from their stability and inertness. Thus, they provide biologically compatible scaffolds for new drugs, cosmetics, and polymeric materials.

Inside the carbon lattice of diamond.

The Golden Jubilee, the world’s biggest diamond.
Chapter 4
Cycloalkanes

The success of these medicine men depends on the discovery and application of physiologically active natural products.

Although tetrahedrane itself is unknown, a tetra(1,1-dimethylethyl) derivative was synthesized in 1978. Despite the measured strain (from $\Delta H_{\text{comb}}^0$ of 129 kcal mol$^{-1}$ (540 kJ mol$^{-1}$), the compound is stable and has a melting point of 135°C. The synthesis of dodecahedrane was achieved in 1982. It required 23 synthetic operations, starting from a simple cyclopentane derivative. The last step gave 1.5 mg of pure compound. Although small, this amount was sufficient to permit complete characterization of the molecule. Its melting point at 430°C is extraordinarily high for a C$_{20}$ hydrocarbon and is indicative of the symmetry of the compound. For comparison, icosane, also with 20 carbons, melts at 36.8°C (Table 2-5). As you might expect on the basis of its component five-membered rings, the strain in dodecahedrane is “only” 61 kcal mol$^{-1}$ (255 kJ mol$^{-1}$), much less than that of its lower homologs.

**In Summary** Carbon atoms in bicyclic compounds are shared by rings in either fused or bridged arrangements. A great deal of strain may be tolerated by carbon in its bonds, particularly to other carbon atoms. This capability has allowed the preparation of molecules in which carbon is severely deformed from its tetrahedral shape.

### 4-7 Carbo cyclic Products in Nature

Let us now take a brief look at the variety of cyclic molecules created in nature. Natural products are organic compounds produced by living organisms. Some of these compounds, such as methane, are extremely simple; others have great structural complexity. Scientists have attempted to classify the multitude of natural products in various ways. Generally, four schemes are followed, in which these products are classified according to (1) chemical structure, (2) physiological activity, (3) organism or plant specificity (taxonomy), and (4) biochemical origin.

Organic chemists are interested in natural products for many reasons. Many of these compounds are powerful drugs, others function as coloring or flavoring agents, and yet others are important raw materials. A study of animal secretions furnishes information concerning the ways in which animals use chemicals to mark trails, defend themselves from predators, and attract the opposite sex. Investigations of the biochemical pathways by which an organism metabolizes and otherwise transforms a compound are sources of insight into the detailed workings of the organism’s bodily functions. Two classes of natural products, terpenes and steroids, have received particularly close attention from organic chemists.

**Terpenes are constructed in plants from isoprene units**

Most of you have smelled the strong odor emanating from freshly crushed plant leaves or orange peels. This odor is due to the liberation of a mixture of volatile compounds called terpenes, usually containing 10, 15, or 20 carbon atoms. Terpenes are used as food flavorings (the extracts from cloves and mint), as perfumes (roses, lavender, sandalwood), and as solvents (turpentine).

Terpenes are synthesized in the plant by the linkage of at least two molecular units, each containing five carbon atoms. The structure of these units is like that of 2-methyl-1,3-butadiene (isoprene), and so they are referred to as isoprene units. Depending on how many isoprene units are incorporated into the structure, terpenes are classified as mono- (C$_{10}$), sesqui- (C$_{15}$), or diterpenes (C$_{20}$). (The isoprene building units are shown in color in the examples given here.)

Chrysanthemic acid is a monocyclic terpene containing a three-membered ring. Its esters are found in the flower heads of pyrethrum (*Chrysanthemum cinerariaefolium*) and are naturally occurring insecticides. A cyclobutane is present in grandisol, the sex-attracting chemical used by the male boll weevil (*Anthonomus grandis*).
Menthol (peppermint oil) is an example of a substituted cyclohexane natural product, whereas camphor (from the camphor tree) and β-cadinene (from juniper and cedar) are simple bicyclic terpenes, the first a norbornane system, the second a decalin derivative.

**Taxol** (paclitaxel) is a complex, functionalized diterpene isolated from the bark of the Pacific yew tree, *Taxus brevifolia*, in 1962 as part of a National Cancer Institute program in search of natural products exhibiting anticancer activity.

Taxol proved to be perhaps the most interesting of more than 100,000 compounds extracted from more than 35,000 plant species and is one of the most effective antitumor drugs on the market. Because roughly six trees must be sacrificed to treat one patient, there has been much effort to improve efficacy and availability and to increase yields. Most of this work has been carried out by synthetic organic chemists, leading to the first two total syntheses of taxol in 1994. (A “total” synthesis is one that makes the target starting from simple, preferably commercial, compounds containing five carbons or less). In addition, chemists found ways to convert more abundant natural products of related structure to taxol itself, a procedure described as “semisynthesis.” As a result, the taxol used in the treatment of cancer is derived from a compound found in the needles of the common English yew, a much more readily available and nonsacrificial source.

**Exercise 4-16**

Draw the more stable chair conformation of menthol.
Steroids are tetracyclic natural products with powerful physiological activities

Steroids are abundant in nature, and many derivatives have physiological activity. They function frequently as hormones, which are regulators of biochemical processes. In the human body, they control sexual development and fertility, in addition to other functions. Because of this feature, many steroids, often the products of laboratory synthesis, are used in the treatment of cancer, arthritis, allergies, and in birth control.

In the steroids, three cyclohexane rings are fused in such a way as to form an angle, also called angular. The ring junctions are usually trans, as in trans-decalin. The fourth ring is a cyclopentane; its addition gives the typical tetracyclic structure. The four rings are labeled A, B, C, D, and the carbons are numbered according to a scheme specific to steroids. Many steroids have methyl groups attached to C10 and C13 and oxygen at C3 and C17. In addition, longer side chains may be found at C17. The trans fusion of the rings allows for a least-strained all-chair configuration in which the methyl groups and hydrogen atoms at the ring junctions occupy axial positions. These features are illustrated below with epiandrosterone, a steroid found in normal human urine.
“Too much cholesterol!” How often have you heard this admonition as you were about to dig into your favorite three-egg breakfast or chocolate-fudge dessert? The reason for the warning is that high levels of cholesterol have been implicated in atherosclerosis and heart disease. Atherosclerosis is the buildup of plaques that can narrow or even block your blood vessels. In the heart, such an event can cause a heart attack. Plaques can break and travel through your bloodstream, causing havoc elsewhere. For example, a blocked blood vessel in the brain can lead to a stroke.

About 20% of the population of the United States has cholesterol levels that exceed the recommended total. Typical adults have about 150 g in their body and for a good reason—cholesterol is vital for the running of the body. It is an essential building block of cell membranes, especially of the nervous system, the brain, and the spinal cord. It is also a key chemical intermediate in the biological production of other steroids, especially the sex and the corticoid hormones, including cortisone. We need cholesterol to produce bile acids, which in turn are key chemicals that help digest the fats we consume, and we need it to form vitamin D, which enables us to utilize calcium in bone construction.

You have probably heard much talk about “good” and “bad” cholesterol. These adjectives refer to the proteins that attach themselves to the molecule to make so-called lipoproteins, which are water soluble and hence allow cholesterol to be transported in the blood (for the general structure of proteins, see Section 26-4). There are two types of these aggregates, low-density lipoprotein (LDL) and high-density lipoprotein (HDL). LDL carries cholesterol from the liver to other parts of the body, wherever it is needed. HDL acts as a cholesterol sweep and delivers it to the liver for conversion into bile acids. If this careful equilibrium is disturbed such that too much LDL is present, that is “bad,” because the excess is deposited in the form of the dangerous plaques mentioned earlier. Conversely, if sufficient HDL is around, this is “good.”

The opening warning notwithstanding, very little cholesterol comes from our food. Rather, our body, especially our liver, makes about a gram a day, which is four times as much as even a high-cholesterol diet would supply. Why is there so much fuss, then? It has to do with that 15 to 20% from our food intake. In people with moderately elevated cholesterol levels, watching their diet may make all the difference. This is where fats come in (see also Section 20-5). To digest fats, we need bile acids. Excessive fat intake stimulates bile acid production, in turn increasing cholesterol synthesis and therefore cholesterol blood levels. Therefore, a balanced low-fat, cholesterol-free diet helps in maintaining the recommended level of cholesterol: 200 mg per 100 mL of blood.

When such a diet is not enough, drugs come to the rescue. One type of drug, such as hydroxypropyl methylcellulose (HPMC; for the structure of cellulose, see Section 24-12), binds cholesterol in the stomach and thus prevents it from being absorbed by the body. Ironically, HPMC is used as a thickener in foods, including cheesecake and desserts! Another type of drug turns off production of cholesterol directly in the liver and has been used with spectacular success in the last decade. Examples are Simvastatin (Zocor) and Atorvastatin (Lipitor), both “top-10” prescription drugs with combined sales of over $10 billion (see Table 25-1).

Cross section of a human coronary artery of the heart blocked by cholesterol plaques (yellow).

Groups attached above the plane of the steroid molecule as written are β substituents, whereas those below are referred to as α. Thus, the structure of epiandrosterone has a 3β-OH, 5α-H, 10β-CH₃, and so forth.

Among the most abundant steroids, cholesterol is present in almost all human and animal tissue (Chemical Highlight 4-2). Bile acids are produced in the liver as part of a fluid delivered to the duodenum to aid in the emulsification, digestion, and absorption of fats. An example is cholic acid. Cortisone, used extensively in the treatment of rheumatoid inflammations, is one of the adrenocortical hormones produced by the outer part (cortex)
Cycloalkanes

of the adrenal glands. These hormones participate in regulating the electrolyte and water balance in the body, as well as in protein and carbohydrate metabolism.

The sex hormones are divided into three groups: (1) the male sex hormones, or androgens; (2) the female sex hormones, or estrogens; and (3) the pregnancy hormones, or progestins. Testosterone is the principal male sex hormone. Produced by the testes, it is responsible for male (masculine) characteristics (deep voice, facial hair, general physical constitution). Synthetic testosterone analogs are used in medicine to promote muscle and tissue growth (anabolic steroids; ana-, Greek, up—i.e., “anabolic,” the opposite of “metabolic”), for example, in patients with muscular atrophy. Unfortunately, such steroids are also abused and consumed illegally, most commonly by “body builders” and athletes, even though the health

The menstrual cycle is controlled by three protein hormones from the pituitary gland. The follicle-stimulating hormone (FSH) induces the growth of the egg, and the luteinizing hormone (LH) induces its release from the ovaries and the formation of an ovarian tissue called the corpus luteum. The third pituitary hormone (luteotropic hormone, also called luteotropin or prolactin), stimulates the corpus luteum and maintains its function.

As the cycle begins and egg growth is initiated, the tissue around the egg secretes increasing quantities of estrogens.

When a certain concentration of estrogen in the bloodstream has been reached, the production of FSH is turned off. The egg is released at this stage in response to LH. At the time of ovulation, LH also triggers the formation of the corpus luteum, which in turn begins to secrete increasing amounts of progesterone. This last hormone suppresses any further ovulation by turning off the production of LH. If the egg is not fertilized, the corpus luteum regresses and the ovum and the endometrium (uterine lining) are expelled (menstruation). Pregnancy, on the other hand, leads to increased production of estrogens and progesterone to prevent pituitary hormone secretion and thus renewed ovulation.

The birth control pill consists of a mixture of synthetic potent estrogen and progesterone derivatives (more potent than the natural hormones), which, when taken throughout most of the menstrual cycle, prevent both development of the ovum and ovulation by turning off production of both FSH and LH. The female body is essentially being tricked into believing that it is pregnant. Some of the commercial pills contain a combination of norethindrone and ethynylestradiol. Other preparations consist of similar analogs with minor structural variations.

A fertilized human egg before cleavage (zygote), approximately 100 µm in size.
risks are numerous, including liver cancer, coronary heart disease, and sterility. Estradiol is the principal female sex hormone. It was first isolated by extraction of 4 tons of sow ovaries, yielding only a few milligrams of pure steroid. Estradiol is responsible for the development of the secondary female characteristics and participates in the control of the menstrual cycle. An example of a progestin is progesterone, responsible for preparing the uterus for implantation of the fertilized egg.

Postcoital contraceptives, such as Preven or Plan B, contain levonorgestrel and/or ethynylestradiol. RU-486 (mifepristone) is a synthetic steroid that binds to the progesterone receptors in the woman’s uterus, thus blocking the action of progesterone. Used in combination with a prostaglandin (Chemical Highlight 11-1) that induces uterine contractions, RU-486 effects abortion when administered in early pregnancy. The drug has been available in Europe since 1988, and, after much discussion and testing, the Food and Drug Administration approved it for the U.S. market in 2000.

You will have noticed the presence of the \( \text{C} \equiv \text{C} \) triple bond attached to C17 in these synthetic compounds, an alteration that makes the drugs particularly potent. Such triple bonds can be hydrogenated ("saturated") with hydrogen in the presence of a catalyst (Section 13-6). It is suspected that it was this simple alteration of the commercial drug gestrinone that led to the dopant tetrahydrogestrinone (THG; see Chapter Opening).

The structural similarity of the steroid hormones is remarkable, considering their widely divergent activity. Steroids are the active ingredients of “the pill,” functioning as an anti-fertility agent for the control of the female menstrual cycle and ovulation. It is estimated that over 70 million women throughout the world take “the pill” as the primary form of contraception (Chemical Highlight 4-3).
In Summary  There is great variety in the structure and function of naturally occurring organic products, as manifested in the terpenes and the steroids. Natural products will be frequently introduced in subsequent chapters to illustrate the presence and chemistry of a functional group, to demonstrate synthetic strategy or the use of reagents, to picture three-dimensional relations, and to exemplify medicinal applications. Several classes of natural products will be discussed more extensively: fats (Sections 19-13 and 20-5), carbohydrates (Chapter 24), alkaloids (Section 25-8), and amino and nucleic acids (Chapter 26).

THE BIG PICTURE
In this chapter, we have expanded our knowledge of organic structure and function to include cyclic and polycyclic frameworks. In particular, we have seen again how much three-dimensionality matters in explaining and predicting the behavior of organic molecules. Their structures are ultimately based on the spatial distribution of bonding electrons surrounding the nuclear components (Sections 1-3 and 1-6 to 1-9) and, from a more mechanical perspective, on the conformational flexibility inherent in C–C bonds (Sections 2-7 and 2-8).

One consequence of three-dimensionality is the existence of stereoisomers, namely cis and trans isomers of substituted cycloalkanes (Section 4-1). We will see in Chapter 5 that the phenomenon of stereoisomerism is more general and occurs in acyclic molecules as well. These concepts influence such diverse areas as relative reactivities and biological effectiveness. Because of its fundamental importance and its powerful utility in biological applications, stereochemistry constitutes a recurring theme through the remainder of this book.

CHAPTER INTEGRATION PROBLEMS
4-19. a. 1, 2, 3, 4, 5, 6-Hexachlorocyclohexane exists as a number of cis-trans isomers. Using the flat cyclohexane stencil and hashed-wedged lines, draw all of them.

SOLUTION
Before starting to solve this part by random trial and error, consider a more systematic approach. We start with the simplest case of all chlorines positioned cis to one another (using all wedged lines) and then look at the various permutations obtained by placing a progressively increasing number of the substituents trans (hashed lines). We can stop at the stage of three chlorines “up” and three chlorines “down” because “two up and four down” is the same as “four up and two down,” and so on. The first two cases, “six up” (A) and “five up and one down” (B), are unique because only one structural possibility exists for each:

Now we look at the “four up and two down” isomers. There are three differing ways of placing two chlorines “down”: Their positioning along the six-membered ring can be only 1, 2 (C), 1, 3 (D),
or 1, 4 (E), because the options 1, 5 and 1, 6 are the same as 1, 3 and 1, 2, respectively. Finally, a similar line of thought leads to the realization that placing three chlorines “down” can be done only in three unique ways: 1, 2, 3 (F), 1, 2, 4 (G), and 1, 3, 5 (H):

\[ \text{F} \quad \text{G} \quad \text{H} \]

b. The so-called γ-isomer is an insecticide (lindane, gammexane, kwell) with the following structure:

\[ \gamma\text{-Hexachlorocyclohexane} \]

Draw the two chair conformations of this compound. Which one is more stable?

SOLUTION

Note that the γ-isomer corresponds to our structure E in (a). To help in converting the flat cyclohexane stencil structures into their chair renditions, look at Figure 4-11 and note the alternating relation of the members of the two sets of hydrogens. As we proceed around the ring, we can see that neighboring members (i.e., those in a “1,2”-relation) of either set (i.e., axial or equatorial neighbors) always have a trans disposition. On the other hand, the 1,3-relation is always cis, whereas that describable as 1,4 is again trans. Conversely, in a hashed-wedged line structure, when two neighboring substituents (i.e., 1,2-relation) are cis, one of the substituents will be axial and the other equatorial in either of the two chair conformations of the molecule. When they are trans, one chair picture will show them diequatorial, the other diaxial. This assignment alternates in 1,3-related substituents: cis results in a diaxial-diequatorial pair of chair conformers, trans in an axial-equatorial or equatorial-axial pair, and so on. These relations are summarized in Table 4-4.

<table>
<thead>
<tr>
<th>Relation of Cis-Trans Stereochemistry in Substituted Cyclohexanes to Equatorial-Axial Positions in the Two Chair Forms</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Table 4-4</strong></td>
</tr>
<tr>
<td><strong>cis-1,2</strong></td>
</tr>
<tr>
<td><strong>trans-1,2</strong></td>
</tr>
<tr>
<td><strong>cis-1,3</strong></td>
</tr>
<tr>
<td><strong>trans-1,3</strong></td>
</tr>
<tr>
<td><strong>cis-1,4</strong></td>
</tr>
<tr>
<td><strong>trans-1,4</strong></td>
</tr>
</tbody>
</table>
The two chair forms of γ-hexachlorocyclohexane thus look as shown here:

\[
\begin{align*}
\text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} \\
\text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl}
\end{align*}
\]

Either structure has three equatorial and three axial chlorine substituents; hence they are equal in energy.

c. For which isomer do you expect the energy difference between the two cyclohexane chair forms to be largest? Estimate the Δ\(G^0\) value.

**SOLUTION**

The biggest Δ\(G^0\) for chair–chair flip is that between an all-equatorial and all-axial hexachlorocyclohexane. Application of Table 4-4 and inspection of Figure 4-11 reveal that this relation holds only for the all-trans isomer. Table 4-3 gives the Δ\(G^0\) (equatorial–axial) for Cl as 0.52 kcal mol\(^{-1}\); hence, for our example, Δ\(G^0\) = 6 × 0.52 = 3.12 kcal mol\(^{-1}\).

\[
\begin{align*}
\text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} \\
\text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl} & \quad \text{Cl}
\end{align*}
\]

Note that this value is only an estimate. For example, it ignores the six Cl–Cl gauche interactions in the all-equatorial form, which would reduce the energy difference between the two conformers. However, it also disregards the six 1,3-diaxial interactions in the all-axial chair, which would counteract this effect. For additional examples try Problems 30–33.

4-20. a. The strained tetracyclic alkane A is thought to isomerize thermally to the cyclic alkene B. Suggest a possible mechanism.

**SOLUTION**

When dealing with mechanistic problems, it is advantageous to carefully assimilate all of the given information, not unlike the situation encountered by an experimentalist who may have observed such a reaction and is faced with the same challenge. First, compound A is said to be strained. How so? Answer (Sections 4-2 and 4-6): It is a polycyclic alkane containing three linked four-membered rings. Second, the A-to-B conversion is an isomerization. We can ascertain quickly the truth of this statement by establishing that both compounds have the same molecular formula, \(\text{C}_{12}\text{H}_{18}\). Third, the process is “purely” thermal: There are no other reagents that could attack A, add to it, or subtract from it. Fourth, what topological (connectivity) changes have occurred?
**Answer:** A tetracycle is unraveled to a monocycle; in other words, the three cyclobutane rings are opened, leaving a cyclododecatriene. Fifth, what are the qualitative bond changes? **Answer:** Three single bonds are lost, three double bonds are gained.

Armed with the results of this analysis, we can now write a mechanism: We need to break the three C–C bonds by pyrolysis (Section 3-3). The result is seemingly a very exotic hexaradical; however, closer inspection shows that the six radical centers divide into three respective pairs of electrons on adjacent carbons: the three double bonds. Thus, a possible mechanism of this process requires only one step.

![Mechanism](image)

**b.** Regardless of the mechanism, is the isomerization thermodynamically feasible? Estimate the approximate $\Delta H^\circ$, using 65 kcal mol$^{-1}$ for the strength of the $\pi$ bond (Section 11-2).

**SOLUTION**

First, let us be clear about the question. It does *not* ask us whether it is kinetically feasible to break the three cyclobutane bonds, either as shown in part (a) or by some other sequence. Instead, the issue is where the equilibrium $A \rightleftharpoons B$ lies: Is it in the forward direction (Section 2-1)? We have learned how to get an estimate of the answer: by calculating $\Delta H^\circ = (\text{sum of strengths of bonds broken}) - (\text{sum of strengths of bonds made})$ (Sections 2-1 and 3-4). The second term in this equation is easy: We are making three $\pi$ bonds, worth 195 kcal mol$^{-1}$. How do we deal with the three $\sigma$ bonds that are broken? Table 3-2 provides an estimate for the strength of a $\text{C}_\text{sec} - \text{C}_\text{sec}$ bond: 85.5 kcal mol$^{-1}$. In our case, this bond is weakened by ring strain (Section 4-2, Table 4-2): $85.5 - 26.3 = 59.2$ kcal mol$^{-1}$. Multiplied by 3, this provides the first term of our $\Delta H^\circ$ equation, 177.6 kcal mol$^{-1}$. Thus, the $\Delta H^\circ (A \rightleftharpoons B) \approx -17.4$ kcal mol$^{-1}$. Conclusion: Indeed, this reaction should go! Note how the strain inherent in structure $A$ affects its function in the thermolysis. Without strain, the reaction would be endothermic.

**Important Concepts**

1. **Cycloalkane** nomenclature is derived from that of the straight-chain alkanes.

2. All but the 1,1-disubstituted cycloalkanes exist as two isomers: If both substituents are on the same face of the molecule, they are **cis**; if they are on opposite faces, they are **trans**. Cis and trans isomers are **stereoisomers**—compounds that have identical connectivities but differ in the arrangement of their atoms in space.

3. Some cycloalkanes are **strained**. Distortion of the bonds about tetrahedral carbon introduces **bond-angle strain**. Eclipsing (torsional) strain results from the inability of a structure to adopt staggered conformations about C–C bonds. Steric repulsion between atoms across a ring leads to **transannular strain**.

4. Bond-angle strain in the small cycloalkanes is largely accommodated by the formation of bent bonds.

5. Bond-angle, eclipsing, and other strain in the cycloalkanes larger than cyclopropane (which is by necessity flat) can be accommodated by deviations from planarity.

6. Ring strain in the small cycloalkanes gives rise to reactions that result in opening of the ring.

7. Deviations from planarity lead to conformationally mobile structures, such as **chair**, **boat**, and **twist-boat** cyclohexane. Chair cyclohexane is almost strain free.

8. Chair cyclohexane contains two types of hydrogens: **axial** and **equatorial**. These interconvert rapidly at room temperature by a conformational **chair–chair** (“flip”) **interconversion**, with an activation energy of 10.8 kcal mol$^{-1}$ (45.2 kJ mol$^{-1}$).
9. In monosubstituted cyclohexanes, the $\Delta G^\circ$ of equilibration between the two chair conformations is substituent dependent. Axial substituents are exposed to 1,3-diaxial interactions.

10. In more highly substituted cyclohexanes, substituent effects are often additive, the bulkiest substituents being the most likely to be equatorial.

11. Completely strain-free cycloalkanes are those that can readily adopt an all-anti conformation and lack transannular interactions.

12. Bicyclic ring systems may be fused or bridged. Fusion can be cis or trans.

13. Natural products are generally classified according to structure, physiological activity, taxonomy, and biochemical origin. Examples of the last class are the terpenes, of the first the steroids.

14. Terpenes are made up of isoprene units of five carbons.

15. Steroids contain three angularly fused cyclohexanes (A, B, C rings) attached to the cyclopentane D ring. Beta substituents are above the molecular plane, alpha substituents below.

16. An important class of steroids are the sex hormones, which have a number of physiological functions, including the control of fertility.

**Problems**

21. Write as many structures as you can that have the formula C$_5$H$_{10}$ and contain one ring. Name them.

22. Write as many structures as you can that have the formula C$_6$H$_{12}$ and contain one ring. Name them.

23. Name the following molecules according to the IUPAC nomenclature system.

(a) \[

24. Draw structural representations of each of the following molecules. Give a systematic name for any compound whose name is not in accord with IUPAC nomenclature: (a) isobutylcyclopentane; (b) cyclopropylcyclobutane; (c) cyclohexylethane; (d) (1-ethylethyl)cyclohexane; (e) (2-chloropropyl)-cyclopentane; (f) tert-butylcycloheptane.

25. Draw structural representations of each of the following molecules: (a) trans-1-chloro-2-ethylcyclopropane; (b) cis-1-bromo-2-chlorocyclopentane; (c) 2-chloro-1,1-diethylcyclopropane; (d) trans-2-bromo-3-chloro-1,1-diethylcyclopropane; (e) cis-1,3-dichloro-2,2-dimethylcyclobutane; (f) cis-2-chloro-1,1-difluoro-3-methylcyclopentane.

26. The kinetic data for the radical chain chlorination of several cycloalkanes (see the adjoining table) illustrate that the C–H bonds of cyclopropane and, to a lesser extent, cyclobutane are somewhat abnormal. (a) What do these data tell you about the strength of the cyclopropane C–H bond and the stability of the cyclopropyl radical? (b) Suggest a reason for the stability characteristics of the cyclopropyl radical. (Hint: Consider bond-angle strain in the radical relative to cyclopropane itself.)

27. Write out a mechanism for the radical monobromination of cyclohexane, showing initiation, propagation, and termination steps. Draw the product in its most stable conformation.

28. Use the data in Tables 3-2 and 4-2 to estimate the $\Delta H^\circ$ value for a C–C bond in (a) cyclopropane; (b) cyclobutane; (c) cyclopentane; and (d) cyclohexane.
29. Draw each of the following substituted cyclobutanes in its two interconverting “puckered” conformations (Figure 4-3). When the two conformations differ in energy, identify the more stable shape and indicate the form(s) of strain that raise the relative energy of the less stable one. (Hint: Puckered cyclobutane has axial and equatorial positions similar to those in chair cyclohexane.)

(a) Methylcyclobutane  (b) cis-1,2-Dimethylcyclobutane  
(c) trans-1,2-Dimethylcyclobutane (d) cis-1,3-Dimethylcyclobutane  
(e) trans-1,3-Dimethylcyclobutane

Which is more stable: cis- or trans-1,2-dimethylcyclobutane; cis- or trans-1,3-dimethylcyclobutane?

30. For each of the following cyclohexane derivatives, indicate (i) whether the molecule is a cis or trans isomer and (ii) whether it is in its most stable conformation. If your answer to (ii) is no, flip the ring and draw its most stable conformation.

(a) 
(b) 
(c) 
(d) 
(e) 
(f) 
(g) 
(h) 
(i) 
(j) 

31. Using the data in Table 4-3, calculate the ΔG° for ring flip to the other conformation of the molecules depicted in Problem 30. Make sure that the sign (i.e., positive or negative) of your values is correct.

32. Draw the most stable conformation for each of the following substituted cyclohexanes; then, in each case, flip the ring and redraw the molecule in the higher energy chair conformation: (a) cyclohexanol; (b) trans-3-methylcyclohexanol (see structures in the margin); (c) cis-1-methyl-3-(1-methylethyl)cyclohexane; (d) trans-1-ethyl-3-methoxycyclohexane (see structure in the margin); (e) trans-1-chloro-4-(1,1-dimethylethyl) cyclohexane.

33. For each molecule in Problem 32, estimate the energy difference between the most stable and next best conformation. Calculate the approximate ratio of the two at 300 K.

34. Sketch a potential-energy diagram (similar to that in Figure 4-9) for methylcyclohexane showing the two possible chair conformations at the left and right ends of the reaction coordinate for conformational interconversion.

35. Draw all the possible all-chair conformers of cyclohexylcyclohexane.

36. What is the most stable of the four boat conformations of methylcyclohexane, and why?

37. The most stable conformation of trans-1,3-bis(1,1-dimethylethyl)cyclohexane is not a chair. What conformation would you predict for this molecule? Explain.

38. The bicyclic hydrocarbon formed by the fusion of a cyclohexane ring with a cyclopentane ring is known as hexahydroindane (in margin). Using the drawings of trans- and cis-decalin for reference (Figure 4-13), draw the structures of trans- and cis-hexahydroindane, showing each ring in its most stable conformation.

39. On viewing the drawings of cis- and trans-decalin in Figure 4-13, which do you think is the more stable isomer? Estimate the energy difference between the two isomers.

40. Several tricyclic compounds exist in nature with a cyclopropane ring fused to a cis-decalin structure, as shown in the molecule tricyclo[5.4.01,3.01,7]undecane (margin). In various countries, some of these substances have a history of use as folk medicines for purposes such as contraception. Make a model of this compound. How does the cyclopropane ring affect the conformations of the two cyclohexane rings? The cyclohexane rings in cis-decalin itself are
capable of (simultaneous) chair–chair interconversion (recall Exercise 4-13). Is the same true in tricyclo[5.4.0^{1,3}.0^{1,7}]undecane?

41. The naturally occurring sugar glucose (Chapter 24) exists in the two isomeric cyclic forms shown below. These are called α and β, respectively, and they are in equilibrium by means of chemical processes that are introduced in Chapter 17.

(a) Which of the two forms is more stable?
(b) At equilibrium the two forms are present in a ratio of approximately 64:36. Calculate the free energy difference that corresponds to this equilibrium ratio. How closely does the value you obtained correlate with the data in Table 4-3?

42. Identify each of the following molecules as a monoterpene, a sesquiterpene, or a diterpene (all names are common).

43. Circle and identify by name each functional group in the structures pictured in Problem 42.

44. Find the 2-methyl-1,3-butadiene (isoprene) units in each of the naturally occurring organic molecules pictured in Problem 42.

45. Circle and identify by name all the functional groups in any three of the steroids illustrated in Section 4-7. Label any polarized bonds with partial positive and negative charges (δ⁺ and δ⁻).
46. Several additional examples of naturally occurring molecules with strained ring structures are shown here.

Identify the terpenes (if any) in the preceding group of structures. Find the 2-methyl-1,3-butadiene units in each structure and classify the latter as a mono-, sesqui-, or diterpene.

47. **CHALLENGE** If cyclobutane were flat, it would have exactly 90° C–C–C bond angles and could conceivably use pure $p$ orbitals in its C–C bonds. What would be a possible hybridization for the carbon atoms of the molecule that would allow all the C–H bonds to be equivalent? Exactly where would the hydrogens on each carbon be located? What are the real structural features of the cyclobutane molecule that contradict this hypothesis?

48. Compare the structure of cyclodecane in an all-chair conformation with that of *trans*-decalin. Explain why all-chair cyclodecane is highly strained, and yet *trans*-decalin is nearly strain free. Make models.

49. Fusidic acid is a steroidlike microbial product that is an extremely potent antibiotic with a broad spectrum of biological activity. Its molecular shape is most unusual and has supplied important clues to researchers investigating the methods by which steroids are synthesized in nature.

(a) Locate all the rings in fusidic acid and describe their conformations.
(b) Identify all ring fusions in the molecule as having either cis or trans geometry.
(c) Identify all groups attached to the rings as being either $\alpha$- or $\beta$-substituents.
(d) Describe in detail how this molecule differs from the typical steroid in structure and stereochemistry. (As an aid to answering these questions, the carbon atoms of the framework of the molecule have been numbered.)

50. The enzymatic oxidation of alkanes to produce alcohols is a simplified version of the reactions that produce the adrenocortical steroid hormones. In the biosynthesis of corticosterone from progesterone (Section 4-7), two such oxidations take place successively ($a$, $b$). It is thought that the monooxygenase enzymes act as complex oxygen-atom donors in these reactions.
A suggested mechanism, as applied to cyclohexane, consists of the two steps shown below the biosynthesis.

![Cyclohexane mechanism](image)

Calculate $\Delta H^\circ$ for each step and for the overall oxidation reaction of cyclohexane. Use the following $\Delta H^\circ$ values: cyclohexane C–H bond, 98.5 kcal mol\(^{-1}\); bond in O–H radical, 102.5 kcal mol\(^{-1}\); cyclohexanol C–O bond, 96 kcal mol\(^{-1}\).

51. **CHALLENGE** Iodobenzene dichloride, formed by the reaction of iodobenzene and chlorine, is a reagent for the chlorination of alkane C–H bonds. Chlorinations in which iodobenzene dichloride is used are initiated by light.

(a) Propose a radical chain mechanism for the chlorination of a typical alkane RH by iodobenzene dichloride. To get you started, the overall equation for the reaction is given below, as is the initiation step.

$$\text{RH} + \text{I} + \text{Cl}_2 \rightarrow \text{RCl} + \text{HCl} + \text{I}$$

Initiation:\n
$$\text{ICl} \quad \text{hv} \rightarrow \text{I} + \text{Cl}.$$

(b) Radical chlorination of typical steroids by iodobenzene dichloride gives, predominantly, three isomeric monochlorination products. On the basis of both reactivity (tertiary, secondary, primary) considerations and steric effects (which might hinder the approach of a reagent toward a C–H bond that might otherwise be reactive), predict the three major sites of chlorination in the steroid molecule. Either make a model or carefully analyze the drawings of the steroid nucleus in Section 4-7.

$$\text{3 major monochlorosteroids}$$

52. **CHALLENGE** As Problem 50 indicates, the enzymatic reactions that introduce functional groups into the steroid nucleus in nature are highly selective, unlike the laboratory chlorination described in Problem 51. However, by means of a clever adaptation of this reaction, it is
possible to partly mimic nature’s selectivity in the laboratory. Two such examples are illus-
trated below.

(a)

(b)

Propose reasonable explanations for the results of these two reactions. Make a model of the
product of the addition of Cl₂ to each iodocompound (compare Problem 51) to help in analyzing
each system.

Team Problem

53. Consider the following compounds:

Conformational analysis reveals that, though compound A exists in a chair conformation, com-
 pound B does not.

(a) Make a model of A. Draw chair conformations and label the substituents as equatorial or
axial. Circle the most stable conformation. (Note that the carbonyl carbon is \(sp^2\) hybridized and
therefore the attached oxygen is neither equatorial nor axial. Do not let that lead you astray.)

(b) Make a model of B. Consider both transannular and \textit{gauche} interactions in your analysis of
its two chair forms. Discuss the steric problems of these conformations in comparison with those
of A. Illustrate the key points of your discussion with Newman projections. Suggest a less steri-
cally encumbered conformation for B.

Preprofessional Problems

54. Which of the following cycloalkanes has the greatest ring strain?

(a) Cyclopropane 	(b) Cyclobutane 	(c) Cyclohexane 	(d) Cycloheptane

55. The following molecule

has (a) one axial chlorine and one \(sp^2\) carbon, (b) one axial chlorine and two \(sp^2\) carbons, (c) one
equatorial chlorine and one \(sp^2\) carbon, or (d) one equatorial chlorine and two \(sp^2\) carbons.
56. In this compound,

(a) the D is equatorial  (b) the methyls are both equatorial
(c) the Cl is axial      (d) the deuterium is axial

57. Which of the following structures has the smallest heat of combustion?
have you ever looked at yourself in the mirror in the morning and exclaimed: “That can’t be me!” Well, you were right. What you see, your mirror image, is not identical with you: You and your mirror image are nonsuperimposable. You can demonstrate this fact by trying to shake hands with your mirror counterpart: As you reach out with your right hand, your mirror image will offer you its left hand! We shall see that many molecules have this property—namely, that image and mirror image are nonsuperimposable and therefore not identical. How do we classify such structures? Do their functions differ, and if so, how?

Because they have the same molecular formula, these molecules are isomers, but of a different kind from those encountered so far. The preceding chapters dealt with two kinds of isomerism: constitutional (also called structural) and stereo (Figure 5-1). Constitutional isomerism describes compounds that have identical molecular formulas but differ in the order in which the individual atoms are connected (Sections 1-9 and 2-4).

The physiological effects of the image and mirror image of the leading bronchodilator albuterol are dramatically different. The R-image increases the bronchial airway diameter, whereas the S-mirror image cancels this effect and is a suspected inflammatory agent.
Stereoisomerism describes isomers whose atoms are connected in the same order but differ in their spatial arrangement. Examples of stereoisomers include the relatively stable and isolable cis-trans isomers and the rapidly equilibrating (and usually not isolable) conformational ones (Sections 2-5 through 2-7 and 4-1).

**Stereoisomers**

- **Constitutional Isomers**: Differ in the order of attachment of atoms (connectivity); Section 1-9

- **Stereoisomers**: Atoms are connected in the same order, but differ in spatial orientation

**Enantiomers**: Image and mirror image are not superimposable; Section 5-1

**Diastereomers**: Not related as image and mirror image; Section 5-5

**Exercise 5-1**

Are cyclopropylcyclopentane and cyclobutylcyclobutane isomers?

**Exercise 5-2**

Draw additional (conformational) stereoisomers of methylcyclohexane. (Hint: Use molecular models in conjunction with Figure 4-8.)
This chapter introduces another type of stereoisomerism, **mirror-image stereoisomerism**. Molecules in this class are said to possess “handedness,” referring to the fact that your left hand is not superimposable on your right hand, yet one hand can be viewed as the mirror image of the other (Figure 5-2A). In this way, hands are different from objects that are superimposable with their mirror images, such as a hammer (Figure 5-2B). The property of handedness in molecules is very important in nature, because most biologically relevant compounds are either “left-” or “right-handed.” As such, they react differently with each other, much as shaking your friend’s right hand is very different from shaking his or her left hand. A summary of isomeric relations is depicted in Figure 5-1.

### 5-1 Chiral Molecules

How can a molecule exist as two nonsuperimposable mirror images? Consider the radical bromination of butane. This reaction proceeds mainly at one of the secondary carbons to furnish 2-bromobutane. A molecular model of the starting material *seems* to show that either of the two hydrogens on that carbon may be replaced to give only one form of 2-bromobutane (Figure 5-3). Is this really true, however?

**Chiral molecules cannot be superimposed on their mirror images**

Look more closely at the 2-bromobutanes obtained by replacing either of the methylene hydrogens with bromine. In fact, the two structures are nonsuperimposable and therefore *not identical* (see the following page). The two molecules are related as object and mirror image, and to convert one into the other would require the breaking of bonds. A molecule that is not superimposable on its mirror image is said to be **chiral**. Each isomer of the image–mirror image pair is called an **enantiomer** (*enantios*, Greek, opposite). In our example of the bromination of butane, a 1:1 mixture of enantiomers is formed.
In contrast with chiral molecules, such as 2-bromobutane, compounds having structures that are superimposable on their mirror images are achiral. Examples of chiral and achiral molecules are shown above. The first two chiral structures depicted are enantiomers of each other. All the chiral examples contain an atom that is connected to four different substituent groups. Such a nucleus is called an asymmetric atom (e.g., asymmetric carbon) or a stereocenter. Centers of this type are sometimes denoted by an asterisk. Molecules with one stereocenter are always chiral. (We shall see in Section 5-6 that structures incorporating more than one such center need not be chiral.)

**Exercise 5-3**

Among the natural products shown in Section 4-7, which are chiral and which are achiral? Give the number of stereocenters in each case.
The symmetry in molecules helps to distinguish chiral structures from achiral ones.

The word *chiral* is derived from the Greek *cheir*, meaning “hand” or “handedness.” Human hands have the mirror-image relation that is typical of enantiomers (see Figure 5-2A). Among the many other objects that are chiral are shoes, ears, screws, and spiral staircases. On the other hand, there are many achiral objects, such as balls, ordinary water glasses, hammers (Figure 5-2B), and nails.

Many chiral objects, such as spiral staircases, do not have stereocenters. The same is true for many chiral molecules. Remember that the only criterion for chirality is the nonsuperimposable nature of object and mirror image. In this chapter, we shall confine our discussion to molecules that are chiral as a result of the presence of stereocenters. But how do we determine whether a molecule is chiral or not? As you have undoubtedly already noticed, it is not

**CHEMICAL HIGHLIGHT 5-1**

**Chiral Substances in Nature**

As we saw in the introduction to this chapter, the human body is chiral. Indeed, handedness pervades our macroscopic natural world. Moreover, there is usually a prevalence of a chiral image compared to its mirror image. For example, most of us are right handed, the heart is left and the liver is right, the bindweed plant winds around a support in a left-handed helix, the honeysuckle prefers the opposite, right-handed shells dominate (on both sides of the Equator), and so on.

![Houses of edible snails: the ratio of right-handed (on the left) to left-handed is 20,000:1.](image)

This preferential handedness is also present in the nano-scopic world of molecules; in fact, it is the presence of chiral molecular building blocks that often imparts macroscopic chirality. Thus, many chiral organic compounds exist in nature as only one enantiomer, although some are present as both. Specific handedness is associated with a specific biological function, dictated by the presence of chiral receptor sites in the body (see Chemical Highlight 5-5). For example, natural alanine is an abundant amino acid that is found in only one form. Lactic acid, however, is present in blood and muscle fluid as one enantiomer but in sour milk and some fruits and plants as a mixture of the two.

![2-Aminopropanoic acid (Alanine) and 2-Hydroxypropanoic acid (Lactic acid)](image)

Another example is carvone [2-methyl-5-(1-methylethyl)-2-cyclohexenone], which contains a stereocenter in a six-membered ring. This carbon atom may be thought of as bearing four different groups, if we consider the ring itself to be two separate and different substituents. They are different because, starting from the stereocenter, the clockwise sequence of atoms differs from the counterclockwise sequence. Carvone is found in nature in either enantiomeric form, each having a very characteristic odor: One enantiomer gives caraway its characteristic smell, whereas the other is responsible for the flavor of spearmint.

In this book, you will encounter numerous examples of chiral molecules from nature that exist as only one enantiomer.

![Caraway seeds and Carvone enantiomers](image)

![Spearmint](image)
Chapter 5
Stereoisomers

5-2 Optical Activity

Our first examples of chiral molecules were the two enantiomers of 2-bromobutane. If we were to isolate each enantiomer in pure form, we would find that we could not distinguish between them on the basis of their physical properties, such as boiling points, melting points, and densities. This result should not surprise us: Their bonds are identical and so are their energy contents. However, when a special kind of light, called plane-polarized light, is passed through a sample of one of the enantiomers, the plane of polarization of the incoming light is rotated in one direction (either clockwise or counterclockwise). When the same experiment is repeated with the other enantiomer, the plane of the polarized light is rotated by exactly the same amount but in the opposite direction.

An enantiomer that rotates the plane of light in a clockwise sense as the viewer faces the light source is dextrorotatory (dexter, Latin, right), and the compound is (arbitrarily) referred to as the (+) enantiomer. Consequently, the other enantiomer, which will effect counterclockwise rotation, is levorotatory (laevus, Latin, left) and called the (−) enantiomer.
This special interaction with light is called **optical activity**, and enantiomers are frequently called **optical isomers**.

### Optical rotation is measured with a polarimeter

What is plane-polarized light, and how is its rotation measured? Ordinary light can be thought of as bundles of electromagnetic waves that oscillate simultaneously in all planes perpendicular to the direction of the light beam. When such light is passed through a material called a polarizer, all but one of these light waves are “filtered” away, and the resulting beam oscillates in only one plane: **plane-polarized light** (Figure 5-5).

When light travels through a molecule, the electrons around the nuclei and in the various bonds interact with the electric field of the light beam. If a beam of plane-polarized light is passed through a chiral substance, the electric field interacts differently with, say, the “left” and “right” halves of the molecule. This interaction results in a rotation of the plane of polarization, called **optical rotation**; the sample giving rise to it is referred to as **optically active**.

Optical rotations are measured by using a **polarimeter** (Figure 5-5). In this instrument, light is first plane polarized and subsequently traverses a cell containing the sample. The angle of rotation of the plane of polarization is measured by aligning another polarizer — called the analyzer — so as to maximize the transmittance of the light beam to the eye of the observer. The measured rotation (in degrees) is the **observed optical rotation**, \( \alpha \), of the sample. Its value depends on the concentration and structure of the optically active molecule, the length of the sample cell, the wavelength of the light, the solvent, and the temperature.

To avoid ambiguities, chemists have agreed on a standard value of the **specific rotation**, \([\alpha]_t\), for each compound. This quantity (which is solvent dependent) is defined as

\[
[\alpha]_t = \frac{\alpha}{l \cdot c}
\]

where
- \([\alpha]\) = specific rotation
- \(t\) = temperature in degrees Celsius
- \(\lambda\) = wavelength of incident light; for a sodium vapor lamp, which is commonly used for this purpose, the yellow D emission line (usually indicated simply by D) has \(\lambda = 589\) nm.
- \(\alpha\) = observed optical rotation in degrees
- \(l\) = length of sample container in decimeters; its value is frequently 1 (i.e., 10 cm).
- \(c\) = concentration (grams per milliliter of solution)

---

*The dimensions of \([\alpha]\) are deg cm\(^2\) g\(^{-1}\), the units (for \(l = 1\)) 10\(^{-1}\) deg cm\(^2\) g\(^{-1}\). (Remember: 1 mL = 1 cm\(^3\).) Because of their awkward appearance, it is common practice to give \([\alpha]\) without units, in contrast with the observed rotation \(\alpha\) (degrees). Moreover, for practical reasons of solubility, some reference works list \(c\) in grams per 100 mL, in which case the observed rotation has to be multiplied by 100.*
Chapter 5  Stereoisomers

The specific rotation of an optically active molecule is a physical constant characteristic of that molecule, just like its melting point, boiling point, and density. Four specific rotations are recorded in Table 5-1.

Exercise 5-6

A solution of 0.1 g mL\(^{-1}\) of common table sugar (the naturally occurring form of sucrose) in water in a 10-cm cell exhibits a clockwise optical rotation of 6.65°. Calculate \([\alpha]\). Does this information tell you \([\alpha]\) for the enantiomer of natural sucrose?

<table>

</table>

Note: Pure liquid for the haloalkane; in aqueous solution for the acids.

The specific rotation of an optically active molecule is a physical constant characteristic of that molecule, just like its melting point, boiling point, and density. Four specific rotations are recorded in Table 5-1.

**Optical rotation indicates enantiomeric composition**

As mentioned, enantiomers rotate plane-polarized light by equal amounts but in opposite directions. Thus, in 2-bromobutane the (−) enantiomer rotates this plane counterclockwise by 23.1°, its mirror image (+)-2-bromobutane clockwise by 23.1°. It follows that a 1:1 mixture of (+) and (−) enantiomers shows no rotation and is therefore optically inactive. Such a mixture is called a **racemic mixture**. If one enantiomer equilibrates with its mirror image, it is said to undergo **racemization**. For example, amino acids such as (+)-alanine (Table 5-1) have been found to undergo very slow racemization in fossil deposits, resulting in reduced optical activity.

The optical activity of a sample of a chiral molecule is directly proportional to the ratio of the two enantiomers. It is at a maximum when only one enantiomer is present, and the sample is optically pure. It is zero when the two enantiomers are present in equal amounts, and the sample is racemic and optically inactive. In practice, one often encounters mixtures in which one enantiomer is in excess of the other. The **enantiomer excess (ee)** tells us by how much:

\[
\text{Enantiomer excess (ee)} = \% \text{ of major enantiomer} - \% \text{ of minor enantiomer}
\]

Since a racemate constitutes a 1:1 mixture of the two (ee = 0), the ee is a measure of how much one enantiomer is present in excess of racemate. The ee can be obtained from the % optical rotation of such a mixture relative to that of the pure enantiomer, also called **optical purity**:

**Optical Purity and Enantiomer Excess**

\[
\text{Enantiomer excess (ee)} = \frac{[\alpha]_{\text{Mixture}}}{[\alpha]_{\text{Pure enantiomer}}} \times 100\%
\]
Exercise 5-7

Working with the Concepts: Ee and Optical Purity

A solution of (+)-alanine from a fossil exhibits a value of $\alpha = +4.25$. What is its $ee$ and optical purity? What is the actual enantiomer composition of the sample, and how is the measured optical rotation derived from it?

**Strategy**
We need to look up what the specific rotation of pure (+)-alanine is and then use the preceding equation to get the answers.

**Solution**
- Table 5-1 gives us the specific rotation of pure (+)-alanine: +8.5.
- Our equation tells us: Enantiomer excess ($ee$) = optical purity = $(4.25/8.5) \times 100\% = 50\%$.
- This means that 50% of the sample is pure (+) isomer and the other 50% is racemic. Because the racemic portion consists of equal amounts of (+)- and (−)-enantiomers, the actual composition of the sample is 75% (+)- and 25% (−)-alanine.
- The 25% (−)-enantiomer cancels the rotation of a corresponding amount of (+)-enantiomer. This mixture is therefore 75% − 25% = 50% optically pure, and the observed optical rotation is one-half that of the pure dextrorotatory enantiomer.

Exercise 5-8

Try It Yourself

What is the optical rotation of a sample of (+)-2-bromobutane that is 75% optically pure? What percentages of (+)- and (−)-enantiomers are present in this sample? Answer the same questions for samples of 50% and 25% optical purity.

In Summary
Two enantiomers can be distinguished by their optical activity, that is, their interaction with plane-polarized light as measured in a polarimeter. One enantiomer always rotates such light clockwise (dextrorotatory), the other counterclockwise (levorotatory) by the same amount. The specific rotation, $[\alpha]$, is a physical constant possible only for chiral molecules. The interconversion of enantiomers leads to racemization and the disappearance of optical activity.

5-3 Absolute Configuration: R–S Sequence Rules

How do we establish the structure of one pure enantiomer of a chiral compound? And, once we know the answer, is there a way to name it unambiguously and distinguish it from its mirror image?

X-ray diffraction can establish the absolute configuration

Virtually all the physical characteristics of one enantiomer are identical with those of its mirror image, except for the sign of optical rotation. Is there a correlation between the sign of optical rotation and the actual spatial arrangement of the substituent groups, the absolute configuration? Is it possible to determine the structure of an enantiomer by measuring its $[\alpha]$ value? The answer to both questions is, unfortunately, no. There is no straightforward correlation between the sign of rotation and the structure of the particular enantiomer. For example, conversion of lactic acid (Table 5-1) into its sodium salt changes the sign (and degree) of rotation, even though the absolute configuration at the stereocenter is unchanged (see margin).
If the sign of rotation does not tell us anything about structure, how do we know which enantiomer of a chiral molecule is which? Or, to put it differently, how do we know that the levorotatory enantiomer of 2-bromobutane has the structure indicated in Table 5-1 (and therefore the dextrorotatory enantiomer the mirror-image configuration)? The answer is that such information can be obtained only through single-crystal X-ray diffraction analysis (Section 1-9 and the picture in the margin). This does not mean that every chiral compound must be submitted to X-ray analysis to ascertain its structure. Absolute configuration can also be established by chemical correlation with a molecule whose own structure has been proved by this method. For example, knowing the stereo-center in (\(\text{2}\))-lactic acid by X-ray analysis also provides the absolute configuration of the (\(\text{1}\))-sodium salt (i.e., the same).

Stereocenters are labeled \(R\) or \(S\)

To name enantiomers unambiguously, we need a system that allows us to indicate the handedness in the molecule, a sort of “left-hand” versus “right-hand” nomenclature. Such a system was developed by three chemists, R. S. Cahn, C. Ingold, and V. Prelog.\(^*\)

Let us see how the handedness around an asymmetric carbon atom is labeled. The first step is to rank all four substituents in the order of decreasing priority, the rules of which will be described shortly. Substituent \(a\) has the highest priority, \(b\) the second highest, \(c\) the third, and \(d\) the lowest. Next, we position the molecule (mentally, on paper, or by using a molecular model set) so that the lowest-priority substituent is placed as far away from us as possible (Figure 5-6). This process results in two (and only two) possible arrangements of the remaining substituents. If the progression from \(a\) to \(b\) to \(c\) is counterclockwise, the configuration at the stereocenter is named \(S\) (\text{sinister, \text{Latin}, left}). Conversely, if the progression is clockwise, the center is \(R\) (\text{rectus, \text{Latin}, right}). The symbol \(R\) or \(S\) is added as a prefix in parentheses to the name of the chiral compound, as in \((\text{R}\))-2-bromobutane and \((\text{S}\))-2-bromobutane. A racemic mixture can be designated \(R, S\), if necessary, as in \((\text{R}, \text{S})\)-bromochlorofluoromethane. The sign of the rotation of plane-polarized light may be added if it is known, as in \((\text{S}, \text{(-)}\))-2-bromobutane and \((\text{R}, \text{(-)}\))-2-bromobutane. It is important to remember, however, that the symbols \(R\) and \(S\) are not necessarily correlated with the sign of \(\alpha\).

Sequence rules assign priorities to substituents

Before applying the \(R,S\) nomenclature to a stereocenter, we must first assign priorities by using sequence rules.

---

**Rule 1.** We look first at the atoms attached directly to the stereocenter. A substituent atom of higher atomic number takes precedence over one of lower atomic number. Consequently, the substituent of lowest priority is hydrogen. In regard to isotopes, the atom of higher atomic mass receives higher priority.

\[ \text{H} \quad \text{(R)}-1\text{-Bromo-1-iodoethane} \]

**Rule 2.** What if two substituents have the same rank when we consider the atoms directly attached to the stereocenter? In such a case, we proceed along the two respective substituent chains until we reach a point of difference.

For example, an ethyl substituent takes priority over methyl. Why? At the point of attachment to the stereocenter, each substituent has a carbon nucleus, equal in priority. Farther from that center, however, methyl has only hydrogen atoms, but ethyl has a carbon atom (higher in priority).

\[
\begin{align*}
\text{H} & \quad \text{C} \quad \text{H} \quad \text{Methyl} \\
\text{H} & \quad \text{C} \quad \text{H} \quad \text{Ethyl}
\end{align*}
\]

However, 1-methylethyl takes precedence over ethyl because, at the first carbon, ethyl bears only one other carbon substituent, but 1-methylethyl bears two. Similarly, 2-methylpropyl takes priority over butyl but ranks lower than 1,1-dimethylethyl.

\[
\begin{align*}
\text{H} & \quad \text{C} \quad \text{CH}_3 \quad \text{Ethyl} \\
\text{H} & \quad \text{C} \quad \text{CH}_3 \quad \text{1-Methylethyl (Isopropyl)}
\end{align*}
\]

We must remember that the decision on priority is made at the first point of difference along otherwise similar substituent chains. When that point has been reached, the constitution of the remainder of the chain is irrelevant.
When we reach a point along a substituent chain at which it branches, we choose the branch that is higher in priority. When two substituents have similar branches, we rank the elements in those branches until we reach a point of difference.

Two examples are shown below.

\[
\text{(R)-2-Iodobutane} \quad (S)-3\text{-Ethyl-2,2,4-trimethylpentane}
\]

**Rule 3.** Double and triple bonds are treated as if they were single, and the atoms in them are duplicated or triplicated at each end by the respective atoms at the other end of the multiple bond.

Examples are shown in the margin and in the structures of \(S\)- and \(R\)-albuterol that appear in the Chapter Opening.
**Exercise 5-9**

Draw the structures of the following substituents and within each group rank them in order of decreasing priority. 

(a) Methyl, bromomethyl, trichloromethyl, ethyl; 
(b) 2-methyl-propyl (isobutyl), 1-methylethyl (isopropyl), cyclohexyl; 
(c) butyl, 1-methylpropyl (sec-butyl), 2-methylpropyl (isobutyl), 1,1-dimethylethyl (tert-butyl); 
(d) ethyl, 1-chloroethyl, 1-bromoethyl, 2-bromoethyl.

---

**Exercise 5-10**

**Working with the Concepts: Assigning R and S**

Assign the absolute configuration of (−)-2-bromobutane, depicted in Table 5-1.

**Strategy**

To establish a molecule’s absolute configuration, we cannot rely on whether it is levorotatory or dextrorotatory. Instead, we focus on the stereocenter and arrange the molecule in space in such a way that the substituent with lowest priority is facing away from us. Therefore, the first task is to assign priorities and the second step is to arrange the molecule in space as required.

**Solution**

Let us look at (−)-2-bromobutane, reproduced below (labeled A) as it appears in Table 5-1.

- According to the Cahn–Ingold–Prelog rules, Br is a, CH₂CH₃ is b, CH₃ is c, and H is d, as depicted in structure B.
- Arranging the molecule in space can be difficult at first, but becomes easier with practice. A safe approach is described in Figure 5-6, in which you move the tetrahedral frame so as to place the C-d bond in the plane of the page pointing to the left and imagine looking down this axis from the right. For structure B, this procedure means rotating the carbon atom to reach structure C (with the C-d bond in the plane of the page) and then rotating the molecule clockwise to reach D. Looking at D from the right as shown reveals the absolute configuration: R.
- As you do more of these assignments, you will become increasingly adept at seeing the molecule in three dimensions and viewing it so that the trio a, b, c is pointing toward you and group d is pointing away from you.

---

**Exercise 5-11**

**Try It Yourself**

Assign the absolute configuration of the remaining three molecules depicted in Table 5-1.

---

**Exercise 5-12**

Draw one enantiomer of your choice (specify which, R or S) of 2-chlorobutane, 2-chloro-2-fluorobutane, and (HC≡C)CH₂=CHC(Br)(CH₃).

To assign correctly the stereostructure of stereoisomers, we must develop a fair amount of three-dimensional “vision,” or “stereoperception.” In most of the structures that we have used to illustrate the priority rules, the lowest-priority substituent
is located at the left of the carbon center and in the plane of the page, and the remainder of the substituents at the right, the upper-right group also being positioned in this plane. However, we already know that this is not the only way of drawing hashed-wedged line structures; others are equally correct. Consider some of the structural drawings of (S)-2-bromobutane (below). These are simply different views of the same molecule.

**Six Ways of Depicting (S)-2-Bromobutane**

In Summary The sign of optical rotation cannot be used to establish the absolute configuration of a stereoisomer. Instead, X-ray diffraction (or chemical correlations) must be used. We can express the absolute configuration of the chiral molecule as R or S by applying the sequence rules, which allow us to rank all substituents in order of decreasing priority. Turning the structures so as to place the lowest-priority group at the back causes the remaining substituents to be arranged in clockwise (R) or counterclockwise (S) fashion.

**The Fischer Stencil**

A Fischer (Chemical Highlight 5-2) projection is a simplified way of depicting tetrahedral carbon atoms and their substituents in two dimensions. With this method, the molecule is drawn in the form of a cross, the central carbon being at the point of intersection. The horizontal lines signify bonds directed toward the viewer; the vertical lines are pointing
Absolute Configuration: A Historical Note

Before the X-ray diffraction technique was developed, the absolute configurations of chiral molecules were unknown. Amusingly, the first assignment of a three-dimensional structure to a chiral molecule was a guess made more than a century ago by the sugar chemist Emil Fischer. He did so in a paper in 1891 to simplify the depiction of the complicated stereochemical relationships of grape sugar (glucose) to other sugars, a topic that we will visit in Chapter 24. His choice (by chemical correlation) assigned the naturally occurring dextrorotatory enantiomer of 2,3-dihydroxypropanal (glyceraldehyde) the three-dimensional structure labeled D-glyceraldehyde. The label “D” does not refer to the sign of rotation of plane-polarized light but to the spatial arrangement of the substituent groups.

D-Configuration

\[ [\alpha]_D^{25\circ} = +8.7 \]

\[ \text{D-} \text{2,3-Dihydroxypropanal} \]

\[ \text{[D-2,3-Glyceraldehyde]} \]

L-Configuration

\[ [\alpha]_D^{25\circ} = -8.7 \]

\[ \text{L-} \text{2,3-Dihydroxypropanal} \]

\[ \text{[L-2,3-Glyceraldehyde]} \]

The other isomer was called L-glyceraldehyde. All chiral compounds that could be converted into D-(+)-glyceraldehyde by reactions that did not affect the configuration at the stereocenter were assigned the D configuration, and their mirror images the L.

In 1951, the Dutch crystallographer Johannes Bijvoet established the absolute configurations of these compounds by the X-ray diffraction analysis of a salt of tartaric acid, which had been correlated by chemical means with Fischer’s sugars and, in turn, glyceraldehyde. As Bijvoet states in his paper (abbreviated), “The result is that Emil Fischer’s convention . . . appears to answer the reality.” Lucky guess! D,L nomenclature is still used for sugars (Chapter 24) and amino acids (Chapter 26).

Conversion of the Hashed-Wedge Line Structures of 2-Bromobutane into Fischer Projections (of the Stereocenter)

Hashed-wedged line structures have to be arranged in this way to facilitate their conversion into Fischer projections.
Notice that just as there are several ways of depicting a molecule in the hashed-wedged line notation, there are several correct Fischer projections of the same stereocenter.

**Two Additional Projections of \((R)\)-2-Bromobutane**

\[
\begin{align*}
\text{CH}_3 & \xrightarrow{C} \text{Br} & \text{CH}_3 & \xrightarrow{C} \text{Br} & \text{H} & \xrightarrow{C} \text{CH}_2\text{CH}_3 & \xrightarrow{C} \text{H} & \xrightarrow{C} \text{CH}_2\text{CH}_3 \\
\text{CH}_2\text{CH}_3 & & \text{CH}_2\text{CH}_3 & & \text{H} & & \text{CH}_2\text{CH}_3 & \\
\end{align*}
\]

A simple mental procedure that will allow you to safely convert any hashed-wedged line structure into a Fischer projection is to picture yourself at the molecular level and grasp any two substituents of the hashed-wedged line rendition with your hands while facing the central carbon, as shown below. In this cartoon, these substituents are labeled arbitrarily \(a\) and \(c\). If you then imagine descending on the page while holding the molecule, the two remaining substituents (positioned behind the carbon center) will submerge below it, and your left and right hands will position the two horizontal, wedged-line groups in the proper orientation. This procedure places the two remaining hashed-line groups vertically (juxtaposing your head and feet, respectively).

**A Simple Mental Exercise:**
**Conversion of Hashed-Wedged Line Structures into Fischer Projections**

Having achieved this conversion, you can change one Fischer projection into another of the same molecule by using certain manipulations: rotations and substituent switches. However, we shall see next that care has to be taken so you don’t inadvertently convert \(R\) into \(S\) configurations.

**Rotating a Fischer projection may or may not change the absolute configuration**

What happens when we rotate a Fischer projection in the plane of the page by 90°? Does the result depict the spatial arrangement of the original molecule? The definition of a Fischer projection—horizontal bonds are pointed above, vertical ones below the plane of the page—tells us that the answer is clearly no, because this rotation has switched the relative spatial disposition of the two sets: The result is a picture of the enantiomer. On the other hand, rotation by 180° is fine, because horizontal and vertical lines have not been interchanged: The resulting drawing represents the same enantiomer.
Exchanging substituents in a Fischer projection also changes the absolute configuration

As is the case for hashed-wedged line structures, there are several Fischer projections of the same enantiomer, a situation that may lead to confusion. How can we quickly ascertain whether two Fischer projections are depicting the same enantiomer or two mirror images? We have to find a sure way to convert one Fischer projection into another in a manner that either leaves the absolute configuration unchanged or converts it into its opposite. It turns out that this task can be achieved by simply making substituent groups trade places. As we can readily verify by using molecular models, any single such exchange turns one enantiomer into its mirror image. Two such exchanges (we may select different substituents every time) produce the original absolute configuration. As shown below, this operation merely results in a different view of the same molecule.
Consider, for example, the two Fischer projections A and B. Do they represent molecules having the same configuration? The answer is found quickly. We convert A into B by two exchanges; so A equals B.

![Fischer projections](image)

**Exercise 5-14**

Draw the hashed-wedged line structures corresponding to Fischer projections A and B, above. Is it possible to transform A into B by means of a rotation about a single bond? If so, identify the bond and the degree of rotation required. Use models if necessary.

**Fischer projections tell us the absolute configuration**

Fischer projections allow us to assign absolute configurations without having to visualize the three-dimensional arrangement of the atoms. For this purpose, we

First draw the molecule as any Fischer projection.
Next, we rank all the substituents in accord with the sequence rules.
Finally, if necessary, we place group d on top by a double exchange.

With d at the top, the three groups of priority a, b, and c can adopt only two arrangements: either clockwise or counterclockwise. The first corresponds unambiguously to the R, the second to the S configuration.

![Fischer projections](image)

**Exercise 5-15**

**Working with the Concepts: Assigning R and S Using Fischer Projections**

What is the absolute configuration of

![Fischer projections](image)

**Strategy**

This molecule, 1-bromo-1-deuterioethane, is chiral because of the presence of a carbon atom bearing four different substituents, one of which happens to be deuterium, an isotope of hydrogen. The first task is to assign priorities, and the second step is to arrange the Fischer projection such as to place the lowest-priority substituent on top.

**Solution**

- According to the Cahn–Ingold–Prelog rules, Br is a, CH₃ is b, D is c, and H is d.
- To simplify matters, we replace the substituents with their stereochemical priority designators:

![Fischer projections](image)
In Summary A Fischer projection is a convenient way of drawing chiral molecules. We can rotate such projections in the plane by $180^\circ$ (retains absolute configuration) but not by $90^\circ$ (changes absolute configuration). Switching substituents reverses absolute configuration, if done an odd number of times, but leaves it intact when the number of such exchanges is even. By placing the substituent of lowest priority on top, we can readily assign the absolute configuration.

5-5 Molecules Incorporating Several Stereocenters: Diastereomers

Many molecules contain several stereocenters. Because the configuration about each center can be $R$ or $S$, several possible structures emerge, all of which are isomeric.

Two stereocenters can give four stereoisomers: chlorination of 2-bromobutane at C3

In Section 5-1 we described how a carbon-based stereocenter can be created by the radical halogenation of butane. Let us now consider the chlorination of racemic 2-bromobutane to give (among other products) 2-bromo-3-chlorobutane. The introduction of a chlorine atom at C3 produces a new stereocenter in the molecule. This center may have either the $R$ or
Chapter 5

Stereoisomers

The S configuration. This reaction can be conveniently shown using Fischer projections. For this purpose, we draw the stem as a vertical line and the stereocenters as horizontal lines.

How many stereoisomers are possible for 2-bromo-3-chlorobutane? There are four, as can be seen by completing a simple exercise in permutation. Each stereocenter can be either R or S, and, hence, the possible combinations are RR, RS, SR, and SS. You can readily establish the existence of four stereoisomers by recognizing that each halogen substituent can be placed either to the right or to the left of the stem, respectively, for a total of four combinations (see below and Figure 5-7).

Because all horizontal lines in Fischer projections signify bonds directed toward the viewer, the Fischer stencil represents an eclipsed conformation and therefore does not depict the molecule in its most stable form, which is anti. This is illustrated below for (2S,3S)-2-bromo-3-chlorobutane (see also Figure 5-7).

Figure 5-7 The four stereoisomers of 2-bromo-3-chlorobutane. Each molecule is the enantiomer of one of the other three (its mirror image) and is at the same time a diastereomer of each of the remaining two. For example, the 2R,3R isomer is the enantiomer of the 2S,3S compound and is a diastereomer of both the 2S,3R and the 2R,3S structures. Notice that two structures are enantiomers only when they possess the opposite configuration at every stereocenter.
To make stereochemical assignments, one treats each stereocenter separately, and the group containing the other stereocenter is regarded as a simple substituent (Figure 5-8).

By looking closely at the structures of the four stereoisomers (Figure 5-7), we see that there are two related pairs of compounds: an $R,R/S,S$ pair and an $R,S/S,R$ pair. The members of each individual pair are mirror images of each other and therefore enantiomers. Conversely, each member of one pair is not a mirror image of either member of the other pair; hence, they are not enantiomeric with respect to each other. Stereoisomers that are not related as object and mirror image, and therefore are not enantiomers, are called diastereomers (dia, Greek, across).

**Exercise 5-18**

The two amino acids isoleucine and alloisoleucine are depicted below in staggered conformations. Convert both into Fischer projections. (Keep in mind that Fischer projections are views of molecules in eclipsed conformations.) Are these two compounds enantiomers or diastereomers?

![Isoleucine and Alloisoleucine](image)

In contrast with enantiomers, diastereomers, because they are not mirror images of each other, are molecules with different physical and chemical properties (see, e.g., Chemical Highlight 5-3). Their steric interactions and energies differ. They can be separated by fractional distillation, crystallization, or chromatography. They have different melting and boiling points and different densities, just as constitutional isomers do. In addition, they have different specific rotations.

**Exercise 5-19**

What are the stereochemical relations (identical, enantiomers, diastereomers) of the following four molecules? Assign absolute configurations at each stereocenter.

![Molecules Incorporating Several Stereocenters](image)

**Figure 5-8** Assigning the absolute configuration at C3 in 2-bromo-3-chlorobutane. We consider the group containing the stereocenter C2 merely as one of the four substituents. Priorities (also noted in color) are assigned in the usual way ($\text{Cl} > \text{CHBrCH}_3 > \text{CH}_3 > \text{H}$), giving rise to the representation shown in the center. Two exchanges place the substituent of lowest priority (hydrogen) at the top of the Fischer projection to facilitate assignment.

**Problem:** $R$ or $S$?

**Solution:** The center under scrutiny is $S$. 2-Bromo-3-chlorobutane $R,R/S,S$-Racemate: b.p. 31–33°C (at 16 torr) 2-Bromo-3-chlorobutane $R,R/S,S$-Racemate: b.p. 31–33°C (at 16 torr)
CHEMICAL HIGHLIGHT 5-3

Stereoisomers of Tartaric Acid

![Tartaric Acid Structures]

Tartaric acid (systematic name 2,3-dihydroxybutanedioic acid) is a naturally occurring dicarboxylic acid containing two stereocenters with identical substitution patterns. Therefore it exists as a pair of enantiomers (which have identical physical properties but which rotate plane-polarized light in opposite directions) and an achiral meso compound (with different physical and chemical properties from those of the chiral diastereomers).

The dextrorotatory enantiomer of tartaric acid is widely distributed in nature. It is present in many fruits, and its monopotassium salt is rare, as is the meso isomer.

Pasteur* obtained a sample of the sodium ammonium salt of this acid and noticed that there were two types of crystals: One set was the mirror image of the second. In other words, the crystals were chiral.

By manually separating the two sets, dissolving them in water, and measuring their optical rotation, Pasteur found one of the crystalline forms to be the pure salt of (+)-tartaric acid and the other to be the levorotatory form. Remarkably, the chirality of the individual molecules in this rare case had given rise to the macroscopic property of chirality in the crystal. He concluded from his observation that the molecules themselves must be chiral. These findings and others led in 1874 to the first proposal, by van’t Hoff and Le Bel† independently, that saturated carbon has a tetrahedral bonding arrangement and is not, for example, square planar. (Why is the idea of a planar carbon incompatible with that of a stereocenter?)

*T. Pasteur (1822-1895), Sorbonne, Paris.
†J. A. Le Bel (1847-1930), Ph.D., Sorbonne, Paris.

Cis and trans isomers are cyclic diastereomers

It is instructive to compare the stereoisomers of 2-bromo-3-chlorobutane with those of a cyclic analog, 1-bromo-2-chlorocyclobutane (Figure 5-9). In both cases, there are four stereoisomers: R,R, S,S, R,S, and S,R. In the cyclic compound, however, the stereoisomeric relation of the first pair to the second is easily recognized: One pair has cis stereochemistry, the other trans. Cis and trans isomers (Section 4-1) in cycloalkanes are in fact diastereomers.

More than two stereocenters means still more stereoisomers

What structural variety do we expect for a compound having three stereocenters? We may again approach this problem by permuting the various possibilities. If we label the three centers consecutively as either R or S, the following sequence emerges:

RRR  RRS  RSR  SRR  RSS  SRS  SSR  SSS
Chapter 5

191

a total of eight stereoisomers. They can be arranged to reveal a division into four enantiomer pairs of diastereomers.

<td>RSR</td>
</tr>
</tbody>
</table>

Generally, a compound with n stereocenters can have a maximum of $2^n$ stereoisomers. Therefore, a compound having three such centers gives rise to a maximum of eight stereoisomers; one having four produces sixteen; one having five, thirty-two; and so forth. The structural possibilities are quite staggering for larger systems.

Exercise 5-20

Draw all the stereoisomers of 2-bromo-3-chloro-4-fluoropentane.

In Summary The presence of more than one stereocenter in a molecule gives rise to diastereomers. These are stereoisomers that are not related to each other as object and mirror image. Whereas enantiomers have opposite configurations at every respective stereocenter, two diastereomers do not. A molecule with n stereocenters may exist in as many as $2^n$ stereoisomers. In cyclic compounds, cis and trans isomers are diastereomers.

5-6 Meso Compounds

We saw that the molecule 2-bromo-3-chlorobutane contains two distinct stereocenters, each with a different halogen substituent. How many stereoisomers are to be expected if both centers are identically substituted?

Two identically substituted stereocenters give rise to only three stereoisomers

Consider, for example, 2,3-dibromobutane, which can be obtained by the radical bromination of 2-bromobutane. As we did for 2-bromo-3-chlorobutane, we have to consider four structures, resulting from the various permutations in R and S configurations (Figure 5-10).
The first pair of stereoisomers, with $R,R$ and $S,S$ configurations, is clearly recognizable as a pair of enantiomers. However, a close look at the second pair reveals that ($S,R$) and mirror image ($R,S$) are superimposable and therefore identical. Thus, the $S,R$ diastereomer of 2,3-dibromobutane is achiral and not optically active, even though it contains two stereocenters. The identity of the two structures can be readily confirmed by using molecular models.

A compound that contains two (or, as we shall see, even more than two) stereocenters but is superimposable with its mirror image is a meso compound ($mesos$, Greek, middle). A characteristic feature of a meso compound is the presence of an internal mirror plane, which divides the molecule such that one half is the mirror image of the other half. For example, in 2,3-dibromobutane, the $2R$ center is the reflection of the $3S$ center. This arrangement is best seen in an eclipsed hashed-wedged line structure (Figure 5-11). The presence of a mirror plane in any energetically accessible conformation of a molecule (Sections 2-7 and 2-8) is sufficient to make it achiral (Section 5-1). As a consequence, 2,3-dibromobutane exists in the form of three stereoisomers only: a pair of (necessarily chiral) enantiomers and an achiral meso diastereomer.

The stereochemical relations of the stereoisomers of 2,3-dibromobutane. The lower pair consists of identical structures. (Make a model.)

This cat's face appears perfectly meso.

Figure 5-11 meso-2,3-Dibromobutane contains an internal mirror plane when rotated into the eclipsed conformation shown. A molecule with more than one stereocenter is meso and achiral as long as it contains a mirror plane in any readily accessible conformation. Meso compounds possess identically substituted stereocenters.

Meso diastereomers can exist in molecules with more than two stereocenters. Examples are 2,3,4-tribromopentane and 2,3,4,5-tetrabromohexane.
Cyclic compounds may also be meso

It is again instructive to compare the stereochemical situation in 2,3-dibromobutane with that in an analogous cyclic molecule: 1,2-dibromocyclobutane. We can see that trans-1,2-dibromocyclobutane exists as two enantiomers (R,R and S,S) and may therefore be optically active. The cis isomer, however, has an internal mirror plane and is meso, achiral, and optically inactive (Figure 5-12).

Notice that we have drawn the ring in a planar shape in order to illustrate the mirror symmetry, although we know from Chapter 4 that cycloalkanes with four or more carbons in the ring are not flat. Is this justifiable? Generally yes, because such compounds, like their acyclic analogs, possess a variety of conformations that are readily accessible at room temperature (Sections 4-2 through 4-4 and Section 5-1). At least one of these conformations will contain the necessary mirror plane to render achiral any cis-disubstituted cycloalkane with identically constituted stereocenters. For simplicity, cyclic compounds may usually be treated as if they were planar for the purpose of identifying a mirror plane.

Exercise 5-22

Draw each of the following compounds, representing the ring as planar. Which ones are chiral? Which are meso? Indicate the location of the mirror plane in each meso compound. (a) cis-1,2-Dichlorocyclopentane; (b) its trans isomer; (c) cis-1,3-dichlorocyclopentane; (d) its trans isomer; (e) cis-1,2-dichlorocyclohexane; (f) its trans isomer; (g) cis-1,3-dichlorocyclohexane; (h) its trans isomer.

Exercise 5-23

For each meso compound in Exercise 5-22, draw the conformation that contains the mirror plane. Refer to Sections 4-2 through 4-4 to identify energetically accessible conformations of these ring systems.

In Summary Meso compounds are diastereomers containing a molecular plane of symmetry. They are therefore superimposable on their mirror images and achiral. Molecules with two or more identically substituted stereocenters may exist as meso stereoisomers.

5-7 Stereochemistry in Chemical Reactions

We have seen that a chemical reaction, such as the halogenation of an alkane, can introduce chirality into a molecule. How exactly does this occur? To find the answer, we need to look more closely at the conversion of achiral butane into chiral 2-bromobutane, which gives
racemic material. Once we have done so, we shall be able to understand the halogenation of 2-bromobutane and the effect of the chiral environment of a stereocenter already present in a molecule on the stereochemistry of the reaction.

**The radical mechanism explains why the bromination of butane results in a racemate**

The radical bromination of butane at C2 creates a chiral molecule (Figure 5-3). This happens because one of the methylene hydrogens is replaced by a new group, furnishing a stereocenter—a carbon atom with four different substituents.

In the first step of the mechanism for radical halogenation (Sections 3-4 and 3-6), one of these two hydrogens is abstracted by the attacking bromine atom. It does not matter which of the two is removed: This step does not generate a stereocenter. It furnishes a planar, $sp^2$-hybridized, and therefore achiral radical. The radical center has two equivalent reaction sites—two lobes of the $p$ orbital (Figure 5-13)—that are equally susceptible to attack by bromine in the second step. We can see that the two transition states resulting in the respective enantiomers of 2-bromobutane are mirror images of each other. They are enantiomeric and therefore energetically equivalent. The rates of formation of $R$ and $S$ products are hence equal, and a racemate is formed. In general, the formation of chiral

![Figure 5-13](image-url)
compounds (e.g., 2-bromobutane) from achiral reactants (e.g., butane and bromine) yields racemates. Or, optically inactive starting materials furnish optically inactive products.\(^\text{a}\)

**The presence of a stereocenter affects the outcome of the reaction: chlorination of (S)-2-bromobutane**

Now we understand why the halogenation of an achiral molecule gives a racemic halide. What products can we expect from the halogenation of a chiral, enantiomerically pure molecule? Or, to put it differently, how does the presence of a stereocenter in the structure affect its function in a reaction?

For example, consider the radical chlorination of the S enantiomer of 2-bromobutane. In this case, the chlorine atom has several options for attack: the two terminal methyl groups, the single hydrogen at C2, and the two hydrogens on C3. Let us examine each of these reaction paths.

### Chlorination of (S)-2-Bromobutane at Either C1 or C4

Chlorination of either terminal methyl group is straightforward, proceeding at C1 to give 2-bromo-1-chlorobutane or at C4 to give 3-bromo-1-chlorobutane. In the latter, the original C4 has now become C1, to maintain the lowest possible substituent numbering. *Both of these chlorination products are optically active because the original stereocenter is left intact.* Note, however, that conversion of the C1 methyl into a chloromethyl unit changes the sequence of priorities around C2. Thus, although the stereocenter itself does not participate in the reaction, its designated configuration changes from S to R.

What about halogenation at C2, the stereocenter? The product from chlorination at C2 of (S)-2-bromobutane is 2-bromo-2-chlorobutane. Even though the substitution pattern at the stereocenter has changed, the molecule remains chiral. However, an attempt to measure the \([\alpha]\) value for the product would reveal the absence of optical activity: *Halogenation at the stereocenter leads to a racemic mixture.* How can this be explained? For the answer, we must look again at the structure of the radical formed in the course of the reaction mechanism.

A racemate forms in this case because hydrogen abstraction from C2 furnishes a planar, \(sp^2\)-hybridized, achiral radical.

### Chlorination of (S)-2-Bromobutane at C2

\(^{a}\)We shall see later that it is possible to generate optically active products from optically inactive starting materials if we use an optically active reagent or catalyst (see, for example, Chemical Highlight 5-4).
Chapter 5  Stereoisomers

Chlorination can occur from either side through enantiomeric transition states of equal energy, as in the bromination of butane (Figure 5-13), producing (S)- and (R)-2-bromo-2-chlorobutane at equal rates and in equal amounts. The reaction is an example of a transformation in which an optically active compound leads to an optically inactive product (a racemate).

Exercise 5-24

What halogenations of (S)-2-bromobutane, other than the ones described above, would furnish optically inactive products?

Chlorination can occur from either side through enantiomeric transition states of equal energy, as in the bromination of butane (Figure 5-13), producing (S)- and (R)-2-bromo-2-chlorobutane at equal rates and in equal amounts. The reaction is an example of a transformation in which an optically active compound leads to an optically inactive product (a racemate).

Exercise 5-24

What halogenations of (S)-2-bromobutane, other than the ones described above, would furnish optically inactive products?

The chlorination of (S)-2-bromobutane at C3 does not affect the existing chiral center. However, the formation of a second stereocenter gives rise to diastereomers. Specifically,
Because of these findings, the U.S. Food and Drug Administration (FDA) revised its guidelines for the commercialization of chiral drugs, making it more advantageous for companies to produce single enantiomers of medicinal products. The logistics of testing pure enantiomers are simpler, the biological efficiencies of the drugs are higher, and, potentially, the lifetime of a patent on a successful drug can be further extended by switching sales from a racemate to the active enantiomer (“chiral switch”). The result has been a flurry of research activities designed to improve resolution of racemates or, even better, to develop methods of enantioselective synthesis. The essence of this approach is that used by nature in enzyme-catalyzed reactions (see the oxidation of dopamine in Section 5-7): An achiral starting material is converted into the chiral product in the presence of an enantiopure environment, often a chiral catalyst. Because enantiomeric transition states (Figure 5-13) become diastereomeric in such an environment (Figure 5-14; note that, in this case, the chiral “environment” of the reacting carbon is provided by the neighboring stereocenter), high stereoselectivity can be achieved. Such selectivity is a nice example of adherence to some of the principles of green chemistry: avoiding generation of 50% “waste” in the form of the wrong enantiomer, the associated cumbersome separation (Section 5-8), atom economy, and catalysis. As shown below, such methods have been applied to the syntheses of drugs such as the antiarthritic and analgesic naproxen and the antihypertensive propranolol in high enantiomeric purity.

To give you an idea of the importance of this emerging technology, the worldwide market for chiral drugs is approaching $200 billion per year; 80% of small-molecule drugs approved currently by the FDA are chiral (see also Table 25-1 for top-selling chiral drugs); and the Nobel prize in chemistry 2001 was given to three researchers who made ground-breaking discoveries in the field of enantioselective catalysis.*

*Dr. William S. Knowles (b. 1917), Monsanto Company, St. Louis, Missouri; Professor Ryoji Noyori (b. 1938), Nagoya University, Japan; Professor K. Barry Sharpless (b. 1941), The Scripps Research Institute, La Jolla, California.

attachment of chlorine to the left side of C3 in the drawing gives \((2S,3S)\)-2-bromo-3-chlorobutane, whereas attachment to the right side gives its \(2S,3R\) diastereomer.
The chlorination at C2 results in a 1:1 mixture of enantiomers. Does the reaction at C3 also give an equimolar mixture of diastereomers? The answer is no. This finding is readily explained on inspection of the two transition states leading to the product (Figure 5-14). Abstraction of either one of the hydrogens results in a radical center at C3. In contrast with the radical formed in the chlorination at C2, however, the two faces of this radical are not mirror images of each other, because the radical retains the asymmetry of the original molecule as a result of the presence of the stereocenter at C2. Thus, the two sides of the p orbital are not equivalent.

What are the consequences of this nonequivalency? If the rate of attack at the two faces of the radical differ, as one would predict on steric grounds, then the rates of formation of the two diastereomers should be different, as is indeed found: (2S,3R)-2-Bromo-3-chlorobutane is preferred over the 2S,3S isomer by a factor of 3 (see Figure 5-14). The two transition states leading to products are not mirror images of each other and are not superimposable: They are diastereomeric. They therefore have different energies and represent different pathways.

**The chlorination of racemic 2-bromobutane gives racemates**

In the preceding discussion, we have used the enantiomerically pure starting material (S)-2-bromobutane to illustrate the stereochemical consequences of further halogenation. This choice was arbitrary with respect to absolute configuration; we might have equally well picked the R enantiomer. The result will be the same, except that all optically active products, namely, those of chlorination at C1, C3, and C4, will exhibit the opposite configurations to...
In this chapter, we have seen that many of the organic molecules in nature are chiral. More important, most natural compounds in living organisms not only are chiral, but also are present in only one enantiomeric form. An example of an entire class of such compounds consists of the amino acids, which are the component units of polypeptides. The large polypeptides in nature are called proteins or, when they catalyze biotransformations, enzymes.

Absolute Configuration of Natural Amino Acids and Polypeptides

Being made up of smaller chiral pieces, enzymes arrange themselves into bigger conglomerates that also are chiral and show handedness. Thus, much as a right hand will readily distinguish another right hand from a left hand, enzymes (and other biomolecules) have “pockets” that, by virtue of their stereochemically defined features, are capable of recognizing and processing only one of the enantiomers in a racemate. The differences in physiological activity of the two enantiomers of a chiral drug are based on this recognition (Chemical Highlight 5-4). A good analogy is that of a chiral key fitting only its image (not mirror image) lock. The chiral environment provided by these structures is also able to effect highly enantioselective conversions of achiral starting materials into enantiopure, chiral products. In this way, how nature preserves and proliferates its own built-in chirality can be readily understood (at least in principle).

What is more difficult to understand is how the enantiomeric homogeneity of nature arose in the first place; in other words, why was only one stereochemical configuration of the amino acids chosen but not the other? Trying to understand this mystery has fascinated many scientists, because it is very likely linked to the evolution of life as we know it. Speculation ranges from the invocation of a chance separation of enantiomers (“spontaneous resolution”) to the postulate of the operation of a chiral physical force, such as handed radiation (as observed during the decay of radioactive elements or in so-called circularly polarized light). Another hypothesis suggests that enantiomeric excess (and perhaps life itself) was simply imported from another planet, with meteorites as carriers (thus really begging the question). A lot of effort has been expended in trying to detect non-racemic amino acids in meteor (and other planetary) samples, so far without success.
Exercise 5-25

Working with the Concepts: Writing All the Products of the Halogenation of a Chiral Compound

Formulate all the products of the monobromination of (R)-1-bromo-1-deuterioethane A (see also Exercise 5-15), and specify whether they are chiral and optically active or not optically active. Remember that D is an isotope of H and will react qualitatively in the same way.

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{Br} \\
\text{H} & \quad \text{D} \\
\text{R} & \quad \text{Br} \\
\text{A} & \\
& \quad \text{Br}_2, \text{hv} \\
\end{align*}
\]

**Strategy**
Let’s first list the possible sites for attack on A by Br·. They are the H on C1, the D on C1, and the three methyl hydrogens of C2. Now we can inspect the outcome of each abstraction and see how the ensuing radical forms product.

**Solution**
- **Attack at H of C1**

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{Br} \\
\text{H} & \quad \text{D} \\
\text{R} & \quad \text{Br} \\
\text{A} & \\
& \quad \text{Br}_2, \text{hv} \\
\end{align*}
\]

This process generates an achiral radical; that fact alone ensures that the product would be at least racemic, hence not optically active. However, in the case of bromination, this point is irrelevant because the product has lost its stereocenter anyway, since C1 now has two bromine atoms.

- **Attack at D of C1**

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{Br} \\
\text{H} & \quad \text{D} \\
\text{R} & \quad \text{Br} \\
\text{A} & \\
& \quad \text{Br}_2, \text{hv} \\
\end{align*}
\]

The situation here is similar: An achiral radical is produced, but its lack of stereochemistry is irrelevant because the product 1,1-dibromoethane is achiral.

- **Attack at H of C2**

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{Br} \\
\text{H} & \quad \text{D} \\
\text{R} & \quad \text{Br} \\
\text{A} & \quad \text{Br}_2, \text{hv} \\
\end{align*}
\]

Attack at C2 leaves the stereocenter untouched. Thus, the intermediate radical is chiral and so is the product 1,2-dibromo-1-deuterioethane (R), which is therefore optically active.

Exercise 5-26

Try It Yourself

Write the structures of the products of monobromination of (S)-2-bromopentane at each carbon atom. Name the products and specify whether they are chiral or achiral, whether they will be formed in equal or unequal amounts, and which will be in optically active form.
those shown: (2S)-2-bromo-1-chlorobutane, (2R,3R)- and (2R,3S)-2-bromo-3-chlorobutane (in a 1:3 ratio), and (3R)-3-bromo-1-chlorobutane, respectively. Attack at C2 will again provide a racemate, because the stereochemistry is lost at the stereocenter during the process. What about carrying out this reaction with racemic 2-bromobutane?

Recalling the rule that states that “optically inactive starting materials furnish optically inactive products,” we expect racemates for all products. Thus, attack at C1, C2, or C4 will result in racemic 2-bromo-1-chlorobutane, 2-bromo-2-chlorobutane, and 3-bromo-1-chlorobutane, respectively. Importantly, attack at C3 will still give two compounds, even though racemic, namely, the 2S,3S/2R,3R (25%) and 2S,3R/2R,3S diastereomers (75%) of 2-bromo-3-chlorobutane.

What are the conventions of writing chemical equations when racemates are involved? Unless specifically indicated by the R/S notation, the sign of optical rotation, or some surrounding text, it is assumed that all ingredients in a reaction are racemic. To avoid the clutter of writing both enantiomers in such cases, only one is shown, the equimolar presence of the other being tacitly assumed. The chlorination of racemic 2-bromobutane at C3 is then written as follows:

\[ \begin{align*}
\text{Br} & \quad \text{or} \quad \text{Br} \\
\text{H} & \\
\text{Cl}_{2}, \text{hv} & \\
\text{Br} & \quad \text{H} \\
\text{Cl} & \quad \text{H}
\end{align*} \]

or

\[ \begin{align*}
\text{Br} & \quad \text{or} \quad \text{Br} \\
\text{H} & \\
\text{Cl}_{2}, \text{hv} & \\
\text{Br} & \quad \text{H} \\
\text{Cl} & \quad \text{H}
\end{align*} \]

or

\[ \begin{align*}
\text{Br} & \quad \text{or} \quad \text{Br} \\
\text{H} & \\
\text{Cl}_{2}, \text{hv} & \\
\text{Br} & \quad \text{H} \\
\text{Cl} & \quad \text{H}
\end{align*} \]

Exercise 5-27

Write the products of the monochlorination of bromocyclohexane at C2. (Caution: Is the starting material chiral?)

Stereoselectivity is the preference for one stereoisomer

A reaction that leads to the predominant (or exclusive) formation of one of several possible stereoisomeric products is stereoselective. For example, the chlorination of (S)-2-bromobutane at C3 is stereoselective, as a result of the chirality of the radical intermediate. The corresponding chlorination at C2, however, is not stereoselective: The intermediate is achiral and a racemate is formed.

How much stereoselectivity is possible? The answer depends very much on substrate, reagents, the particular reaction in question, and conditions. In the laboratory, chemists use enantiomerically pure reagents or catalysts to convert achiral compounds into one enantiomer of product (enantioselectivity; see Chemical Highlight 5-4). In nature, enzymes perform this job (see Chemical Highlight 5-5). In all cases, it is the handedness of that reagent, catalyst, or enzyme that is responsible for introducing the stereocenter compatible with their own chirality. An example from nature is the enzyme-catalyzed oxidation of dopamine to (−)-norepinephrine, discussed in detail in Problem 65 at the end of the chapter. The chiral reaction environment created by the enzyme gives rise to 100% stereoselectivity in favor of the enantiomer shown. The situation is very similar to shaping flexible achiral objects with your hands. For example, clasping a piece of modeling clay with your left hand furnishes a shape that is the mirror image of that made with your right hand.

In Summary Chemical reactions, as exemplified by radical halogenation, can be stereoselective or not. Starting from achiral materials, such as butane, a racemic (nonstereoselective) product is formed by halogenation at C2. The two hydrogens at the methylene carbons of
butane are equally susceptible to substitution, the halogenation step in the mechanism of radical bromination proceeding through an achiral intermediate and two enantiomeric transition states of equal energy. Similarly, starting from chiral and enantiomerically pure 2-bromobutane, chlorination of the stereocenter also gives a racemic product. However, stereoselectivity is possible in the formation of a new stereocenter, because the chiral environment retained by the molecule results in two unequal modes of attack on the intermediate radical. The two transition states have a diastereomeric relation, a condition that leads to the formation of products at unequal rates.

**5-8 Resolution: Separation of Enantiomers**

As we know, the generation of a chiral structure from an achiral starting material furnishes a racemic mixture. How, then, can pure enantiomers of a chiral compound be obtained?

One possible approach is to start with the racemate and separate one enantiomer from the other. This process is called the **resolution** of enantiomers. Some enantiomers, such as those of tartaric acid, crystallize into mirror-image shapes, which can be manually separated (as done by Pasteur; see Chemical Highlight 5-3). However, this process is time consuming, not economical for anything but minute-scale separations, and applicable only in rare cases.

A better strategy for resolution is based on the different physical properties of diastereomers. Suppose we can find a reaction that converts a racemate into a mixture of diastereomers. All the R forms of the original enantiomer mixture should then be separable from the corresponding S forms by fractional crystallization, distillation, or chromatography of the diastereomers. How can such a process be developed? The trick is to add an enantiomerically pure reagent that will attach itself to the components of the racemic mixture. For example, we can imagine reaction of a racemate, \(X_R + X_S\) (in which \(X_R\) and \(X_S\) are the two enantiomers), with an optically pure compound \(Y_S\) (the choice of the S configuration is arbitrary; the pure R mirror image would work just as well). The reaction produces two optically active diastereomers, \(X_R Y_S\) and \(X_S Y_S\), separable by standard techniques (Figure 5-15). Now the bond

**Figure 5-15** Flowchart for the separation (resolution) of two enantiomers. The procedure is based on conversion into separable diastereomers by means of reaction with an optically pure reagent.
between X and Y in each of the separated and purified diastereomers is broken, liberating $X_R$ and $X_S$ in their enantiomerically pure states. In addition, the optically active agent $Y_S$ may be recovered and reused in further resolutions.

What we need, then, is a readily available, enantiomerically pure compound, Y, that can be attached to the molecule to be resolved in an easily reversible chemical reaction. In fact, nature has provided us with a large number of pure optically active molecules that can be used. An example is (+)-2,3-dihydroxybutanedioic acid [(+)-tartaric acid]. A popular reaction employed in the resolution of enantiomers is salt formation between acids and bases. For example, (+)-tartaric acid functions as an effective resolving agent of racemic amines. Figure 5-16 shows how this works for 3-butyn-2-amine. The racemate is first treated with (+)-tartaric acid to form two diastereomeric tartrate salts. The salt incorporating the $R$-amine crystallizes on standing and can be filtered away from the solution, which contains the more soluble salt of the $S$-amine. Treatment of the (+)-salt with aqueous base liberates the free amine, (+)-(R)-3-butyn-2-amine. Similar treatment of the solution gives the (−)-S enantiomer (evidently slightly less pure: Note the slightly lower optical rotation). This process is just one of many ways in which the formation of diastereomers can be used in the resolution of racemates.

A very convenient way of separating enantiomers without the necessity of isolating diastereomers is by so-called chiral chromatography (Figure 5-17). The principle is the same as that illustrated in Figure 5-16, except that the optically active auxiliary [such as (+)-tartaric acid or any other suitable cheap optically active compound] is immobilized on a solid support (such as silica gel, SiO$_2$, or aluminum oxide, Al$_2$O$_3$). This material is then used to fill a column, and a solution of the racemate is allowed to pass through it. The individual enantiomers will reversibly bind to the chiral support to different extents (because this interaction is diastereomeric) and therefore be held on the column for different lengths of time (retention time). Therefore, one enantiomer will elute from the column before the other, enabling separation.
THE BIG PICTURE

The end of this chapter marks a milestone in your learning of organic chemistry. From here on, we will add very few fundamentally new ideas to our understanding of molecular structure. Rather, we will build on the basic principles outlined so far. You may find it useful to refer back to Chapters 1–5 as often as needed as a reminder of the several complementary viewpoints from which we have examined molecular structure:

1. Molecules consist of nuclei surrounded by electrons. The rules that govern their interactions are Coulomb’s law, Lewis structures, and orbitals (Chapter 1).

2. The hydrocarbon skeletons of organic molecules, as exemplified by the alkanes, can be modeled as chains of linked carbon atoms that rotate, flip, have spatial requirements, and can be distorted away from ideal bond angles (Chapters 2 and 4).

3. The diversity of structures in organic chemistry is due to the ability of carbon atoms to assemble chains in linear, branched, cyclic, or polycyclic forms, all of which can bear multiple substituents and functional groups. Because of carbon’s tetrahedral bonding, organic molecules assume a variety of three-dimensional shapes, with variations that have important consequences in their physical properties and reactivity.

4. When tetrahedral carbon bears four different substituents, it constitutes a stereocenter, giving rise to enantiomers — image and nonsuperimposable mirror image. Two or more such stereocenters generate new stereoisomers, differing only in the spatial arrangement of their component groups.

5. Organic molecules can be attacked by external reagents. Attack often occurs at nuclei attached to the remainder of the molecule by relatively weak bonds, or at polar functions, and is subject to steric and electronic constraints.
Most of the rest of this book examines in turn the classes of organic compounds characterized by their functional group. We focus primarily on the reactions these compounds undergo, emphasizing how the mechanism of each reaction is affected by the details of molecular structure. There are only a limited number of different reaction mechanisms; understanding them and the conditions that favor one over the other is the key to understanding organic chemistry.

CHAPTER INTEGRATION PROBLEMS

5-28. Selectivity in chemical reactions is a primary goal of the synthetic chemist. We have learned how such selectivity may be achieved, at least to some extent, in radical halogenations: in Sections 3-6 and 3-7, with respect to the type of hydrogen to be replaced (e.g., primary versus secondary versus tertiary) and, in Section 5-7, with respect to stereochemistry. You will have recognized that, because of the reactivity of radicals and the planarity of the carbon-centered radical intermediates, radical halogenations often lack selectivity. Thus, any synthetic plan considering them must take into account all possible outcomes of a proposed conversion. For example, looking again at our picture of the generalized steroid nucleus (Section 4-7), you can see that there are many types of hydrogens, all of which are, in principle, susceptible to abstraction by a halogen atom.

Because the steroids are important biological molecules, their selective functionalization has been the focus of attention for many researchers. By developing carefully controlled conditions with special halogenating agents, chemists have been able to restrict attack not only to the tertiary centers, but also selectively to C5, C9, or C14 (see also Problems 48–50 in Chapter 4). The following problem illustrates the kind of analyses that they undertook with a less complex cyclohexane fragment of the steroid nucleus.

How many products are there of the radical monobromination of (S)-1-bromo-2,2-dimethylcyclohexane at C1 and C3? Draw the structure of the starting material, name the resulting dibromodimethylcyclohexanes, label them as chiral or achiral, specify whether they are formed in equal or unequal amounts, and state whether they are optically active or not.

SOLUTION

We begin by drawing the structure of our starting material, first ignoring stereochemistry (A).

We then designate the priority sequence (B) according to the rules in Section 5-3. We now have a choice of two enantiomeric arrangements (C and D), and the task is to orient the molecule in our minds in such a way as to place the substituent of lowest priority (H atom) as far away as possible. To assist in this mental exercise, picture yourself at the molecular scale (shrunk by a factor of 10¹⁰) and stand on the stereocenter in question with the C–H bond pointing away from you. The three remaining substituents will now surround you either in clockwise (R) or counterclockwise (S) fashion: D is the correct structure of the S enantiomer.

In order to avoid the complication of carbon atoms changing their numbers during the reactions of molecule A, we have used names that do not conform to IUPAC numbering rules for several of the structures in this problem.
Now we are ready to introduce bromine at either C1 or C3. It is important here to remember
the mechanism of free-radical halogenation: The crucial intermediate is a radical center — in our

\[
\text{E} \quad \text{sp}^2 \quad \text{sp}^2 \quad \text{Br} \quad \text{Br} \\
\text{F} \quad \text{Br} \quad \text{H} \quad \text{sp}^2 \quad \text{Br} \\
\text{G} \quad \text{Br} \quad \text{Br} \quad \text{H} \quad \\n\text{H} \quad \text{Mirror plane} \\
\text{I} \quad \text{H} \quad \text{H} \\
\]

In E, the molecule is symmetrical, and the rate of attack from the top is equal to that from the bot-

tom. If the halogenation were to be executed by using F₂ or Cl₂, C₁ would remain a stereocenter, the
\( R \) and \( S \) enantiomers having been formed in equal amounts (racemate; Section 5-7, Figure 5-13).

However, in our case, bromination at C₁ removes the asymmetry of this carbon: Compound G,
1,1-dibromo-2,2-dimethylcyclohexane, is achiral and hence not optically active.

Turning to F, the situation is different. Here, the presence of the unchanged original stereo-

center (C₁ in D) makes the two faces of the intermediate radical center unequal. Two diastereomers
(H and I) are formed at unequal rates and therefore in unequal amounts (Section 5-7, Figure 5-14).

In H, cis-1,3-dibromo-2,2-dimethylcyclohexane, the second bromine is attached in such a way as
to introduce a mirror plane into the molecule: H is a meso compound, achiral, and hence not
optically active (Section 5-6). Another way of describing what has happened is that the chirality of
C₁ in D — namely, \( S \) — is canceled out by the introduction of its “mirror image” at C₃ — namely, \( R \).

The two stereoisomers are indistinguishable because (1\( S \),3\( R \))-H is the same as (1\( R \),3\( S \))-H. (You
can verify that statement by simply rotating compound H about the dashed line representing the
mirror plane.)

On the other hand, compound I, (1\( S \),3\( S \))-1,3-dibromo-2,2-dimethylcyclohexane, contains no mir-
ror plane: The molecule is chiral, enantiomerically pure, and, hence, optically active. In other words,
the reaction leaves the stereochemical integrity and identity of C₁ intact, generating only one enan-
tiomer of the product, which is nonsuperimposable with its mirror image, the (1\( R \),3\( R \)) diastereomer
(Section 5-5).

5-29. We shall learn in Section 11-5 and 12-2 that double bonds in alkenes can be hydrogenated by
using hydrogen gas and specific metal catalysts (Section 3-3), leading to the corresponding alkanes:

\[
\text{H—H} + \text{C= C} \quad \text{and} \quad \text{C= C} + \text{H—H} \quad \text{Catalyst} \quad \text{H—C—H} \quad \text{and} \quad \text{H—C—H} \\
\]

The two enantiomers of limonene (shown in the margin) smell quite differently. The \( S \)-isomer
is present in the cones of spruce trees and has a turpentine-like odor; the \( R \)-isomer gives oranges
their characteristic fragrance. \( R \)-Limonene is a by-product of the juice industry and is the major
constituent of citrus peel oil. Every year, more than 110 million pounds of the oil are made in the
United States alone. Draw the respective products of the hydrogenation of both double bonds in
(R)- and (S)-limonene. Are these products isomers, identical, chiral, achiral, or optically active/inactive?

SOLUTION
First draw the respective products of double hydrogenation of (R)- and (S)-limonene. As indicated
above, the two hydrogens can be added from either the top or the bottom of the \( \pi \) bond (see Fig-
ure 1-21). This is of no consequence for hydrogenation of the substituent but is important for the
outcome of the ring hydrogenation: One mode leads to a trans, the other to a cis disubstituted cyclo-
hexane. Thus, we obtain two stereoisomers from each enantiomer. How do the respective pairs of
products from the (R) and (S) starting materials relate to each other? It is apparent that the two trans
and the two cis isomers are superimposable: They are identical. In other words, the two enantiomers
of limonene give an identical mixture of stereoisomers. Are they chiral? The answer is no: The resulting
1,4-disubstituted cyclohexanes contain a mirror plane. Consequently, hydrogenation of limonene causes symmetrization of the molecule, rendering it achiral. Therefore, the products are optically inactive.

![Chemical Structures](image)

**Important Concepts**

1. Isomers have the same molecular formula but are different compounds. Constitutional (structural) isomers differ in the order in which the individual atoms are connected. Stereoisomers have the same connectivity but differ in the three-dimensional arrangement of the atoms. **Mirror-image stereoisomers** are related to each other as object and mirror image.

2. An object that is not superimposable on its mirror image is **chiral**.

3. A carbon atom bearing four different substituents (asymmetric carbon) is an example of a **stereocenter**.

4. Two stereoisomers that are related to each other as image–nonsuperimposable mirror image are called **enantiomers**.

5. A compound containing one stereocenter is chiral and exists as a pair of enantiomers. A 1:1 mixture of enantiomers is a **racemate (racemic mixture)**.

6. Chiral molecules cannot have a plane of symmetry (mirror plane). If a molecule has a **mirror plane**, then it is achiral.

7. **Diastereomers** are stereoisomers that are not related to each other as object to mirror image. Cis and trans isomers of cyclic compounds are examples of diastereomers.

8. Two stereocenters in a molecule result in as many as four stereoisomers—two diastereomerically related pairs of enantiomers. The maximum number of stereoisomers that a compound with \( n \) stereocenters can have is \( 2^n \). This number is reduced when equivalently substituted stereocenters give rise to a plane of symmetry. A molecule containing stereocenters and a mirror plane is identical with its mirror image (achiral) and is called a **meso compound**. The presence of a mirror plane in any energetically accessible conformation of a molecule is sufficient to make it achiral.

9. Most of the physical properties of enantiomers are the same. A major exception is their interaction with **plane-polarized light**: One enantiomer will rotate the polarization plane clockwise (dextrorotatory), the other counterclockwise (levorotatory). This phenomenon is called **optical activity**. The extent of the rotation is measured in degrees and is expressed by the **specific rotation**, \([\alpha]\). Racemates and meso compounds show zero rotation. The **enantiomer excess** or **optical purity** of an unequal mixture of enantiomers is given by

\[
\text{enantiomer excess (ee)} = \text{optical purity} = \left(\frac{[\alpha]_{\text{observed}}}{[\alpha]}\right) \times 100\%
\]

10. The “handedness” of a stereocenter (its absolute configuration) is revealed by X-ray diffraction and can be assigned as **R** or **S** by using the **sequence rules** of Cahn, Ingold, and Prelog.
11. **Fischer projections** provide stencils for the quick drawing of molecules with stereocenters.

12. Chirality can be introduced into an achiral compound by radical halogenation. When the transition states are enantiomeric (related as object and mirror image), the result is a racemate because the faces of the planar radical react at equal rates.

13. Radical halogenation of a chiral molecule containing one stereocenter will give a racemate if the reaction takes place at the stereocenter. When reaction elsewhere leads to two diastereomers, they will be formed in unequal amounts.

14. The preference for the formation of one stereoisomer, when several are possible, is called **stereoselectivity**.

15. The separation of enantiomers is called **resolution**. It is achieved by the reaction of the racemate with the pure enantiomer of a chiral compound to yield separable diastereomers. Chemical removal of the chiral reagent frees both enantiomers of the original racemate. Another way of separating enantiomers is by **chiral chromatography** on an optically active support.

**Problems**

30. Classify each of the following common objects as being either chiral or achiral. Assume in each case that the object is in its simplest form, without decoration or printed labels. (a) A ladder; (b) a door; (c) an electric fan; (d) a refrigerator; (e) Earth; (f) a baseball; (g) a baseball bat; (h) a baseball glove; (i) a flat sheet of paper; (j) a fork; (k) a spoon; (l) a knife.

31. Each part of this problem lists two objects or sets of objects. As precisely as you can, describe the relation between the two sets, using the terminology of this chapter; that is, specify whether they are identical, enantiomeric, or diastereomeric. (a) An American toy car compared with a British toy car (same color and design but steering wheels on opposite sides); (b) two left shoes compared with two right shoes (same color, size, and style); (c) a pair of skates compared with two left skates (same color, size, and style); (d) a right glove on top of a left glove (palm to palm) compared with a left glove on top of a right glove (palm to palm; same color, size, and style).

32. For each pair of the following molecules, indicate whether its members are identical, structural isomers, conformers, or stereoisomers. How would you describe the relation between conformations when they are maintained at a temperature too low to permit them to interconvert?

33. Which of the following compounds are chiral? (Hint: Look for stereocenters.)

(a) 2-Methylheptane  
(b) 3-Methylheptane  
(c) 4-Methylheptane  
(d) 1,1-Dibromopropane  
(e) 1,2-Dibromopropane  
(f) 1,3-Dibromopropane  
(g) Ethene, \( \text{H}_2\text{C}≡\text{CH}_2 \)  
(h) Ethyne, \( \text{HC}≡\text{CH} \)
(i) Benzene, \( \text{C}_6\text{H}_6 \) (Note: Like ethene, benzene contains all \( sp^2 \)-hybridized carbons and is therefore planar.)

(j) Epinephrine, \( \text{HO-CHCH}_2\text{NHCH}_3\text{HO} \)

(k) Vanillin, \( \text{HO-CH}_3\text{O} \)

(l) Citric acid, \( \text{HOCH}_3\text{CCH}_3\text{COH} \)

(m) Ascorbic acid, \( \text{HOCH}_2\text{HOCH}_2\text{HO} \)

(n) \( p \)-Mentane-1,8-diol (terpin hydrate),

(o) Meperidine (demerol),

34. Each of the following molecules has the molecular formula \( \text{C}_5\text{H}_{12}\text{O} \) (check for yourself). Which ones are chiral?

(a) \( \text{OH} \)
(b) \( \text{OH} \)
(c) \( \text{OH} \)
(d) \( \text{OH} \)

35. Draw either one of the enantiomers for each chiral molecule in Problem 34 and label its stereocenter as \( R \) or \( S \).

36. Which of the following cyclohexane derivatives are chiral? For the purpose of determining the chirality of a cyclic compound, the ring may generally be treated as if it were planar.

(a) \( \text{CH}_3 \)
(b) \( \text{CH}_3 \)
(c) \( \text{CH}_3 \)
(d) \( \text{CH}_3 \)

37. Label every stereocenter in the molecules in Problem 36 as \( R \) or \( S \).

38. Circle each chiral molecule. Put a star (*) next to each chiral carbon and label it as \( R \) or \( S \).
39. For each pair of structures shown, indicate whether the two species are constitutional isomers, enantiomers, diastereomers of one another, or identical molecules.

(a) \( \text{CH}_3\text{Cl} \) and \( \text{CH}_3\text{Cl} \)

(b) \( \text{CH}_3\text{F} \) and \( \text{CH}_3\text{F} \)

(c) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

(d) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

(e) \( \text{CH}_3\text{F} \) and \( \text{CH}_3\text{F} \)

(f) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

(g) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

(h) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

(i) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

(j) \( \text{CH}_3\text{H} \) and \( \text{CH}_3\text{H} \)

40. For each of the following formulas, identify every structural isomer containing one or more stereocenters, give the number of stereoisomers for each, and draw and fully name at least one of the stereoisomers in each case.

(a) \( \text{C}_7\text{H}_{16} \)

(b) \( \text{C}_8\text{H}_{18} \)

(c) \( \text{C}_5\text{H}_{10} \), with one ring

41. Assign the appropriate designation of configuration (R or S) to the stereocenter in each of the following enantiomers. (Hint: Regarding cyclic structures containing stereocenters, treat the ring as if it were two separate substituents that happen to be attached to each other at the far end of the molecule—look for the first point of difference, just as you would for acyclic structures.)

(a) \( \text{H}_3\text{C} \) and \( \text{H}_3\text{C} \)

(b) \( \text{H}_3\text{O} \) and \( \text{H}_3\text{O} \)

(c) \( \text{Cl}_3\text{H}_2 \) and \( \text{Cl}_3\text{H}_2 \)

(d) \( \text{F}_3\text{OH} \) and \( \text{F}_3\text{OH} \)

(e) \( \text{O}_3\text{H} \) and \( \text{O}_3\text{H} \)

(f) \( \text{O}_3\text{H} \) and \( \text{O}_3\text{H} \)

(g) \( \text{O}_3\text{H} \) and \( \text{O}_3\text{H} \)

(h) \( \text{O}_3\text{H} \) and \( \text{O}_3\text{H} \)

(i) \( \text{H}_3\text{C} \) and \( \text{H}_3\text{C} \)

(j) \( \text{O}_3\text{H} \) and \( \text{O}_3\text{H} \)
42. Mark the stereocenters in each of the chiral molecules in Problem 33. Draw any single stereoisomer of each of these molecules, and assign the appropriate designation (R or S) to each stereocenter.

43. The two enantiomers of carvone [systematic name: 2-methyl-5-(1-methylethenyl)-2-cyclohexenone; Chemical Highlight 5-1] are drawn in the margin. Which is R and which is S?

44. Draw structural representations of each of the following molecules. Be sure that your structure clearly shows the configuration at the stereocenter. (Hint: You may find it useful to first draw the enantiomer whose configuration is easiest for you to determine and then, if necessary, modify your structure to fit the one requested in the problem.) (a) (R)-2-chloropentane; (b) (S)-2-methyl-3-bromohexane; (c) (S)-1,3-dichlorobutane; (d) (R)-2-chloro-1,1,1-trifluoro-3-methylbutane.

45. Draw structural representations of each of the following molecules. Be sure that your structure clearly shows the configuration at each stereocenter. (a) (R)-3-bromo-3-methylhexane; (b) (3R,5S)-3,5-dimethylpentane; (c) (2R,3S)-2-bromo-3-methylpentane; (d) (S)-1,1,2-trimethylcyclopropane; (e) (1S,2S)-1-chloro-1-trifluoromethyl-2-methylcyclobutane; (f) (1R,2R,3S)-1,2-dichloro-3-ethylcyclohexane.

46. Draw and name all possible stereoisomers of \((\text{CH}_3)_2\text{CHCHBrCHClCH}_3\).

47. **CHALLENGE** For each of the following questions, assume that all measurements are made in 10-cm polarimeter sample containers. (a) A 10-mL solution of 0.4 g of optically active 2-butanol in water displays an optical rotation of \(-0.56^\circ\). What is its specific rotation? (b) The specific rotation of sucrose (common sugar) is +66.4. What would be the observed optical rotation of such a solution containing 3 g of sucrose? (c) A solution of pure (S)-2-bromobutane in ethanol is found to have an observed \(\alpha = 57.3^\circ\). If \([\alpha]_D^{25} = 23.1\), what is the concentration of the solution?

48. Natural epinephrine, \([\alpha]_D^{25} = -50\), is used medicinally. Its enantiomer is medically worthless and is, in fact, toxic. You, a pharmacist, are given a solution said to contain 1 g of epinephrine in 20 mL of liquid, but the optical purity is not specified. You place it in a polarimeter (10-cm tube) and get a reading of \(-2.5^\circ\). What is the optical purity of the sample? Is it safe to use medicinally?

49. Sodium hydrogen [(S)-monosodium glutamate], \([\alpha]_D^{25} = +24\), is the active flavor enhancer known as MSG. The condensed formula of MSG is shown in the margin. (a) Draw the structure of the S enantiomer of MSG. (b) If a commercial sample of MSG were found to have a \([\alpha]_D^{25} = +8\), what would be its optical purity? What would be the percentages of the S and R enantiomers in the mixture? (c) Answer the same questions for a sample with \([\alpha]_D^{25} = +16\).

50. The molecule in the margin is menthol, with the stereochemistry omitted. (a) Identify all stereocenters in menthol. (b) How many stereoisomers exist for the menthol structure? (c) Draw all the stereoisomers of menthol, and identify all pairs of enantiomers.

51. **CHALLENGE** Natural (−)-menthol, the essential oil primarily responsible for the flavor and aroma of peppermint, is the \(1R,2S,5R\)-stereoisomer. (a) Identify (−)-menthol from the structures you drew for Problem 50, part (b). (b) Another of the naturally occurring diastereomers of menthol is (+)-isomenthol, the \(1S,2R,5R\)-stereoisomer. Identify (+)-isomenthol among your structures. (c) A third is (+)-neomenthol, the \(1S,2S,5R\)-compound. Find (+)-neomenthol among your structures. (d) Based on your understanding of the conformations of substituted cyclohexanes (Section 4-4), what is the stability order (from most stable to least) for the three diastereomers, menthol, isomenthol, and neomenthol?

52. Of the stereoisomers described in the two problems above, (−)-menthol ([\(\alpha\])_D = −51) and (+)-neomenthol ([\(\alpha\])_D = +21) are the major constituents in mentha oil, their main natural source. The menthol–neomenthol mixture in a natural sample of mentha oil exhibits [\(\alpha\])_D = −33. What are the percentages of menthol and neomenthol in this oil?

53. For each of the following pairs of structures, indicate whether the two compounds are identical or enantiomers of each other.

(a) \(\text{CH}_3\text{CH}_2\text{Br} / \text{CH}_2\text{Cl}_2\)

(b) \(\text{CH}_3\text{Cl} / \text{HBr}\)

(c) \(\text{ClCH}_3 / \text{CF}_3\text{CH}_3\)

(d) \(\text{H}_2\text{NCH}_2\text{CO}_2\text{H} / \text{CH}_3\text{CO}_2\text{H}\)
54. Determine the \(R\) or \(S\) designation for each stereocenter in the structures in Problem 53.

55. The compound pictured in the margin is a sugar called \((-\)-arabinose. Its specific rotation is \(-105\).  
   \(\textbf{(a)}\) Draw the enantiomer of \((-\)-arabinose.  \(\textbf{(b)}\) Does \((-\)-arabinose have any other enantiomers?  
   \(\textbf{(c)}\) Draw a diastereomer of \((-\)-arabinose.  \(\textbf{(d)}\) Does \((-\)-arabinose have any other diastereomers?  
   \(\textbf{(e)}\) If possible, predict the specific rotation of the structure that you drew for \(\textbf{(a)}\).  \(\textbf{(f)}\) If possible, predict the specific rotation of the structure that you drew for \(\textbf{(c)}\).  \(\textbf{(g)}\) Does \((-\)-arabinose have any optically inactive diastereomers? If it does, draw one.

56. Write the complete IUPAC name of the following enantiomer (do not forget stereochemical designations).

\[
\begin{align*}
\text{CH}_2\text{CH}_3 & \quad \text{Cl} \\
\text{CH}_2\text{Cl} & \quad \text{C}_6\text{H}_{10}\text{Cl}_2
\end{align*}
\]

Reaction of this compound with 1 mol of \(\text{Cl}_2\) in the presence of light produces several isomers of the formula \(\text{C}_6\text{H}_9\text{Cl}_3\). For each part of this problem, give the following information: How many stereoisomers are formed? If more than one is formed, are they generated in equal or unequal amounts? Designate every stereocenter in each stereoisomer as \(R\) or \(S\).  
\(\textbf{(a)}\) Chlorination at \(C_3\)  \(\textbf{(b)}\) Chlorination at \(C_4\)  \(\textbf{(c)}\) Chlorination at \(C_5\)

57. Mono-chlorination of methylcyclopentane can result in several products. Give the same information as that requested in Problem 56 for the mono-chlorination of methylcyclopentane at \(C_1\), \(C_2\), and \(C_3\).

58. Draw all possible products of the chlorination of \((S)-2\)-bromo-1,1-dimethylcyclobutane. Specify whether they are chiral or achiral, whether they are formed in equal or unequal amounts, and which are optically active when formed.

59. Illustrate how to resolve racemic 1-phenylethanolamine (shown in the margin), using the method of reversible conversion into diastereomers.

60. Draw a flowchart that diagrams a method for the resolution of racemic 2-hydroxypropanoic acid (lactic acid, Table 5-1), using \((S)-1\)-phenylethanolamine.

61. How many different stereoisomeric products are formed in the monobromination of \(\textbf{(a)}\) racemic \(\text{trans}\)-1,2-dimethylcyclohexane and \(\textbf{(b)}\) pure \((R,R)\)-1,2-dimethylcyclohexane? \(\textbf{(c)}\) For your answers to \(\textbf{(a)}\) and \(\textbf{(b)}\), indicate whether you expect equal or unequal amounts of the various products to be formed. Indicate to what extent products can be separated on the basis of having different physical properties (e.g., solubility, boiling point).

62. Make a model of \(\text{cis}\)-1,2-dimethylcyclohexane in its most stable conformation. If the molecule were rigidly locked into this conformation, would it be chiral? (Test your answer by making a model of the mirror image and checking for superimposability.)

   Flip the ring of the model. What is the stereoisomeric relation between the original conformation and the conformation after flipping the ring? How do the results that you have obtained in this problem relate to your answer to Problem 36(a).

63. Morphinane is the parent substance of the broad class of chiral molecules known as the morphine alkaloids. Interestingly, the \((+\) and \((-\) enantiomers of the compounds in this family have rather different physiological properties. The \((-\) compounds, such as morphine, are “narcotic analgesics” (painkillers), whereas the \((+\) compounds are “antitussives” (ingredients in cough syrup). Dextromethorphan is one of the simplest and most common of the latter.
(a) Locate and identify all the stereocenters in dextromethorphan. (b) Draw the enantiomer of dextromethorphan. (c) As best you can (it is not easy), assign R and S configurations to all the stereocenters in dextromethorphan.

64. We will learn in Chapter 18 that hydrogens on the carbon atom adjacent to the carbonyl functional group (C=O) are acidic. The compound (S)-3-methyl-2-pentanone, loses its optical activity when it is dissolved in a solution containing a catalytic amount of base. Explain.

\[
\text{(S)-3-Methyl-2-pentanone}
\]

65. The enzymatic introduction of a functional group into a biologically important molecule is not only specific with regard to the location at which the reaction occurs in the molecule (see Chapter 4, Problem 50), but also usually specific in the stereochemistry obtained. The biosynthesis of epinephrine first requires that a hydroxy group be introduced specifically to produce (2)-norepinephrine from the achiral substrate dopamine. (The completion of the synthesis of epinephrine will be presented in Problem 71 of Chapter 9.) Only the (2) enantiomer is functional in the appropriate physiological manner, so the synthesis must be highly stereoselective.

\[
\text{Dopamine} \quad \xrightarrow{\text{Dopamine } \beta\text{-monoxygenase, } \text{O}_2} \quad \text{(-)-Norepinephrine}
\]

(a) Is the configuration of (2)-norepinephrine R or S? (b) In the absence of an enzyme, would the transition states of a radical oxidation leading to (2)- and (+)-norepinephrine be of equal or unequal energy? What term describes the relation between these transition states? (c) In your own words, describe how the enzyme must affect the energy of these transition states to favor production of the (2) enantiomer. Does the enzyme have to be chiral or can it be achiral?

Team Problem

66. Studies have shown that one stereoisomeric form of compound A is an effective agent against certain types of neurodegenerative disorders. Recognize that structure A contains a decalin-type system, as illustrated in structure B, and that the nitrogen can be treated just like a carbon.

\[
\text{A} \quad \text{B}
\]

(a) Use your model kits to analyze the ring juncture. Make models of the cis as well as the trans ring juncture of structure B. You should have four different models. Identify the stereochemical relation between them as diastereomeric or enantiomeric. Draw the isomers and assign the R or S configuration to the stereocenters at the ring fusion. (b) Although the trans ring juncture is the energetically more favorable one, the compound with cis ring juncture is the stereoisomer of structure A that shows biological activity. Make models of structure A that have the cis ring juncture exclusively. Set the stereochemistry of C3 as shown in structure A and vary the center at C6 in relation to that at C3. Again, there are four different models. Draw them and convince yourselves that none of them are enantiomers by assigning the R or S configuration to all four of the stereocenters in each of the compounds. (c) The stereoisomer of compound A that shows the greatest biological activity has a cis ring fusion with substituents at C3 and C6 that are both equatorial. Which of the stereoisomers that you drew encompasses these constraints? Identify it by recording the absolute configuration at C3, C4a, C6, and C8a.
Preprofessional Problems

67. Which compound will not exhibit optical activity? (Note that these are all Fischer projections.)

(a) \[
\begin{array}{c}
\text{H} \\
\text{Cl}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{H} \\
\text{OH}
\end{array}
\]

(c) \[
\begin{array}{c}
\text{H} \\
\text{OH}
\end{array}
\]

(d) \[
\begin{array}{c}
\text{Cl} \\
\text{H}
\end{array}
\]

68. The enantiomer of

\[
\begin{array}{c}
\text{Cl} \\
\text{H} \\
\text{CH}_3
\end{array}
\]

(a) is \(\text{CH}_3\text{CH}_2\text{C}^R\text{H} \text{CH}_3\) (b) can exist only at low temperatures

(c) is nonisomeric (d) is incapable of existence

69. The molecule that is of the \(R\) configuration according to the Cahn–Ingold–Prelog convention is (remember these are Fischer projections):

(a) \[
\begin{array}{c}
\text{H} \\
\text{CH}_3
\end{array}
\]

(b) \[
\begin{array}{c}
\text{H} \\
\text{Cl}
\end{array}
\]

(c) \[
\begin{array}{c}
\text{CH}_3 \\
\text{Br}
\end{array}
\]

(d) \[
\begin{array}{c}
\text{H} \\
\text{CH}_2\text{F}
\end{array}
\]

(e) \[
\begin{array}{c}
\text{H} \\
\text{CH}_3
\end{array}
\]

70. Which compound is not a meso compound?

(a) \[
\begin{array}{c}
\text{Cl} \\
\text{Cl}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{Cl} \\
\text{CH}_3
\end{array}
\]

(c) \[
\begin{array}{c}
\text{Cl} \\
\text{Cl}
\end{array}

\text{CH}_3
\end{array}
\]

(e) \[
\begin{array}{c}
\text{Cl} \\
\text{Br}
\end{array}
\]
**Properties and Reactions of Haloalkanes**

Organic chemistry provides us with innumerable ways to convert one substance into another. The products of these transformations are literally all around us. Recall from Chapter 2, however, that functional groups are the centers of reactivity in organic molecules; before we can make practical use of organic chemistry, we must develop our ability to work with these functional groups. In Chapter 3 we examined halogenation of alkanes, a process by which the carbon–halogen group is introduced into an initially unfunctionalized structure. Where do we go from here?

In this chapter we turn to the chemistry of the products of halogenation, the haloalkanes. We shall see how the polarized carbon–halogen bond governs the reactivity of these substances and how it can be converted into other functional groups. On the basis of the kinetics observed for a common reaction of haloalkanes, we introduce a new mechanism and learn the effects of different solvents on its progress. We shall review principles that govern the general mechanistic behavior of molecules with polar functional groups. Finally, we shall begin to apply these principles and see the role they play in many conversions of halogenated organic compounds into other substances, such as amino acids—the building blocks of proteins.

---

A haloalkane

---

6-1 Physical Properties of Haloalkanes

The physical properties of the haloalkanes are quite distinct from those of the corresponding alkanes. To understand these differences, we must consider the size of the halogen substituent and the polarity of the carbon–halogen bond. Let us see how these factors affect bond strength, bond length, molecular polarity, and boiling point.

**The bond strength of C–X decreases as the size of X increases**

The C–X bond-dissociation energies in the halomethanes, CH₃X, decrease along the series F, Cl, Br, I. At the same time, the C–X bond lengths increase (Table 6-1). The bond between carbon and halogen is made up mainly by the overlapping of an sp³ hybrid orbital on carbon
Properties and Reactions of Haloalkanes

with a \( p \) orbital on the halogen (Figure 6-1). In the progression from fluorine to iodine in the periodic table, the size of the halogen increases, and the electron cloud around the halogen atom becomes more diffuse. As a consequence of this growing mismatch in size between the halogen \( p \) orbital and the relatively compact orbital on carbon, bonding overlap diminishes along the series, leading to both longer and weaker C–X bonds. This phenomenon is general: Short bonds are stronger than longer bonds.

The C–X bond is polarized

The leading characteristic of the haloalkanes is their polar C–X bond. Recall from Section 1-3 that halogens are more electronegative than carbon. Thus, the electron density along the C–X bond is displaced in the direction of X, giving the halogen a partial negative charge (\( \delta^- \)) and the carbon a partial positive charge (\( \delta^+ \)). This polarization can be seen in the electrostatic potential map of chloromethane shown in the margin. The chlorine atom is electron rich (red), whereas the region around the carbon atom is electron poor (blue). How does this bond polarization govern the chemical behavior of the haloalkanes? As we saw in Chapter 2, the electrophilic \( \delta^+ \) carbon atom is subject to attack by anions and other electron-rich, nucleophilic species. Cations and other electron-deficient species, however, attack the \( \delta^- \) halogen.

Haloalkanes have higher boiling points than the corresponding alkanes

The polarity of the C–X bond affects the physical properties of the haloalkanes in predictable ways. Their boiling points are generally higher than those of the corresponding alkanes (Table 6-2). The most important contributor to this effect is coulombic attraction between the \( \delta^+ \) and \( \delta^- \) ends of C–X bond dipoles in the liquid state (dipole–dipole interaction; Figure 2-6).

Boiling points also rise with increasing size of X, the result of greater London interactions (Section 2-6). Recall that London forces arise from mutual correlation of electrons among molecules (Figure 2-6). This effect is strongest when the outer electrons are not held very tightly around the nucleus, as in the larger atoms. To measure it, we define the polarizability of an atom or group as the degree to which its electron cloud is deformed under the influence of an external electric field. The more polarizable an atom or group, the more effectively will it enter into London interactions, and the higher will be the boiling point.

CHEMICAL HIGHLIGHT 6-1

Halogenated Steroids as Anti-Inflammatory and Anti-Asthmatic Agents

Cortisol (also known as hydrocortisone) is a member of the class of naturally occurring compounds called corticosteroids, so-named because they are secreted by the cortex of the adrenal gland. The corticosteroids are anti-inflammatory agents with numerous medicinal applications. In recent years it has become clear that inflammation of the breathing passages is a contributing factor to the bronchoconstriction associated with attacks of asthma. Thus, oral administration of corticosteroids together with inhalation of bronchodilators has been an effective course of treatment. However, ingestion of steroids exposes patients to potential side effects. Unlike the steroids used for illicitly enhancing athletic performance (Chapter 4 Opening), corticosteroids administered at high doses can inhibit growth, a side effect that is of particular concern with children. As a result, synthetic corticosteroids have been developed that are suitable for use via inhalation and are not absorbed systemically to a significant extent.

One such synthetic steroid is pictured above: fluticasone propionate. The presence of haloalkane functionality has a marked effect on anti-inflammatory potency. Fluticasone is one of a growing number of synthetic pharmaceuticals in which replacement of hydrogen by fluorine either generates novel therapeutic behavior or enhances properties already present. As the smallest element in the second row of the periodic table, fluorine is closest in size to hydrogen. Therefore, fluorine-containing molecules are sterically similar to their natural unsubstituted counterparts and can often interact with the same biomolecules in living systems. In addition, the highly polarized C–F bonds can induce dipole attractions that strengthen these interactions. In the case of fluticasone, the steroid binds to a protein residing in cell nuclei called the glucocorticoid receptor, thereby interrupting the body’s inflammatory response.

An international study published in early 2004 found that fluticasone was effective in reducing asthma-inducing inflammation in babies from one to three years of age, while having no significant effect on their growth. Nevertheless, the biochemistry of the glucocorticoid receptor is complex — it does much more than just mediate inflammation — and the search continues for new synthetics whose interaction with the receptor will be more specific and will not interfere with the receptor’s other, essential biological functions. Furthermore, synthetic corticosteroids are medically useful for a number of other conditions, including inflammatory bowel disease and transplant rejection, for which oral administration is preferable. Thus, the design of variants that will prove to be safe for use in this way is an active area of current research as well.

Applications and Hazards of Haloalkanes: “Greener” Alternatives

The properties of haloalkanes have made this class of compounds a rich source of commercially useful substances. For example, fully halogenated liquid bromomethanes, such as CBrF₃ and CBrClF₂ (“Halons”), are extremely effective fire retardants. Heat-induced cleavage of the weak C–Br bond releases bromine atoms, which suppress combustion by inhibiting the free-radical chain reactions occurring in flames (see Chapter 3, Problem 40). Like Freon refrigerants, however, bromomethanes are ozone depleting (Section 3-9) and have been banned for all uses except fire-suppression systems in aircraft engines. Phosphorus tribromide, PBr₃, a non-ozone-depleting liquid with a high weight percent of bromine, is a promising replacement. In 2006, a PBr₃-based fire-suppression cartridge system (under the trade name PhostrEx™) was approved by both the U.S. Environmental Protection Agency (EPA) and the U.S. Federal Aviation Administration (FAA). It is now in commercial use in the Eclipse 500 jet aircraft.

The polarity of the carbon–halogen bond makes haloalkanes useful for applications such as dry cleaning of clothing and degreasing of mechanical and electronic components. Alternatives
for these purposes include fluorinated solvents such as 1,1,1,2,2,3,4,5,5,5-decafluoropentane (CF₃CF₂CHFCHFCF₃), a DuPont™ product that does not decompose to release ozone-destroying halogen atoms because the C–F bond is strong. This solvent is safe, stable, usable for a wide variety of industrial functions, and may be readily recovered and recycled. Problem 50 introduces yet another class of “green” solvents — ionic liquids — that are revolutionizing industrial chemistry.

In Summary

The halogen orbitals become increasingly diffuse along the series F, Cl, Br, I. Hence, (1) the C–X bond strength decreases; (2) the C–X bond becomes longer; (3) for the same R, the boiling points increase; (4) the polarizability of X becomes greater; and (5) London interactions increase. We shall see next that these interrelated effects also play an important role in the reactions of haloalkanes.

6-2 Nucleophilic Substitution

Haloalkanes contain an electrophilic carbon atom, which may react with nucleophiles — substances that contain an unshared electron pair. The nucleophile can be an anion, such as hydroxide (\(\text{OH}^–\)), or a neutral species, such as ammonia (\(\text{NH}_3\)). In this process, which we call nucleophilic substitution, the reagent attacks the haloalkane and replaces the halide. A great many species are transformed in this way, particularly in solution. The reaction occurs widely in nature and can be controlled effectively even on an industrial scale. Let us see how it works in detail.

Nucleophiles attack electrophilic centers

The nucleophilic substitution of a haloalkane is described by either of two general equations. Recall (Section 2-2) that the curved arrows denote electron-pair movement.

In the first example, a negatively charged nucleophile reacts with a haloalkane to yield a neutral substitution product. In the second example, an uncharged Nu produces a positively charged product, which, together with the counterion, constitutes a salt. In both cases, the group displaced is the halide ion, \(\text{X}^–\), which is called the leaving group. We shall see later that there are leaving groups other than \(\text{X}^–\). Specific examples of these two types of nucleophilic substitution are shown in Table 6-3. As will be the case in many equations and mechanisms that follow, nucleophiles, electrophiles, and leaving groups are shown here in red, blue, and green, respectively. The general term substrate (\(\text{substratus}\), Latin, to have been subjected) is applied to the organic starting material — in this case, the haloalkane — that is the target of attack by a nucleophile.

Nucleophilic substitution exhibits considerable diversity

Nucleophilic substitution changes the functional group in a molecule. A great many nucleophiles are available to participate in this process; therefore, a wide variety of new molecules are accessible through substitution. Note that Table 6-3 depicts only primary and secondary halides. In Chapter 7 we shall see that tertiary substrates behave differently toward these...
nucleophiles and that secondary halides may sometimes give other products as well. Methyl and primary haloalkanes give the "cleanest" substitutions, relatively free of side products.

Let us inspect these transformations in greater detail. In reaction 1, a hydroxide ion, typically derived from sodium or potassium hydroxide, displaces chloride from chloromethane to give methanol. This substitution is a general synthetic method for converting a methyl or primary haloalkane into an alcohol.

A variation of this transformation is reaction 2. Methoxide ion reacts with iodoethane to give methoxyethane, an example of the synthesis of an ether (Section 9-6).

In reactions 1 and 2, the species attacking the haloalkane is an anionic oxygen nucleophile. Reaction 3 shows that a halide ion may function not only as a leaving group, but also as a nucleophile.

Reaction 4 depicts a carbon nucleophile, cyanide (often supplied as sodium cyanide, Na$^-$CN), and leads to the formation of a new carbon–carbon bond, an important means of modifying molecular structure.

**Note:** Remember that nucleophiles are red, electrophiles are blue, and leaving groups are green. Anionic nucleophiles give neutral products (Reactions 1–5). Neutral nucleophiles give salts as products (Reactions 6 and 7).
Chapter 6

Properties and Reactions of Haloalkanes

Reaction 5 shows the sulfur analog of reaction 2, demonstrating that nucleophiles in the same column of the periodic table react similarly to give analogous products. This conclusion is also borne out by reactions 6 and 7. However, the nucleophiles in these two reactions are neutral, and the expulsion of the negatively charged leaving group results in a cationic species, an ammonium or phosphonium salt, respectively.

All of the nucleophiles shown in Table 6-3 are quite reactive, but not all for the same reasons. Some are reactive because they are strongly basic (HO₂⁻, CH₃O₂⁻). Others are weak bases (I⁻) whose nucleophilicity derives from other characteristics. Notice that, in each example, the leaving group is a halide ion. Halides are unusual in that they may serve as leaving groups as well as nucleophiles (therefore making reaction 3 reversible). However, the same is not true of some of the other nucleophiles in Table 6-3 (in particular, the strong bases); the equilibria of their reactions lie strongly in the direction shown. These topics are addressed in Sections 6-7 and 6-8, as are factors that affect the reversibility of displacement reactions. First, however, we shall examine the mechanism of nucleophilic substitution.

Exercise 6-1

What are the substitution products of the reaction of 1-bromobutane with (a) I⁻; (b) CH₃CH₂O⁻; (c) N₃⁻; (d) As(CH₃)₃; (e) (CH₃)₂Se⁻?

Exercise 6-2

Working with the Concepts: Planning a Synthesis

Suggest starting materials for the preparation (synthesis) of CH₃CH₂SCH₃.

Strategy

The question does not specify a method for preparing this molecule, but it makes sense to use our newest reaction, nucleophilic substitution. A powerful method for designing synthetic preparations involves working backward from the structure of the target molecule and is called retrosynthetic analysis. We demonstrate the idea here and will return to it in Section 8-9. Begin by rephrasing the question as “What substances must react by nucleophilic substitution to give the desired product?” Write the structure in full, so as to see clearly all the bonds it contains, and identify one that might be formed in the course of nucleophilic substitution.

Solution

• Example 5 from Table 6-3 gives us a model for a reaction that forms a sulfur compound with two C–S bonds. Proceed in the same way, even though the problem does not tell us which halide leaving group to displace by the sulfur nucleophile. We may choose any one that will work, namely, chloride, bromide, or iodide:

```
Delete C–S bond
H₂C⁻S⁻CH₂⁻CH₃ \rightleftharpoons H₂C⁻S⁻ \quad \text{Br}⁻-CH₂⁻CH₃
```

Attach any suitable halide leaving group

• We finish by writing the preparation in the forward direction, the way we would actually carry it out:

```
CH₃S⁻⁻ + CH₃CH₂Br⁻ \rightarrow CH₃SCH₂CH₃ + Br⁻⁻
```

• Notice that we could have just as easily conducted our reverse analysis by deleting the bond between the sulfur and the methyl carbon, rather than the ethyl. That would give us a second, equally correct method of preparation:

```
CH₄⁺⁻ + S⁻⁻CH₂⁺⁻ \rightarrow CH₃SCH₂CH₃ + I⁻⁻
```

As before, the choice of halide leaving group is immaterial.
In Summary  Nucleophilic substitution is a fairly general reaction for primary and secondary haloalkanes. The halide functions as the leaving group, and several types of nucleophilic atoms enter into the process.

6-3 Reaction Mechanisms Involving Polar Functional Groups: Using “Electron-Pushing” Arrows

In our consideration in Chapter 3 of radical halogenation, we found that a knowledge of its mechanism was helpful in explaining the experimental characteristics of the process. The same is true for nucleophilic substitution and, indeed, virtually every chemical process that we encounter. Nucleophilic substitution is an example of a polar reaction: It includes charged species and polarized bonds. Recall (Chapter 2) that an understanding of electrostatics is essential if we are to comprehend how such processes take place. Opposite charges attract—nucleophiles are attracted to electrophiles—and this principle provides us with a basis for understanding the mechanisms of polar organic reactions. In this section, we expand the concept of electron flow and review the conventional methods for illustrating polar reaction mechanisms by moving electrons from electron-rich to electron-poor sites.

Curved arrows depict the movement of electrons

As we learned in Section 2-2, acid-base processes require electron movement. Let us briefly reexamine the Brønsted-Lowry process in which the acid HCl donates a proton to a molecule of water in aqueous solution:

**Depiction of a Brønsted-Lowry Acid-Base Reaction by Using Curved Arrows**

\[
\text{H—O—H} + \text{H—Cl} \rightarrow \text{H—O—H}^+ + \text{Cl}^- 
\]

This electron pair becomes shared

This electron pair is completely displaced

Notice that the arrow starting at the lone pair on oxygen and ending at the hydrogen of HCl does not imply that the lone electron pair departs from oxygen completely; it just becomes a shared pair between that oxygen atom and the atom to which the arrow points. In contrast, however, the arrow beginning at the H—Cl bond and pointing toward the chlorine atom does signify heterolytic cleavage of the bond; that electron pair becomes separated from hydrogen and ends up entirely on the chloride ion.

Exercise 6-4

Use curved arrows to depict the flow of electrons in each of the following acid-base reactions.
(a) Hydrogen ion + hydroxide ion; (b) fluoride ion + boron trifluoride, BF₃; (c) ammonia + hydrogen chloride; (d) hydrogen sulfide, H₂S, + sodium methoxide, NaOCH₃; (e) dimethyloxonium ion, (CH₃)₂OH⁺, + water; (f) the self-ionization of water to give hydronium ion and hydroxide ion.
Properties and Reactions of Haloalkanes

Curved “electron-pushing” arrows are the means by which we describe mechanisms in organic chemistry. We have already noted the close parallels between acid-base reactions and reactions between organic electrophiles and nucleophiles (Section 2-2). Curved arrows show how nucleophilic substitution occurs when a lone pair of electrons on a nucleophile is transformed into a new bond with an electrophilic carbon, “pushing” a bonding pair of electrons away from that carbon onto a leaving group. However, nucleophilic substitution is just one of many kinds of processes for which electron-pushing arrows are used to depict the mechanisms of electrophile–nucleophile interactions. Several additional examples based on the reaction types introduced in Chapter 2 are shown here.

**Curved-Arrow Representations of Several Common Types of Mechanisms**

```
\[ \text{H}^+ + \text{C} = \text{O} \rightarrow \text{H}^+ \text{C} = \text{O} \quad \text{Electrophilic addition} \]
```

```
\[ \text{H}^+ \text{C} = \text{O} + \text{H}^+ \rightarrow \text{H}_2\text{O} \quad \text{H}^+ \text{C} = \text{O} \quad \text{Carbon–carbon double bond acting as a Lewis base} \]
```

```
\[ \text{C} = \text{O} + \text{C} \rightarrow \text{C} = \text{C} \quad \text{Dissociation} \]
```

```
\[ \text{H}^+ \text{O}^- + \text{C} = \text{O} \rightarrow \text{H}^+ \text{C} = \text{O} \quad \text{Nucleophilic addition} \]
```

```
\[ \text{H}^- \text{O}^- + \text{C} = \text{O} \rightarrow \text{C} = \text{O}^- \quad \text{Nucleophilic substitution} \]
```

In every case the curved arrows start from either a lone electron pair on an atom or the center of a bond. Curved arrows never start at electron-deficient atoms, such as H\(^+\) (last equation): The movement of a proton is depicted by an arrow pointing *from an electron source* (lone pair or bond) *toward the proton*. Although this may seem counterintuitive at first, it is a very important aspect of the curved-arrow formalism. Curved arrows represent movement of electrons, not atoms.

The first and third examples illustrate a characteristic property of electron movement: If an electron pair moves toward an atom, that atom must have a “place to put that electron pair,” so to speak. In nucleophilic substitution, the carbon atom in a haloalkane has a filled outer shell; another electron pair cannot be added without displacement of the electron pair bonding carbon to halogen. The two electron pairs can be viewed as “flowing” in a synchronous manner: As one pair arrives at the closed-shell atom, the other departs, thereby preventing violation of the octet rule at carbon. When you depict electron movement with curved arrows, *it is absolutely essential to keep in mind the rules for drawing Lewis structures*. Correct use of electron-pushing arrows helps in drawing such structures, because all electrons are moved to their proper destinations.

There are other types of processes, but, surprisingly, *not that many*. One of the most powerful consequences of studying organic chemistry from a mechanistic point of view is the way in which this approach highlights similarities between types of polar reactions even if the specific atoms and bonds are not the same.

**Exercise 6-5**

Identify the electrophilic and nucleophilic sites in the four mechanisms shown earlier as curved-arrow representations.

**Exercise 6-6**

Write out in detail the equations for the reactions in Exercise 6-2, using curved arrows to denote the movement of electron pairs.
In Summary

Curved arrows depict movement of electron pairs in reaction mechanisms. Electrons move from nucleophilic, or Lewis basic, atoms toward electrophilic, or Lewis acidic, sites. If a pair of electrons approaches an atom already containing a closed shell, a pair of electrons must depart from that atom so as not to exceed the maximum capacity of its valence orbitals.

6-4 A Closer Look at the Nucleophilic Substitution Mechanism: Kinetics

Many questions can be raised at this stage. What are the kinetics of nucleophilic substitution, and how does this information help us determine the underlying mechanism? What happens with optically active haloalkanes? Can we predict relative rates of substitution? These questions will be addressed in the remainder of this chapter.

When a mixture of chloromethane and sodium hydroxide in water is heated (denoted by the uppercase Greek letter \(\Delta\), at the right of the arrow in the equation in the margin), a high yield of two compounds — methanol and sodium chloride — is the result. This outcome, however, does not tell us anything about how starting materials are converted into products. What experimental methods are available for answering this question?

One of the most powerful techniques employed by chemists is the measurement of the kinetics of the reaction (Section 2-1). By comparing the rate of product formation beginning with several different concentrations of the starting materials, we can establish the rate equation, or rate law, for a chemical process. Let us see what this experiment tells us about the reaction of chloromethane with sodium hydroxide.

The reaction of chloromethane with sodium hydroxide is bimolecular

We can monitor rates by measuring either the disappearance of one of the reactants or the appearance of one of the products. When we apply this method to the reaction of chloromethane with sodium hydroxide, we find that the rate depends on the initial concentrations of both of the reagents. For example, doubling the concentration of hydroxide doubles the rate at which the reaction proceeds. Likewise, at a fixed hydroxide concentration, doubling the concentration of chloromethane has the same effect. Doubling the concentrations of both increases the rate by a factor of 4. These results are consistent with a second-order process (Section 2-1), which is governed by the following rate equation:

\[
\text{Rate} = k[\text{CH}_3\text{Cl}][\text{HO}^-] \text{ mol L}^{-1} \text{ s}^{-1}
\]

All the examples given in Table 6-3 exhibit such second-order kinetics: Their rates are directly proportional to the concentrations of both substrate and nucleophile.
Properties and Reactions of Haloalkanes

Exercise 6-9

Working with the Concepts: Concentrations and Rates

When a solution containing 0.01 M sodium azide (Na\(^{+}\)N\(_3\)\(^{-}\)) and 0.01 M iodomethane in methanol at 0°C is monitored kinetically, the results reveal that iodide ion is produced at a rate of \(3.0 \times 10^{-10}\) mol L\(^{-1}\) s\(^{-1}\). Write the formula of the organic product of this reaction and calculate its rate constant \(k\). What would be the rate of appearance of I\(^{-}\) for an initial concentration of reactants of [Na\(_3\)N] = 0.02 M and [CH\(_3\)I] = 0.01 M?

**Strategy**

Write the formula describing the reaction by finding a closely analogous example in Table 6-3. Then determine \(k\) by solving the rate equation using the given information.

**Solution**

- Example 1 from Table 6-3 is the model. The nucleophile is azide rather than hydroxide, and the substrate is iodomethane rather than chloromethane. Thus,
  \[
  \text{CH}_3\text{I} + \text{Na}^{+}\text{N}_3^{-} \rightarrow \text{CH}_3\text{N}_3 + \text{Na}^{+}\text{I}^{-}
  \]

- The rate of appearance of I\(^{-}\) is the same as the rate of appearance of the organic product and the rate of disappearance of both starting materials. Solve the equation for \(k\):
  \[
  3.0 \times 10^{-10} \text{ mol L}^{-1} \text{ s}^{-1} = k(10^{-2} \text{ mol L}^{-1})(10^{-2} \text{ mol L}^{-1})
  \]
  \[
  k = 3.0 \times 10^{-6} \text{ L mol}^{-1} \text{ s}^{-1}
  \]

- Now use \(k\) to solve for the new rate given the changed set of initial concentrations.
  \[
  \text{New rate} = (3.0 \times 10^{-6} \text{ L mol}^{-1} \text{ s}^{-1})(2 \times 10^{-2} \text{ mol L}^{-1})(10^{-2} \text{ mol L}^{-1})
  \]
  \[
  = 6.0 \times 10^{-10} \text{ mol L}^{-1} \text{ s}^{-1}
  \]

(Hint: As a shortcut in problems like this, simply multiply the original rate by the factor by which any concentration has changed. Caution: Consider only changes in concentration of substances that appear in the rate equation.)

Exercise 6-10

Try It Yourself

What is the rate of appearance of I\(^{-}\) in the reaction in Exercise 6-9 for the following initial concentrations of reactants? (a) [Na\(_3\)N] = 0.03 M and [CH\(_3\)I] = 0.01 M; (b) [Na\(_3\)N] = 0.02 M and [CH\(_3\)I] = 0.02 M; (c) [Na\(_3\)N] = 0.03 M and [CH\(_3\)I] = 0.03 M.

What kind of mechanism is consistent with a second-order rate law? The simplest is one in which the two reactants interact in a single step. We call such a process bimolecular, and the general term applied to substitution reactions of this type is bimolecular nucleophilic substitution, abbreviated as S\(_N2\) (S stands for substitution, N for nucleophilic, and 2 for bimolecular).

Bimolecular nucleophilic substitution is a concerted, one-step process

Bimolecular nucleophilic substitution is a one-step transformation: The nucleophile attacks the haloalkane, with simultaneous expulsion of the leaving group. Bond making takes place at the same time as bond breaking. Because the two events occur “in concert,” we call this process a concerted reaction.

We can envisage two stereochemically distinct alternatives for such concerted displacements. The nucleophile could approach the substrate from the same side as the leaving
group, one group exchanging for the other. This pathway is called **frontside displacement** (Figure 6-2). As we shall see in the next section, it does not occur. The second possibility is a **backside displacement**, in which the nucleophile approaches carbon from the side opposite the leaving group (Figure 6-3). In both equations, an electron pair from the negatively charged hydroxide oxygen moves toward carbon, creating the C–O bond, while that of the C–Cl linkage shifts onto chlorine, thereby expelling the latter as $\text{Cl}^{-}$.

In either of the two respective transition states, the negative charge is distributed over both the oxygen and the chlorine atoms.

Note that the formation of the transition state is **not** a separate step; the transition state only describes the geometric arrangement of the reacting species as they pass through the **maximum energy point** of a single-step process (Section 2-1).

---

**Figure 6-2** Hypothetical frontside nucleophilic substitution (does not occur). The (hypothetical) transition state is enclosed in brackets and labeled with the ‡ symbol.

**Figure 6-3** Backside nucleophilic substitution. Attack is from the side opposite the leaving group. The concerted nature of bond making (to OH) and bond breaking (from Cl) is indicated by the dotted lines, which signify the partial bonding of both to carbon in the transition state.
Chapter 6
Properties and Reactions of Haloalkanes

In Summary
The reaction of chloromethane with hydroxide to give methanol and chloride, as well as the related transformations of a variety of nucleophiles with haloalkanes, are examples of the bimolecular process known as the $S_N2$ reaction. Two single-step mechanisms—frontside attack and backside attack—may be envisioned for the reaction. Both are concerted processes, consistent with the second-order kinetics obtained experimentally. Can we distinguish between the two? To answer this question, we return to a topic that we have considered in detail: stereochemistry.

6-5 Frontside or Backside Attack? Stereochemistry of the $S_N2$ Reaction

When we compare the structural drawings in Figures 6-2 and 6-3 with respect to the arrangement of their component atoms in space, we note immediately that in the first conversion the three hydrogens stay put and to the left of the carbon, whereas in the second they have “moved” to the right. In fact, the two methanol pictures are related as object and mirror image. In this example, the two are superimposable and therefore indistinguishable—properties of an achiral molecule. The situation is entirely different for a chiral haloalkane in which the electrophilic carbon is a stereocenter.

The $S_N2$ reaction is stereospecific

Consider the reaction of (S)-2-bromobutane with iodide ion. Frontside displacement should give rise to 2-iodobutane with the same (S) configuration as that of the substrate; backside displacement should furnish a product with the opposite configuration.

What is actually observed? It is found that (S)-2-bromobutane gives (R)-2-iodobutane on treatment with iodide: This and all other $S_N2$ reactions proceed with inversion of configuration. A process whose mechanism requires that each stereoisomer of the starting material transform into a specific stereoisomer of product is described as stereospecific. The $S_N2$ reaction is therefore stereospecific, proceeding by a backside displacement mechanism to give inversion of configuration at the site of the reaction.

In the three equations that follow, the progress of the reaction of (S)-2-bromobutane with iodide ion is shown using conventional drawings, molecular models, and electrostatic potential maps. You can see that in the transition state, the negative charge on the nucleophile has spread partly onto the leaving group. As the reaction comes to completion, the leaving group evolves to a fully charged anion. In the electrostatic potential map of the transition state, this process is reflected in the attenuated red color around the two halogen nuclei, compared with the full red visible in the starting and ending halide ions. Note that in the reaction schemes preceding the electrostatic potential renditions, we use the mechanistic color scheme of green for the leaving group, and not red. In other respects, the colors match, as you would expect.

Stereochemistry of the Backside Displacement Mechanism for $S_N2$ Reactions

![Stereochemistry Diagram]
The stereochemistry of displacement at a primary carbon is more difficult to observe directly, because a primary carbon atom is attached to two hydrogens in addition to the leaving group: it is not a stereocenter. This obstacle may be overcome by replacing one of the two hydrogen atoms by deuterium, the hydrogen isotope with mass \( \frac{2}{3} \). The result is a stereocenter at the primary carbon and a chiral molecule. This strategy has been employed to confirm that SN2 displacement at a primary carbon atom does indeed occur with inversion of configuration, as the example below illustrates.

**Stereochemistry of SN2 Displacement at a Primary Carbon Atom**

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{C}^-\text{Cl}^- + \text{NaN}_3, \text{CH}_3\text{OH}, \text{H}_2\text{O} \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{N}_3^- + \text{Cl}^-
\]

**S-1-Chloro-1-deuteriobutane**

(Chiral and optically active)

**R-1-Azido-1-deuteriobutane**

(Chiral and optically active; configuration inverted)

The nucleophile, azide ion \((\text{N}_3^-)\), gives rise to stereospecific backside displacement of chloride, giving the azidoalkane product with the inverted configuration at the chiral carbon.

**Exercise 6-12**

Write the products of the following SN2 reactions:

(a) \((R)-3\)-chloroheptane + Na\(^+\)SH

(b) \((S)-2\)-bromoocctane + N(CH\(_3\))\(_3\)

(c) \((3R,4R)-4\)-iodo-3-methyl octane + K\(^+\)SeCH\(_3\).

**Exercise 6-13**

Write the structures of the products of the SN2 reactions of cyanide ion with:

(a) meso-2,4-dibromopentane (double SN2 reaction);

(b) trans-1-iodo-4-methylcyclohexane.
The transition state of the $S_N2$ reaction can be described in an orbital picture

The transition state for the $S_N2$ reaction can be described in orbital terms, as shown in Figure 6-4. As the nucleophile approaches the back lobe of the $sp^3$ hybrid orbital used by carbon to bind the halogen atom, the rest of the molecule becomes planar at the transition state by changing the hybridization at carbon to $sp^2$. As the reaction proceeds to products, the inversion motion is completed and the carbon returns to the tetrahedral $sp^3$ configuration. A depiction of the course of the reaction using a potential energy–reaction coordinate diagram is shown in Figure 6-5.

6-6 Consequences of Inversion in $S_N2$ Reactions

What are the consequences of the inversion of stereochemistry in the $S_N2$ reaction? Because the reaction is stereospecific, we can design ways to use displacement reactions to synthesize a desired stereoisomer.
We can synthesize a specific enantiomer by using $\text{S}_\text{N}2$ reactions

Consider the conversion of 2-bromo-octane into 2-octanethiol in its reaction with hydrogen sulfide ion, $\text{HS}^-$.

If we were to start with optically pure $R$ bromide, we would obtain only $S$ thiol and none of its $R$ enantiomer.

![Inversion of Configuration of an Optically Pure Compound by $\text{S}_\text{N}2$ Reaction](image)

But what if we wanted to convert $(R)$-2-bromo-octane into the $R$ thiol? One technique uses a sequence of two $\text{S}_\text{N}2$ reactions, each resulting in inversion of configuration at the stereocenter. For example, an $\text{S}_\text{N}2$ reaction with iodide would first generate $(S)$-2-iodooctane. We would then use this haloalkane with an inverted configuration as the substrate in a second displacement, now with $\text{HS}^-$ ion, to furnish the $R$ thiol. This double inversion sequence of two $\text{S}_\text{N}2$ processes gives us the result we desire, a net retention of configuration.

![Using Double Inversion to Give Net Retention of Configuration](image)

**Exercise 6-14**

As we saw for carvone (Chapter 5, Problem 43), enantiomers can sometimes be distinguished by odor and flavor. 3-Octanol and some of its derivatives are examples: The dextrorotatory compounds are found in natural peppermint oil, whereas their $(−)$ counterparts contribute to the essence of lavender. Show how you would synthesize optically pure samples of each enantiomer of 3-octyl acetate, starting with $(S)$-3-iodooctane. (The conversion of acetates into alcohols will be shown in Section 8-5.)

![3-Octyl acetate](image)

**Exercise 6-15**

**Working with the Concepts: Stereochemical Consequences of $\text{S}_\text{N}2$ Displacement**

Treatment of $(S)$-2-iodooctane with NaI in solution causes the optical activity of the starting organic compound to disappear. Explain.

**Strategy**

If you write out the equation for this reaction, you will notice something unusual about it: This $\text{S}_\text{N}2$ reaction uses iodide as the nucleophile as well as the leaving group. Therefore, iodide displaces iodide. This is the key insight to approaching the problem.
Properties and Reactions of Haloalkanes

Solution
- The optical activity of (S)-2-iodooctane originates from the fact that it is chiral and a single enantiomer. Its structure appears in the text on the previous page. The stereocenter is C2, the carbon bearing the iodine atom. (S)-2-Iodoctane is a secondary haloalkane and, as we have seen in several examples in this chapter, it may undergo SN2 reaction, which proceeds by backside displacement and inversion at the site of reactivity.
- As noted earlier, I\(^{-}\) is both a good nucleophile and a good leaving group. Because it functions in both roles in this reaction, the transformation occurs rapidly. Each time displacement occurs, the stereocenter undergoes stereochemical inversion. Because the process is fast, it takes place multiple times for every substrate molecule, inverting the stereochemistry each time. Ultimately, this leads to an equilibrium (i.e., racemic) mixture of (R) and (S) stereoisomers of the starting (and ending) compound.

Exercise 6-16

Try It Yourself

Amino acids are the building blocks of peptides and proteins in nature. They may be prepared in the laboratory by SN2 displacement of the halogen in 2-halocarboxylic acids using ammonia as the nucleophile, as illustrated by the conversion of 2-bromopropanoic acid into alanine.

\[
\begin{align*}
\text{Br} & \quad \text{CH}_3\text{CHCOOH} \\
\text{2-Bromopropanoic acid} & \quad \text{NH}_3, \text{H}_2\text{O}, \quad 25^\circ\text{C}, \text{4 days} \\
& \quad \text{CH}_3\text{CHCOO}^- \quad \text{Alanine}
\end{align*}
\]

The stereocenter in alanine, like that in most naturally occurring amino acids, has the S configuration. Draw both a clear stereochemical structure for S-alanine and one for the enantiomer of 2-bromopropanoic acid that would be required to produce S-alanine according to the equation above.

In substrates bearing more than one stereocenter, inversion takes place only at the carbons that undergo reaction with the incoming nucleophile. Note that the reaction of (2S,4R)-2-bromo-4-chloropentane with excess cyanide ion results in a meso product. This outcome is particularly readily recognized using Fischer projections.
In these equations, ethanol and acetone, respectively, are the solvents for the indicated transformations. These solvents are polar (Section 1-3) and particularly good at dissolving salts. We shall come back to the influence of the nature of the solvent on the SN2 reaction in Section 6-8. In the second example, notice that the reaction taking place at C2 has no effect on the stereocenter at C3.

Exercise 6-17

As an aid in the prediction of stereochemistry, organic chemists often use the guideline that “diastereomers produce diastereomers.” Replace the starting compound in each of the two preceding examples with one of its diastereomers, and write the product of SN2 displacement with the nucleophile shown. Are the resulting structures in accord with this “rule”?  

Similarly, nucleophilic substitution of a substituted halocycloalkane may change the stereochemical relation between the substituents. For example, in the disubstituted cyclohexane below, the stereochemistry changes from cis to trans.

In Summary Inversion of configuration in the SN2 reaction has distinct stereochemical consequences. Optically active substrates give optically active products, unless the nucleophile and the leaving group are the same or meso compounds are formed. In cyclic systems, cis and trans stereochemical relations may be interconverted.

6-7 Structure and SN2 Reactivity: The Leaving Group

The relative facility of SN2 displacements depends on several factors, including the nature of the leaving group, the reactivity of the nucleophile (which is affected by the choice of reaction solvent), and the structure of the alkyl portion of the substrate. We employ kinetics as our tool to evaluate the degree to which changes in each of these structural features affect their function in the SN2 reaction. We begin by examining the leaving group. Subsequent sections will address the nucleophile and the substrate.

Leaving-group ability is a measure of the ease of its displacement

As a general rule, nucleophilic substitution occurs only when the group being displaced, X, is readily able to depart, taking with it the electron pair of the C–X bond. Are there structural features that might allow us to predict, at least qualitatively, whether a leaving group is “good” or “bad”? Not surprisingly, the relative rate at which it can be displaced, its leaving-group ability, can be correlated with its capacity to accommodate a negative charge. Remember that a certain amount of negative charge is transferred to the leaving group in the transition state of the reaction (Figure 6-4).

For the halogens, leaving-group ability increases along the series from fluorine to iodine. Thus, iodide is regarded as a “good” leaving group; fluoride, however, is so “poor” that SN2 reactions of fluoroalkanes are rarely observed.
Chapter 6  Properties and Reactions of Haloalkanes

Exercise 6-18

Predict the product of the reaction of 1-chloro-6-iodohexane with one equivalent of sodium methyl-selenide (Na\textsuperscript{+}SeCH\textsubscript{3}).

Halides are not the only groups that can be displaced by nucleophiles in S\textsubscript{N}2 reactions. Other examples of good leaving groups are sulfur derivatives of the type ROSO\textsubscript{3}\textsuperscript{2-} and RSO\textsubscript{3}\textsuperscript{2-}, such as methyl sulfate ion, CH\textsubscript{3}OSO\textsubscript{3}\textsuperscript{2-}, and various sulfonate ions. Alkyl sulfate and sulfonate leaving groups are used so often that trivial names, such as mesylate, triflate, and tosylate, have found their way into the chemical literature.

**Sulfate and Sulfonate Leaving Groups**

\[
\begin{align*}
\text{Methyl sulfate ion} & :O: \quad \text{CH}_3\text{O}^-\text{S}^-\text{O}^- \\
\text{Methanesulfonate ion (Mesylate ion)} & :O: \quad \text{CH}_3\text{S}^-\text{O}^-\text{S}^- \\
\text{Trifluoromethanesulfonate ion (Triflate ion)} & :O: \quad \text{CF}_3\text{S}^-\text{O}^-\text{S}^- \\
\text{4-Methylbenzenesulfonate ion (p-Toluenesulfonate ion, tosylate ion)} & :O: \quad \text{CH}_3\text{S}^-\text{O}^-\text{C}^-\text{H}_4
\end{align*}
\]

**Weak bases are good leaving groups**

Is there some characteristic property that distinguishes good leaving groups from poor ones? Yes: *Leaving-group ability is inversely related to base strength.* Weak bases are best able to accommodate negative charge and are the best leaving groups. Among the halides, iodide is the weakest base and therefore the best leaving group in the series. Sulfates and sulfonates are weak bases as well.

Is there a way to recognize weak bases readily? The weaker \(X^-\) as a base, the stronger is its conjugate acid HX. Therefore, *good leaving groups are the conjugate bases of strong acids.* This rule applies to the four halides: HF is the weakest of the conjugate acids, HCl is stronger, and HBr and HI are stronger still. Table 6-4 lists a number of acids, in order of descending strength, and their \(pK_a\) values. Their conjugate bases are listed alongside in order of increasing strength and, therefore, decreasing leaving group ability.

In Summary  The leaving-group ability of a substituent correlates with the strength of its conjugate acid. Both depend on the ability of the leaving group to accommodate negative charge. In addition to the halides Cl, Br, and I, sulfates and sulfonates (such as methane- and 4-methylbenzenesulfonates) are good leaving groups. Good leaving groups are weak bases, the conjugate bases of strong acids. We shall return in Section 9-4 to uses of sulfates and sulfonates as leaving groups in synthesis.

6-8 Structure and $S_N2$ Reactivity: The Nucleophile

Now that we have looked at the effect of the leaving group, let us turn to a consideration of nucleophiles. How can we predict their relative nucleophilic strength, their nucleophilicity? We shall see that nucleophilicity depends on a variety of factors: charge, basicity, solvent, polarizability, and the nature of substituents. To grasp the relative importance of these effects, let us analyze the outcome of a series of comparative experiments.

Increasing negative charge increases nucleophilicity

If the same nucleophilic atom is used, does charge play a role in the reactivity of a given nucleophile as determined by the rate of its $S_N2$ reaction? The following experiments answer this question.

Experiment 1

$$\text{CH}_3\text{Cl}^- + \text{H}_2\text{O}^- \rightarrow \text{CH}_3\text{OH}^- + \text{Cl}^- \quad \text{Fast}$$

$$\text{CH}_3\text{Cl}^- + \text{H}_2\text{O} \rightarrow \text{CH}_3\text{OH} + \text{Cl}^- \quad \text{Very slow}$$

Experiment 2

$$\text{CH}_3\text{Cl}^- + \text{H}_2\text{N}^- \rightarrow \text{CH}_3\text{NH}^- + \text{Cl}^- \quad \text{Very fast}$$

$$\text{CH}_3\text{Cl}^- + \text{H}_2\text{N} \rightarrow \text{CH}_3\text{NH}^+ + \text{Cl}^- \quad \text{Slower}$$

Conclusion. Of a pair of nucleophiles containing the same reactive atom, the species with a negative charge is the more powerful nucleophile. Or, of a base and its conjugate acid, the base is always more nucleophilic. This finding is intuitively very reasonable. Because nucleophilic attack is characterized by the formation of a bond with an electrophilic carbon center, the more negative the attacking species, the faster the reaction should be.

Exercise 6-19

Predict the relative acidities within each of the following groups. Review Section 2-2 if necessary. (a) H$_2$S, H$_2$Se; (b) PH$_3$, H$_2$S; (c) HClO$_3$, HClO$_2$; (d) HBr, H$_2$Se; (e) NH$_4^+$, H$_3$O$^+$. Within each of the groups, identify the conjugate bases and predict their relative leaving-group abilities.

Exercise 6-20

Predict the relative basicities within each of the following groups. (a) $\text{OH}^-$, $\text{SH}^-$; (b) $\text{PH}_2^-$, $\text{SH}^-$; (c) $\text{I}^-$, $\text{SeH}^-$; (d) HOSO$_2^-$, HOSO$_3^-$. Predict the relative acidities of the conjugate acids within each group.

In Summary  The leaving-group ability of a substituent correlates with the strength of its conjugate acid. Both depend on the ability of the leaving group to accommodate negative charge. In addition to the halides Cl, Br, and I, sulfates and sulfonates (such as methane- and 4-methylbenzenesulfonates) are good leaving groups. Good leaving groups are weak bases, the conjugate bases of strong acids. We shall return in Section 9-4 to uses of sulfates and sulfonates as leaving groups in synthesis.

Exercise 6-21

Predict which member in each of the following pairs is a better nucleophile. (a) HS$^-$ or H$_2$S; (b) CH$_3$SH or CH$_3$S$^-$; (c) CH$_3$NH$^-$ or CH$_3$NH$_2$; (d) HSe$^-$ or H$_2$Se.
Nucleophilicity decreases to the right in the periodic table

Experiments 1 and 2 compared pairs of nucleophiles containing the same nucleophilic element (e.g., oxygen in H₂O versus HO⁻ and nitrogen in H₃N versus H₂N⁻). What about nucleophiles of similar structure but with different nucleophilic atoms? Let us examine the elements along one row of the periodic table.

**Experiment 3**

\[ \text{CH}_3\text{CH}_2\text{Br}^- + \text{H}_3\text{N} \rightarrow \text{CH}_3\text{CH}_2\text{NH}_3^+ + \text{Br}^- \]  
Fast

\[ \text{CH}_3\text{CH}_2\text{Br}^- + \text{H}_2\text{O} \rightarrow \text{CH}_3\text{CH}_2\text{OH}_2^+ + \text{Br}^- \]  
Very slow

**Experiment 4**

\[ \text{CH}_3\text{CH}_2\text{Br}^- + \text{H}_2\text{N}^- \rightarrow \text{CH}_3\text{CH}_2\text{NH}_2^- + \text{Br}^- \]  
Very fast

\[ \text{CH}_3\text{CH}_2\text{Br}^- + \text{H}_2\text{O}^- \rightarrow \text{CH}_3\text{CH}_2\text{OH}_2^- + \text{Br}^- \]  
Slower

**Conclusion.** Nucleophilicity again appears to correlate with basicity: The more basic species is the more reactive nucleophile. Therefore, in the progression from the left to the right of the periodic table, nucleophilicity decreases. The approximate order of reactivity for nucleophiles in the first row is

- Increasing basicity:
  
  \[ \text{H}_2\text{N}^- > \text{HO}^- > \text{NH}_3 > \text{F}^- > \text{H}_2\text{O} \]

- Increasing nucleophilicity:

Observations using other nucleophiles demonstrate that the trends revealed in Experiments 1–4 are generally applicable to all of the nonmetallic elements (groups 15–17) of the periodic table. Increasing negative charge (Experiments 1 and 2) usually has a greater effect than moving one group to the left (Experiments 3 and 4). Thus, in the order of reactivity shown above, both HO⁻ and NH₃ are more nucleophilic than water, but HO⁻ is more nucleophilic than NH₃.

**Exercise 6-22**

In each of the following pairs of molecules, predict which is the more nucleophilic. (a) Cl⁻ or CH₃S⁻; (b) P(CH₃)₃ or S(CH₃)₂; (c) CH₃CH₂Se⁻ or Br⁻; (d) H₂O or HF.

**Should basicity and nucleophilicity be correlated?**

The parallels between nucleophilicity and basicity first described in Section 2-2 make sense: Strong bases typically make good nucleophiles. However, a fundamental difference between the two properties is based on how they are measured. Basicity is a thermodynamic property, measured by an equilibrium constant:

\[ \text{A}^- + \text{H}_2\text{O} \rightleftharpoons \text{AH} + \text{HO}^- \quad K = \text{equilibrium constant} \]

In contrast, nucleophilicity is a kinetic phenomenon, quantified by comparing rates of reactions:

\[ \text{Nu}^- + \text{R} \rightarrow \text{Nu}^-\text{R} + \text{X}^- \quad k = \text{rate constant} \]

Despite these inherent differences, we have observed good correlation between basicity and nucleophilicity in the cases of charged versus neutral nucleophiles along a row of the periodic
table. What happens if we look at nucleophiles in a column of the periodic table? We shall find that the situation changes, because now solvent plays a role.

**Solvation impedes nucleophilicity**

If it is a general rule that nucleophilicity correlates with basicity, then the elements considered from top to bottom of a column of the periodic table should show decreasing nucleophilic power. Recall (Section 2-2) that basicity decreases in an analogous fashion. To test this prediction, let us consider another series of experiments. In the equations below, we have explicitly added the solvent methanol to the reaction scheme, because, as we shall see, consideration of the solvent will be important in understanding the outcome of these experiments.

**Experiment 5**

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_2\text{OSCH}_3 + \text{Br}^- &\xrightarrow{\text{CH}_3\text{OH} (\text{Solvent})} \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl}^- + \text{O}_3\text{SCH}_3 & \text{Slow} \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{OSCH}_3 + \text{Br}^- &\xrightarrow{\text{CH}_3\text{OH} (\text{Solvent})} \text{CH}_3\text{CH}_2\text{CH}_2\text{Br}^- + \text{O}_3\text{SCH}_3 & \text{Faster} \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{OSCH}_3 + \text{I}^- &\xrightarrow{\text{CH}_3\text{OH} (\text{Solvent})} \text{CH}_3\text{CH}_2\text{CH}_2\text{I}^- + \text{O}_3\text{SCH}_3 & \text{Fastest}
\end{align*}
\]

**Experiment 6**

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_2\text{Br}^- + \text{CH}_3\text{OS}^- &\xrightarrow{\text{CH}_3\text{OH} (\text{Solvent})} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 + \text{Br}^- & \text{Not very fast} \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{Br}^- + \text{CH}_3\text{S}^- &\xrightarrow{\text{CH}_3\text{OH} (\text{Solvent})} \text{CH}_3\text{CH}_2\text{CH}_2\text{SCH}_3 + \text{Br}^- & \text{Very fast}
\end{align*}
\]

**Conclusion.** Surprisingly, nucleophilicity *increases* in the progression down the periodic table, a trend *directly opposing* that expected from the basicity of the nucleophiles tested. For example, in the series of halides, iodide is the fastest, although it is the weakest base.

**Increasing basicity**

\[F^- < Cl^- < Br^- < I^-\]

**Increasing nucleophilicity in CH\(_3\)OH**

Moving one column to the left in the periodic table, sulfide nucleophiles are more reactive than the analogous oxide systems, and, as other experiments have shown, their selenium counterparts are even more reactive. Thus, this column exhibits the same trend as that observed for the halides. The phenomenon is general for other columns in the periodic table.

How can these trends be explained? An important consideration is the interaction of the solvent methanol with the anionic nucleophile. We have largely ignored the solvent in our discussion of organic reactions so far, in particular, radical halogenations (Chapter 3), in which they play an insignificant role. Nucleophilic substitution features polar starting materials and a polar mechanism, and the nature of the solvent becomes more important. Let us see how the solvent can become involved.
When a solid dissolves, the intermolecular forces that held it together (Section 2-6; Figure 2-6) are replaced by intermolecular forces between molecules and solvent. Such molecules, especially the ions derived from the starting salts of many \( \text{S}_2\text{N} \) reactions, are said to be solvated. Salts dissolve well in alcohols and water, because these solvents contain highly polarized \( \delta^+ - \delta^- \) bonds that act by ion–dipole interactions. Thus, cations are solvated by the negatively polarized oxygens (Figure 6-6A), anions by the positively polarized hydrogens (Figure 6-6B and C). This solvation of anions is particularly strong, because the small size of the hydrogen nucleus makes the \( \delta^- \) charge relatively dense. We shall study these interactions, called hydrogen bonds, more closely in Chapter 8. Solvents capable of hydrogen bonding are also called protic, in contrast to aprotic solvents, such as acetone, which will be discussed later.

Returning to the problem of our experimental results: What accounts for the increasing nucleophilicity of negatively charged nucleophiles from the top to the bottom of a column of the periodic table? The answer is that solvation weakens the nucleophile by forming a shell of solvent molecules around the nucleophile and thus impeding its ability to attack an electrophile. As we move down the periodic table, such as from \( \text{F}^- \) to \( \text{I}^- \), the solvated ion becomes larger and its charge more diffuse. As a result, solvation is diminished along the series and nucleophilicity increases. Figures 6-6B and C depict this effect for \( \text{F}^- \) and \( \text{I}^- \). The smaller fluoride ion is much more heavily solvated than the larger iodide. Is this true in other solvents as well?

### Figure 6-6

(A) Solvation of \( \text{Na}^+ \) by ion-dipole interactions with methanol. (B) Approximate representation of the relatively dense solvation of the small \( \text{F}^- \) ion by hydrogen bonds to methanol. (C) Approximate representation of the comparatively diminished solvation of the large \( \text{I}^- \) ion by hydrogen bonds to methanol. The tighter solvent shell around \( \text{F}^- \) reduces its ability to participate in nucleophilic substitution reactions.

When a solid dissolves, the intermolecular forces that held it together (Section 2-6; Figure 2-6) are replaced by intermolecular forces between molecules and solvent. Such molecules, especially the ions derived from the starting salts of many \( \text{S}_2\text{N} \) reactions, are said to be solvated. Salts dissolve well in alcohols and water, because these solvents contain highly polarized \( \delta^+ - \delta^- \) bonds that act by ion–dipole interactions. Thus, cations are solvated by the negatively polarized oxygens (Figure 6-6A), anions by the positively polarized hydrogens (Figure 6-6B and C). This solvation of anions is particularly strong, because the small size of the hydrogen nucleus makes the \( \delta^- \) charge relatively dense. We shall study these interactions, called hydrogen bonds, more closely in Chapter 8. Solvents capable of hydrogen bonding are also called protic, in contrast to aprotic solvents, such as acetone, which will be discussed later.

Returning to the problem of our experimental results: What accounts for the increasing nucleophilicity of negatively charged nucleophiles from the top to the bottom of a column of the periodic table? The answer is that solvation weakens the nucleophile by forming a shell of solvent molecules around the nucleophile and thus impeding its ability to attack an electrophile. As we move down the periodic table, such as from \( \text{F}^- \) to \( \text{I}^- \), the solvated ion becomes larger and its charge more diffuse. As a result, solvation is diminished along the series and nucleophilicity increases. Figures 6-6B and C depict this effect for \( \text{F}^- \) and \( \text{I}^- \). The smaller fluoride ion is much more heavily solvated than the larger iodide. Is this true in other solvents as well?

### Aprotic solvents: the effect of solvation is diminished

Other solvents that are useful in \( \text{S}_2\text{N} \) reactions are highly polar but aprotic. Several common examples are shown in Table 6-5; all lack protons capable of hydrogen bonding but do exhibit polarized bonds. Nitromethane even exists as a charge-separated species.

Polar, aprotic solvents also dissolve salts by ion–dipole interactions, albeit not as well as protic solvents. Because they cannot form hydrogen bonds, they solvate anionic nucleophiles relatively weakly. The consequences are twofold. First, compared to protic solvents, the reactivity of the nucleophile is raised, sometimes dramatically. For example, bromomethane reacts with...
potassium iodide 500 times faster in acetone than in methanol. Table 6-6 compares the rates of $S_N2$ reactions of iodomethane with chloride in three protic solvents—methanol, formamide, and $N$-methylformamide—and one aprotic solvent, $N,N$-dimethylformamide (DMF). (Formamide and $N$-methylformamide can form hydrogen bonds by virtue of their polarized $N–H$ linkages.) The rate of reaction in DMF is more than a million times greater than it is in methanol.

The second consequence of comparatively weaker solvation of anions by aprotic solvents is that the nucleophilicity trend observed in protic solvents inverts. Thus, while the reactivity of all anions increases, that of the smaller ones increases more than that of the others. For many nucleophiles, including the halide series, base strength overrides solvation: Back to our original expectation!

### Increasing polarizability improves nucleophilic power

The solvation effects just described should be very pronounced only for charged nucleophiles. Nevertheless, the degree of nucleophilicity increases down the periodic table, even for uncharged nucleophiles, for which solvent effects should be much less strong, for example, $H_2Se > H_2S > H_2O$, and $PH_3 > NH_3$. Therefore, there must be an additional factor that comes into play.

This factor is the polarizability of the nucleophile (Section 6-1). Larger elements have larger, more diffuse, and more polarizable electron clouds. These electron clouds allow for more effective orbital overlap in the $S_N2$ transition state (Figure 6-7). The result is a lower transition-state energy and faster nucleophilic substitution.

Increasing basicity

$F^- < Cl^- < Br^- < I^-$

Increasing nucleophilicity in aprotic solvents

**Figure 6-7** Comparison of $I^-$ and $F^-$ in the $S_N2$ reaction. (A) In protic solvents the larger iodide is a better nucleophile, in part because its polarizable $5p$ orbital is distorted toward the electrophilic carbon atom. (B) The tight, less polarizable $2p$ orbital on fluoride does not interact as effectively with the electrophilic carbon at a point along the reaction coordinate comparable to the one for (A).
Chapter 6
Properties and Reactions of Haloalkanes

Sterically hindered nucleophiles are poorer reagents

We have seen that the bulk of the surrounding solvent may adversely affect the power of a nucleophile, another example of steric hindrance (Section 2-8). Such hindrance may also be built into the nucleophile itself in the form of bulky substituents. The effect on the rate of reaction can be seen in Experiment 7.

Experiment 7

\[
\begin{align*}
\text{CH}_3\text{I} + \text{CH}_3\text{O}^- & \rightarrow \text{CH}_3\text{OCCH}_3 + \text{I}^- & \text{Fast} \\
\text{CH}_3\text{I} + \text{CH}_3\text{CO}^- & \rightarrow \text{CH}_3\text{OCCH}_3 + \text{I}^- & \text{Slower}
\end{align*}
\]

Conclusion. Sterically bulky nucleophiles react more slowly.

Exercise 6-24
Which of the two nucleophiles in the following pairs will react more rapidly with bromomethane?

(a) CH₃S⁻ or CH₃SeH⁻; (b) (CH₃)₂NH or (CH₃)₂PH

Exercise 6-25
Working with the Concepts: Suggesting a Reaction Product by Mechanistic Reasoning

Treatment of 4-chloro-1-butanol, HO⁻CH₂CH₂CH₂CH₂OH, with NaOH in DMF solvent leads to rapid formation of a compound with the molecular formula C₄H₈O. Propose a structure for this product and suggest a mechanism for its formation.

Strategy
Rather than immediately trying to figure out the structure of the product of the reaction, it is often more productive to “think mechanistically” and consider the reaction pathways available. If the first pathway doesn’t work, try to refine the problem—what is the change that takes place in the molecule, and how could this change come about?

Solution
• The most obvious mechanism to try is an SN₂ trajectory for the substrate and hydroxide:

\[
\begin{align*}
\text{HO}^- + \text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^- & \rightarrow \text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH} + \text{HO}^- \\
\end{align*}
\]

Unfortunately, the product in this equation cannot be correct, because its molecular formula is C₄H₁₀O₂, not C₄H₈O.
• Let’s consider another approach. The substrate has the molecular formula C₄H₄OCl. Therefore, the change in its conversion to C₄H₈O is loss of one hydrogen and the chlorine—that is, a molecule of the strong acid HCl. How could we effect this change?
• Hydroxide is a base as well as a nucleophile; therefore, a reasonable alternative to the (incorrect) SN₂ reaction above is an acid-base reaction with the most acidic hydrogen in the substrate:

\[
\begin{align*}
\text{HO}^- + \text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^- & \rightarrow \text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^- + \text{H}^+ \\
\end{align*}
\]
Nucleophilic substitutions may be reversible

The halide ions Cl\(^-\), Br\(^-\), and I\(^-\) are both good nucleophiles and good leaving groups. Therefore, their S\(_{N2}\) reactions are reversible. For example, in acetone, the reactions between lithium chloride and primary bromo- and iodoalkanes form an equilibrium that lies on the side of the chloroalkane products:

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{I} + \text{LiCl} \rightleftharpoons \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl} + \text{LiI}
\]

This result correlates with the relative stabilities of the product and starting material, which favor the chloroalkane. However, this equilibrium may be driven in the reverse direction by a simple “trick”: Whereas all of the lithium halides are soluble in acetone, solubility of the sodium halides decreases dramatically in the order NaI > NaBr > NaCl, the last being virtually insoluble in this solvent. Indeed, the reaction between NaI and a primary or secondary chloroalkane in acetone is completely driven to the side of the iodoalkane (the reverse of the reaction just shown) by the precipitation of NaCl:

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl} + \text{NaI} \rightleftharpoons \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{I} + \text{NaCl}
\]

In summary, nucleophilicity is controlled by a number of factors. Increased negative charge and progression from right to left and down (protic solvent) or up (aprotic solvent) the periodic table generally increase nucleophilic power. Table 6-7 compares the reactivity of various nucleophiles with iodomethane in methanol (protic solvent).

Increasing nucleophility
of a range of nucleophiles relative to that of the very weakly nucleophilic methanol (arbitrarily set at 1). We can confirm the validity of the conclusions of this section by inspecting the various entries. The use of aprotic solvents improves nucleophilicity, especially of smaller anions, by eliminating hydrogen bonding.

6-9 Structure and S_N2 Reactivity: The Substrate

Finally, does the structure of the alkyl portion of the substrate, particularly in the vicinity of the atom bearing the leaving group, affect the rate of nucleophilic attack? Once again, we can get a sense of comparative reactivities by looking at relative rates of reaction. Let us examine the kinetic data that have been obtained.

Branching at the reacting carbon decreases the rate of the S_N2 reaction

What happens if we successively replace each of the hydrogens in a halomethane with a methyl group? Will this affect the rate of its S_N2 reactions? In other words, what are the relative bimolecular nucleophilic reactivities of methyl, primary, secondary, and tertiary halides? Kinetic experiments show that reactivities decrease rapidly in the order shown in Table 6-8.

We can find an explanation by comparing the transition states for these four substituents. Figure 6-8A shows this structure for the reaction of chloromethane with hydroxide ion. The carbon is surrounded by the incoming nucleophile, the outgoing leaving group, and three substituents (all hydrogen in this case). Although the presence of these five groups increases the crowding about the carbon relative to that in the starting halomethane, the hydrogens do not give rise to serious steric interactions with the nucleophile because of their small size. However, replacement of one hydrogen by a methyl group, as in a haloethane, creates substantial steric repulsion with the incoming nucleophile, thereby raising the transition-state energy (Figure 6-8B). This effect significantly retards nucleophilic attack.

If we continue to replace hydrogen atoms with methyl groups, we find that steric hindrance to nucleophilic attack increases dramatically. The two methyl groups in the secondary substrate severely shield the backside of the carbon attached to the leaving group; the rate of reaction diminishes considerably (Figure 6-8C and Table 6-8). Finally, in the tertiary substrate, in which a third methyl group is present, access to the backside of the halide-bearing carbon is entirely blocked (Figure 6-8D); the transition state for S_N2 substitution is energetically:

Chapter 6

**CHEMICAL HIGHLIGHT 6-2**

**The Dilemma of Bromomethane: Highly Useful but Also Highly Toxic**

Bromomethane, CH₃Br, is a substance with numerous uses. Easy and inexpensive to prepare, it is employed as an insect fumigant for large storage spaces such as warehouses and railroad boxcars. It is also effective in eradicating insect infestations in soil around several major crops, including potatoes and tomatoes. Not surprisingly, it owes part of its value to its high toxicity, which can be attributed largely to its SN₂ reactivity. The chemistry of life is highly dependent on several classes of molecules containing nucleophilic groups such as amines (–NH₂ and related functions) and thiols (–SH). The biochemical roles of these substituents are many and varied, as well as being critical to the survival of living organisms. Highly reactive electrophiles such as bromomethane wreak havoc on this biochemistry by indiscriminately alkylating such nucleophilic atoms, that is, reacting through the SN₂ mechanism to attach alkyl groups (in this case, a methyl group) to them (see, for example, the reaction below). Some of these processes can generate HBr as a by-product, which amplifies the danger posed by this material to living systems.

The toxicity of bromomethane is not limited to insects. Human exposure is known to cause numerous health problems: Direct contact causes burns to the skin; chronic exposure leads to kidney, liver, and central nervous system damage; and inhalation of high concentrations can lead to the destruction of lung tissue, to pulmonary edema, and to death. The limit set for bromomethane exposure in the workplace is a concentration of 20 parts per million of bromomethane vapor in ambient air. As is the case for so many substances that have been found to be useful in large-scale applications in our society, bromomethane’s toxicity poses a dilemma that requires the most responsible control of its use. The resolution between the issues of utility and safety does not always come easily, and the costs — human, environmental, and economic — must be assessed most carefully.

Plant pathologist Frank Westerlund demonstrates the “bromomethane difference” between strawberries grown in a fumigated plot (right) and those not (left). The latter are withered by verticillium wilt, a fungus.

- (b) CH₃CH₂Br and CH₃CH₂CH₂Br
Properties and Reactions of Haloalkanes

Now that we have seen the effect of major structural changes on substrate reactivity in the $S_N2$ process, we are in a position to evaluate the effects of more subtle structural modifications. In all cases, we shall find that steric hindrance to attack at the backside of the reacting carbon is the most important consideration.

Lengthening the chain by one or two carbons reduces $S_N2$ reactivity

As we have seen, the replacement of one hydrogen atom in a halomethane by a methyl group (Figure 6-8B) causes significant steric hindrance and reduction of the rate of $S_N2$ reaction. Chloroethane is about two orders of magnitude less reactive than chloromethane in $S_N2$ displacements. Will elongation of the chain of the primary alkyl substrate by the addition of methylene (CH$_2$) groups further reduce $S_N2$ reactivity? Kinetic experiments reveal that 1-chloropropane reacts about half as fast as chloroethane with nucleophiles such as I$^-$. Does this trend continue as the chain gets longer? The answer is no: Higher haloalkanes, such as 1-chlorobutane and 1-chloropentane, react at about the same rate as does 1-chloropropane.

Again, an examination of the transition states to backside displacement provides an explanation for these observations. In Figures 6-9A and 6-9B, one of the hydrogens on the methyl carbon of chloroethane is partially obstructing the path of attack of the incoming nucleophile. The 1-halopropanes have an additional methyl group near the reacting carbon center. If reaction occurs from the most stable anti conformer of the substrate, the incoming nucleophile faces severe steric hindrance (Figure 6-9C). However, rotation to a gauche conformation before attack gives an $S_N2$ transition state similar to that derived from a haloethane (Figure 6-9D). The propyl substrate exhibits only a small decrease in reactivity relative to the ethyl, the decrease resulting from the energy input needed to attain a gauche conformation. Further chain elongation has no effect, because the added carbon atoms do not increase steric hindrance around the reacting carbon in the transition state.

![Figure 6-9](image-url)

**Figure 6-9** Hashed-wedged line and space-filling drawings of the transition states for $S_N2$ reactions of hydroxide ion with (A) chloromethane; (B) chloroethane; and (C and D) two conformers of 1-chloropropane: (C) anti and (D) gauche. Steric interference is illustrated strikingly in the space-filling drawings. Partial charges have been omitted for clarity. (See Figure 6-3.)
Branching next to the reacting carbon also retards substitution

What about multiple substitution at the position next to the electrophilic carbon? Let us compare the reactivities of bromoethane and its derivatives (Table 6-9). A dramatic decrease in rate is seen on further substitution: 1-Bromo-2-methylpropane is ~25 times less reactive toward iodide than is 1-bromopropane, and 1-bromo-2,2-dimethylpropane is virtually inert. Branching at positions farther from the site of reaction has a much smaller effect.

We know that rotation into a gauche conformation is necessary to permit nucleophilic attack on a 1-halopropane (Figure 6-10A). We can use the same picture to understand the data in Table 6-9. For a 1-halo-2-methylpropane, the only conformation that permits the nucleophile to approach the backside of the reacting carbon experiences two gauche methyl–halide interactions, a considerably worse situation (Figure 6-10B). With the addition of a third methyl group, as in a 1-halo-2,2-dimethylpropane, commonly known as a neopentyl halide, backside attack is blocked almost completely (Figure 6-10C).

In Summary The structure of the alkyl part of a haloalkane can have a pronounced effect on the rate of nucleophilic attack. Simple chain elongation beyond three carbons has little effect on the rate of the SN2 reaction. However, increased branching leads to strong steric hindrance and rate retardation.

Exercise 6-28
Predict the order of reactivity in the SN2 reaction of

![Diagram of two molecules]

In Summary The structure of the alkyl part of a haloalkane can have a pronounced effect on the rate of nucleophilic attack. Simple chain elongation beyond three carbons has little effect on the rate of the SN2 reaction. However, increased branching leads to strong steric hindrance and rate retardation.

Decreasing reactivity
Increasing size of R

Figure 6-10 Hashed-wedged line and space-filling renditions of the transition states for SN2 reactions of hydroxide ion with (A) 1-chloropropane, (B) 1-chloro-2-methylpropane, and (C) 1-chloro-2,2-dimethylpropane. Increasing steric hindrance from a second gauche interaction reduces the rate of reaction in (B). SN2 reactivity in (C) is eliminated almost entirely because a methyl group prevents backside attack by the nucleophile in all accessible conformations of the substrate. (See also Figures 6-8 and 6-9.)
Chapter 6
Properties and Reactions of Haloalkanes

THE BIG PICTURE

In the first five chapters, we examined the most basic ideas of organic chemistry. We applied principles of general chemistry, such as orbital theory, thermodynamics, and kinetics, to organic molecules. We also introduced topics of particular relevance to organic chemistry, such as isomerism and stereochemistry. The properties and reactions of alkanes gave us an opportunity to observe many of these basic principles in action.

The products of halogenation of alkanes, the haloalkanes, are functionalized molecules. Their carbon–halogen bond is a typical polar functional group and reacts by bimolecular nucleophilic substitution, or the SN₂ mechanism. This process, involving backside displacement, is one of the fundamental mechanisms of organic chemistry. Its characteristics include sensitivity to the identity of the nucleophile, substrate structure, leaving group, and solvent. Close attention to these details enables us to understand why the reaction occurs and what makes it easier or more difficult—in short, how changes in structure affect function. With this understanding comes the ability to predict: to extrapolate by analogy from examples of reactions we have seen to reactions we have not seen. Rational prediction is an essential component of scientific reasoning, which we illustrate often throughout this book, beginning in the very next chapter. There, we shall expand our study of haloalkanes and examine additional processes they can undergo. Our continued focus will be the effect that structural changes have on chemical behavior.

CHAPTER INTEGRATION PROBLEMS

6-29. a. Write a mechanism and final product for the reaction between sodium ethoxide, NaO\text{CH}_2\text{CH}_3, and bromoethane, CH\text{3}CH\text{2}Br, in ethanol solvent, CH\text{3}CH\text{2}OH.

SOLUTION
The mechanism is backside attack in which the nucleophilic atom of the reagent attacks the atom of the substrate that contains the leaving group (Section 6-5). We begin by identifying each of these components. The nucleophilic atom is the negatively charged oxygen atom in ethoxide ion, CH\text{3}CH\text{2}–\text{O}^–. Attack occurs at the carbon attached to bromine in the substrate molecule, CH\text{3}–\text{C}H\text{2}Br:

\[
\begin{align*}
\text{CH}_3\text{CH}_2^\text{O}^- + \text{H}_2\text{C}^- + \text{C}^-\text{Br}^- & \rightarrow \text{CH}_3\text{CH}_2\text{O}^-\text{CH}_2\text{CH}_3 + \text{Br}^- \\
\end{align*}
\]

The products are bromide ion and ethoxyethane, CH\text{3}CH\text{2}O\text{CH}_2\text{CH}_3, an ether.

b. How would the preceding reaction be affected by each of the following changes?
1. Replace bromoethane with fluoroethane.
2. Replace bromoethane with bromomethane.
3. Replace sodium ethoxide with sodium ethanethiolate, NaS\text{CH}_2\text{CH}_3.
4. Replace ethanol with dimethylformamide (DMF).

SOLUTION
1. Table 6-4 tells us that fluoride is a stronger base than bromide and, therefore, a poorer leaving group. The reaction would still take place but would be very much slower. (The actual rate decrease is of the order of 10^3.)

2. The carbon containing the leaving group in bromomethane is less sterically hindered than that in bromoethane, so the rate of reaction would increase (Section 6-9). The product of the reaction would be CH\text{3}O\text{CH}_2\text{CH}_3, methoxyethane.

3. Both ethoxide and ethanethiolate are negatively charged. Oxygen in ethoxide is more basic than sulfur in ethanethiolate (Table 6-4), but the sulfur atom in ethanethiolate is larger, more polarizable, and less tightly solvated in the hydrogen-bonding ethanol solvent (compare Figure 6-6). We know that strong bases are good nucleophiles, but base strength is outweighed by the increased polarizability and reduced solvation of the larger atoms within the same column of the periodic table (Section 6-9). Ethanethiolate reacts hundreds of times as fast, giving as a product CH\text{3}CH\text{2}S\text{CH}_2\text{CH}_3, an example of a sulfide (Section 9-10).

4. Conversion from a protic, hydrogen-bonding solvent to a polar, aprotic one accelerates the reaction enormously by reducing solvation of the negatively charged oxygen atom (compare Table 6-6). See Problem 57 for a similar exercise.
6-30. a. Which of the following compounds would be expected to react in an $S_N2$ manner at a reasonable rate with sodium azide, $\text{NaN}_3$, in ethanol? Which will not? Why not?

SOLUTION

As we did in Chapter Integration Problem 3-14, let us apply the WHIP approach to break down the process of solving this problem. Again, this strategy will be described in detail in the Interlude that follows Chapter 11.

What is the problem asking? This may be obvious—in part ‘a’ one merely has to identify which of the compounds shown reacts with azide in ethanol via an $S_N2$ process. However, there is a bit more to it, and the clue is the presence of the word “why” in the question. “How” and “why” questions invariably require a closer look at the situation, usually from a mechanistic perspective. It will be necessary to consider finer details of the $S_N2$ mechanism in light of the structures of each of the substrate molecules.

How to begin? Characterize each substrate in the context of the $S_N2$ process. Does it contain a viable leaving group? To what kind of carbon atom is the potential leaving group attached? Are other relevant structural features present?

Information needed? Does each of these six molecules contain a good leaving group? If necessary, look in Section 6-7 for guidance: To be a good leaving group, a species must be a weak base. Next, can you tell if the leaving group is attached to a primary, secondary, or tertiary carbon atom? See their definitions in Section 2-5. Anything else? Section 6-9 tells you what to look for: steric hindrance in the substrate that may obstruct the approach of the nucleophile.

Proceed. We identify first the molecules with good leaving groups. Referring to Table 6-4, we see that, as a general rule, only species that are the conjugate bases of strong acids (i.e., with $pK_a$ values $< 0$) qualify. So, (i), (iv), and (vi) will not undergo $S_N2$ displacement. They lack good leaving groups: $\text{NH}_2$, $\text{OH}$, and $\text{CN}$ are too strongly basic for this purpose (thus answering the “why not” for these three).

Substrate (ii) contains a good leaving group, but the reaction site is a tertiary carbon and sterically incapable of following the $S_N2$ mechanism. That leaves substrates (iii) and (v), both of which are primary haloalkanes with minimal steric hindrance around the site of displacement. Both will transform readily by the $S_N2$ mechanism.

b. Compare the rates at which the $S_N2$ reactions of substrates (iii) and (v) with azide will proceed.

SOLUTION

Following the WHIP protocol, we look for any differences between the two substrates that might be significant in the context of the $S_N2$ mechanism. Both are comparable in steric bulk with respect to backside displacement: Both possess branching only at the remote $\gamma$-carbon, sterically without adverse consequences. That leaves as the only reasonable deciding factor the identity of the leaving group itself. Bromide is better than chloride in this respect ($\text{HBr}$ is a stronger acid than $\text{HCl}$—Table 6-4) and is more readily displaced. Therefore we expect the rate of reaction of (iii) to be greater. Problem 56 requires similar reasoning.

c. Name substrates (iii) and (v) according to the IUPAC system.

SOLUTION

Review Sections 2-5 and 4-1 if necessary.

(iii) 1-Bromo-3-methylbutane  (v) (2-Chloroethyl)cyclopentane

Important Concepts

1. A haloalkane, commonly termed an alkyl halide, consists of an alkyl group and a halogen.

2. The physical properties of the haloalkanes are strongly affected by the polarization of the C–X bond and the polarizability of X.

3. Reagents bearing lone electron pairs are called nucleophilic when they attack positively polarized centers (other than protons). The latter are called electrophilic. When such a reaction leads to displacement of a substituent, it is a nucleophilic substitution. The group being displaced by the nucleophile is the leaving group.
Properties and Reactions of Haloalkanes

4. The kinetics of the reaction of nucleophiles with primary (and most secondary) haloalkanes are second order, indicative of a bimolecular mechanism. This process is called bimolecular nucleophilic substitution (S\textsubscript{N}2 reaction). It is a concerted reaction, one in which bonds are simultaneously broken and formed. Curved arrows are typically used to depict the flow of electrons as the reaction proceeds.

5. The S\textsubscript{N}2 reaction is stereospecific and proceeds by backside displacement, thereby producing inversion of configuration at the reacting center.

6. An orbital description of the S\textsubscript{N}2 transition state includes an sp\textsuperscript{2}-hybridized carbon center, partial bond making between the nucleophile and the electrophilic carbon, and simultaneous partial bond breaking between that carbon and the leaving group. Both the nucleophile and the leaving group bear partial charges.

7. Leaving-group ability, a measure of the ease of displacement, is roughly proportional to the strength of the conjugate acid. Especially good leaving groups are weak bases such as chloride, bromide, iodide, and the sulfonates.

8. Nucleophilicity increases (a) with negative charge, (b) for elements farther to the left and down the periodic table, and (c) in polar aprotic solvents.

9. Polar aprotic solvents accelerate S\textsubscript{N}2 reactions because the nucleophiles are well separated from their counterions but are not tightly solvated.

10. Branching at the reacting carbon or at the carbon next to it in the substrate leads to steric hindrance in the S\textsubscript{N}2 transition state and decreases the rate of bimolecular substitution.

Problems

31. Name the following molecules according to the IUPAC system.
   (a) CH\textsubscript{3}CH\textsubscript{2}Cl  (b) BrCH\textsubscript{2}CH\textsubscript{2}Br  (c) CH\textsubscript{3}CH\textsubscript{2}CHCH\textsubscript{2}F  (d) (CH\textsubscript{3})\textsubscript{3}CCH\textsubscript{2}I  (e) CH\textsubscript{2}CH\textsubscript{2}Cl

32. Draw structures for each of the following molecules: (a) 3-ethyl-2-iodopentane; (b) 3-bromo-1,1-dichlorobutane; (c) cis-1-(bromomethyl)-2-(2-chloroethyl)cyclobutane; (d) (trichloromethyl)cyclopropane; (e) 1,2,3-trichloro-2-methylpropane.

33. Draw and name all possible structural isomers having the formula C\textsubscript{3}H\textsubscript{6}BrCl.

34. Draw and name all structurally isomeric compounds having the formula C\textsubscript{3}H\textsubscript{7}Br.

35. For each structural isomer in Problems 33 and 34, identify all stereocenters and give the total number of stereoisomers that can exist for the structure.

36. For each reaction in Table 6-3, identify the nucleophile, its nucleophilic atom (draw its Lewis structure first), the electrophilic atom in the substrate molecule, and the leaving group.

37. A second Lewis structure can be drawn for one of the nucleophiles in Problem 36. (a) Identify it and draw its alternate structure (which is simply a second resonance form). (b) Is there a second nucleophilic atom in the nucleophile? If so, rewrite the reaction of Problem 36, using the new nucleophilic atom, and write a correct Lewis structure for the product.

38. For each reaction shown here, identify the nucleophile, its nucleophilic atom, the electrophilic atom in the substrate molecule, and the leaving group. Write the organic product of the reaction.

(a) CH\textsubscript{3}I + NaNH\textsubscript{2} →
(b) \begin{align*} \text{Br} & \quad \text{S} \\ \text{O} & \quad \text{O} \end{align*} + NaI →
(c) CH\textsubscript{3}Cl + \begin{align*} \text{O} & \quad \text{N} \\ \text{O} & \quad \text{CH}_{3} \end{align*} →
(d) \begin{align*} \text{Cl} & \quad \text{H} \\ \text{H} & \quad \text{Cl} \end{align*} + NaN\textsubscript{3} →
(e) CH\textsubscript{3}I + NaNH\textsubscript{2} →
(f) \begin{align*} \text{Br} & \quad \text{KSeCN} \\ \text{I} & \quad \text{O} \end{align*} →
39. For each reaction presented in Problem 38, write out the mechanism using the curved-arrow notation.

40. A solution containing 0.1 M CH₃Cl and 0.1 M KSCN in DMF reacts to give CH₃SCN and KCl with an initial rate of $2 \times 10^{-8}$ mol L⁻¹ s⁻¹. (a) What is the rate constant for this reaction? (b) Calculate the initial reaction rate for each of the following sets of reactant concentrations: (i) [CH₃Cl] = 0.2 M, [KSCN] = 0.1 M; (ii) [CH₃Cl] = 0.2 M, [KSCN] = 0.3 M; (iii) [CH₃Cl] = 0.4 M, [KSCN] = 0.4 M.

41. Write the product of each of the following bimolecular substitutions. The solvent is indicated above the reaction arrow.

(a) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} + \text{Na}^+\text{I}^- \rightarrow \text{Acetone} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{SCN} + \text{K}^+\text{Cl}^- \)
(b) \( \text{CH}_2\text{CH}_2\text{I} + \text{Na}^+\text{CN}^- \rightarrow \text{DMSO} \quad \text{CH}_3\text{CH}_2\text{SCN} + \text{K}^+\text{Cl}^- \)
(c) \( \text{CH}_2\text{Cl} + \text{CH}_3\text{CH}_2\text{SeCH}_2\text{CH}_3 \rightarrow \text{Acetone} \quad \text{CH}_3\text{CH}_2\text{SCN} + \text{K}^+\text{Cl}^- \)
(d) \( \text{CH}_3\text{CH}_2\text{Br} + \text{Na}^+\text{I}^- \rightarrow \text{CH}_3\text{CH}_2\text{SCN} + \text{K}^+\text{Cl}^- \)

42. Determine the R/S designations for both starting materials and products in the following S_N2 reactions. Which of the products are optically active?

(a) \( \text{H}^+ + \text{Br}^- \rightarrow \text{CH}_3\text{CH}_2\text{CH}_3 \quad \text{H}^+ + \text{I}^- \rightarrow \text{CH}_3\text{CH}_2\text{CH}_3 \)
(b) \( \text{H}^+ + \text{CH}_2\text{Br}^- \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} \quad \text{H}^+ + \text{CH}_3\text{I}^- \rightarrow \text{CH}_3\text{CH}_2\text{CH}_3 \)

43. For each reaction presented in Problems 41 and 42, write out the mechanism using curved-arrow notation.

44. List the product(s) of the reaction of 1-bromopropane with each of the following reagents. Write “no reaction” where appropriate. (Hint: Carefully evaluate the nucleophilic potential of each reagent.)

(a) \( \text{H}_2\text{O} \) (b) \( \text{H}_2\text{SO}_4 \) (c) \( \text{KOH} \) (d) \( \text{CsI} \) (e) \( \text{NaCN} \)
(f) \( \text{HCl} \) (g) \( \text{(CH}_3\text{)}_2\text{S} \) (h) \( \text{NH}_3 \) (i) \( \text{Cl}_2 \) (j) \( \text{KF} \)

45. Formulate the potential product of each of the following reactions. As you did in Problem 44, write “no reaction” where appropriate. (Hint: Identify the expected leaving group in each of the substrates and evaluate its ability to undergo displacement.)

(a) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} + \text{K}^+\text{OH}^- \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{OH} \)
(b) \( \text{CH}_3\text{CH}_2\text{I} + \text{K}^+\text{Cl}^- \rightarrow \text{DMF} \quad \text{CH}_3\text{CH}_2\text{I} + \text{Na}^+\text{Cl}^- \rightarrow \text{DMF} \)

46. Show how each of the following transformations might be achieved.

(a) \( \text{(R)}\text{-CH}_3\text{CHCH}_2\text{CH}_3 \rightarrow \text{(S)}\text{-CH}_3\text{CHCH}_2\text{CH}_3 \)
(b) \( \text{CH}_3\text{CH}_2\text{OH} + \text{H}^+\text{Br}^- \rightarrow \text{CH}_3\text{CH}_2\text{OH} \quad \text{CH}_3\text{CH}_2\text{OH} + \text{H}^+\text{CN}^- \rightarrow \text{CH}_3\text{CH}_2\text{OH} \)
(c) \( \text{Br}^- + \text{CH}_3\text{CHCH}_2\text{CH}_3 \rightarrow \text{SCH}_3 \quad \text{H}_2\text{O} + \text{CH}_3\text{CHCH}_2\text{CH}_3 \rightarrow \text{SCH}_3 \)
(d) \( \text{CH}_3\text{CH}_2\text{OH} + \text{H}^+\text{Br}^- \rightarrow \text{CH}_3\text{CH}_2\text{OH} \quad \text{CH}_3\text{CH}_2\text{OH} + \text{H}^+\text{CN}^- \rightarrow \text{CH}_3\text{CH}_2\text{OH} \)
47. Rank the members of each of the following groups of species in the order of basicity, nucleophilicity, and leaving-group ability. Briefly explain your answers. (a) H₂O, HO⁻, CH₃CO₂⁻; (b) Br⁻, Cl⁻, F⁻, I⁻; (c) NH₂, NH₃, PH₅⁺; (d) OCN⁻, SCN⁻, H⁻; (e) F⁻, HO⁻, O⁻; (f) H₂O, H₂S, NH₃.

48. Write the product(s) of each of the following reactions. Write “no reaction” as your answer, if appropriate.

(a) CH₃CH₂CH₂CH₃ + Na⁺Cl⁻ → CH₃OH
(b) CH₃CH₂Cl + Na⁺OCH₃ → Acetone
(c) H₃C
(d) H₃C
(e) CH₃CH₂CH₂OH + Na⁺CN → Acetone
(f) CH₃CH₂CH₂OH + HCN → CH₃CH₂OH

49. For each reaction presented in Problem 48 that actually proceeds to a product, write out the mechanism using the curved-arrow notation.

50. The substance 1-butyl-3-methylimidazolium (BMIM) hexafluorophosphate (margin) is a liquid at room temperature, even though it is a salt composed of positive and negative ions. BMIM and other ionic liquids constitute a new class of solvents for organic reactions, because they are capable of dissolving both organic and inorganic substances. More important, they are relatively benign environmentally, or “green,” because they can be easily separated from reaction products and reused virtually indefinitely. Therefore they do not constitute a waste-disposal problem, unlike conventional solvents. (a) How would you characterize BMIM as a solvent? Polar or aprotic? Protic or aprotic? (b) How would changing the solvent from ethanol to BMIM affect the rate of the nucleophilic substitution reaction between sodium cyanide and 1-chloropentane?

51. (2S,3S)-3-Hydroxyleucine is an amino acid (Chapter 26) that is a key component in the structures of many “depsipeptide” antibiotics, such as sanjoinine (margin). (a) Find the part of the sanjoinine molecule that is derived structurally from (2S,3S)-3-hydroxyleucine. (b) Although many depsipeptide antibiotics occur in nature, the quantities available are too small to be useful pharmaceutically; thus these molecules must be synthesized. (2S,3S)-3-Hydroxyleucine, which is also not available in quantity from nature, must be synthesized as well. Possible starting materials are the four diastereomers of 2-bromo-3-hydroxy-4-methylpentanoic acid (margin). Draw structural formulas for each of these diastereomers and identify which of the four should be the best starting material for a preparation of (2S,3S)-3-hydroxyleucine.

52. **Challenge** Iodoalkanes are readily prepared from the corresponding chloro compounds by S₂ reaction with sodium iodide in acetone. This particular procedure is especially useful because the inorganic by-product, sodium chloride, is insoluble in acetone; its precipitation drives the equilibrium in the desired direction. Thus, it is not necessary to use excess NaI, and the process goes to completion in a very short time. Because of its great convenience, this method is named after its developer (the Finkelstein reaction). In an attempt to synthesize optically pure (R)-2-iodohexane, a student prepared a solution of (S)-2-chlorohexane in acetone. In order to ensure success, he added excess sodium iodide and allowed the mixture to stir over the weekend. His yield of 2-iodohexane was high, but, to his dismay, he found that his product was racemic. Explain.

53. **Challenge** Using the information in Chapters 3 and 6, propose the best possible synthesis of each of the following compounds with propane as your organic starting material and any other reagents needed. [Hint: On the basis of the information in Section 3-7, you should not expect to find very good answers for (a), (c), and (e). One general approach is best, however.]

(a) 1-Chloropropane  
(b) 2-Chloropropane  
(c) 1-Bromopropane  
(d) 2-Bromopropane  
(e) 1-Iodopropane  
(f) 2-Iodopropane
54. Propose two syntheses of trans-1-methyl-2-(methylthio)cyclohexane (shown in the margin), beginning with the starting compound (a) cis-1-chloro-2-methylcyclohexane; (b) trans-1-chloro-2-methylcyclohexane.

55. In each pair of molecules that follows, indicate the member of the pair that would be better suited in its indicated function for an S_N2 reaction.

(a) Nucleophile: NH_3, PH_3
(b) Substrate: [structure]
(c) Solvent: HOCN(CH_3)_2, HOCNH_2
(d) Leaving group: CH_3OH, CH_3SH

56. Rank each of the following sets of molecules in order of increasing S_N2 reactivity.

(a) CH_3CH_2Br, CH_3Br, (CH_3)_2CHBr
(b) (CH_3)_2CHCH_2Cl, (CH_3)_2CHCH_2Cl, (CH_3)_2CHCl
(c) CH_3CH_2Cl, CH_3CH_2Cl
(d) (CH_3)_2CHCH_2Br, CH_3CH_2CHCH_2Br, (CH_3)_2CHCH_2Br

57. Predict the effect of the changes given below on the rate of the reaction

\[ \text{CH}_3\text{Cl} + \text{OCH}_3^+ \rightarrow \text{CH}_3\text{OCH}_3 + \text{Cl}^{-}. \]

(a) Change substrate from CH_3Cl to CH_3I;
(b) change nucleophile from CH_3O^+ to CH_3S^+;
(c) change substrate from CH_3Cl to (CH_3)_2CHCl;
(d) change solvent from CH_3OH to (CH_3)_2SO.

58. The following table presents rate data for the reactions of CH_3I with three different nucleophiles in two different solvents. What is the significance of these results regarding relative reactivity of nucleophiles under different conditions?

<table>
<thead>

59. Explain the outcome of the following transformations mechanistically.

(a) HSCH_2CH_2Br + NaOH \xrightarrow{CH_3\text{CH}_2\text{OH}} [structure]

(b) BrCH_2CH_2CH_2CH_2Br + NaOH \rightarrow [structure]

(c) BrCH_2CH_2CH_2CH_2Br + NH_3 \rightarrow [structure]

60. **CHALLENGE** S_N2 reactions of halocyclopropane and halocyclobutane substrates are very much slower than those of analogous acyclic secondary haloalkanes. Suggest an explanation for this finding. **(Hint:** Consider the effect of bond-angle strain on the energy of the transition state; see Figure 6-4.)

61. Nucleophilic attack on halocyclohexanes is also somewhat retarded compared with that on acyclic secondary haloalkanes, even though in this case bond-angle strain is not an important factor. Explain. **(Hint:** Make a model, and refer to Chapter 4 and Section 6-9.)
Team Problem

62. Compounds A through H are isomeric bromoalkanes with the molecular formula $\text{C}_5\text{H}_{11}\text{Br}$. With your team, draw all eight constitutional isomers. Indicate any stereocenter(s), but do not label it (them) as $R$ or $S$ until you have completed your analysis. Using the data below, assign structures to A through H. Divide the problem into equal parts to share the effort of finding a solution. Reconvene and discuss your analysis. At this point, you should indicate the stereochemistry with wedged and hashed lines as appropriate.

- Treatment of compounds A through G with NaCN in DMF followed second-order kinetics and showed the following relative rates:
  \[ A \gg B > C > D > E > F > G \]

- Compound H does not undergo the $S_N2$ reaction under the preceding conditions.
- Compounds C, D, and F were found to be optically active, each having $S$ absolute configuration at the stereocenter. Substitution reactions of D and F with NaCN in DMF proceeded with inversion of configuration, while treatment of C in the same way proceeded with retention of configuration.

Preprofessional Problems

63. The $S_N2$ reaction mechanism best applies to
(a) cyclopropane and $\text{H}_2$  
(b) 1-chlorobutane and aqueous $\text{NaOH}$
(c) $\text{KOH}$ and $\text{NaOH}$  
(d) ethane and $\text{H}_2\text{O}$

64. The reaction $\text{CH}_3\text{Cl} + \text{OH}^- \rightarrow \text{CH}_3\text{OH} + \text{Cl}^-$ is first order in both chloromethane and hydroxide. Given the rate constant $k = 3.5 \times 10^{-3}$ mol L$^{-1}$ s$^{-1}$, what is the observed rate at the following concentrations?

- $[\text{CH}_3\text{Cl}] = 0.50$ mol L$^{-1}$  
- $[\text{OH}^-] = 0.015$ mol L$^{-1}$

(a) $2.6 \times 10^{-5}$ mol L$^{-1}$ s$^{-1}$  
(b) $2.6 \times 10^{-6}$ mol L$^{-1}$ s$^{-1}$  
(c) $2.6 \times 10^{-3}$ mol L$^{-1}$ s$^{-1}$  
(d) $1.75 \times 10^{-3}$ mol L$^{-1}$ s$^{-1}$  
(e) $1.75 \times 10^{-5}$ mol L$^{-1}$ s$^{-1}$

65. Which ion is the strongest nucleophile in aqueous solution?
(a) $\text{F}^-$  
(b) $\text{Cl}^-$  
(c) $\text{Br}^-$  
(d) $\text{I}^-$  
(e) all of these are equally strong

66. Only one of the following processes will occur measurably at room temperature. Which one?

(a) $\text{Cl}^- + \text{C} <\longrightarrow \text{CH}_3\text{Cl}$  
(b) $\text{N}==\text{C} <\longrightarrow \text{CH}_3\text{C}==\text{N}$  
(c) $\text{N}==\text{N} <\longrightarrow \text{CH}_3\text{N}==\text{N}$  
(d) $\text{O}==\text{O} <\longrightarrow \text{CH}_2\text{O}==\text{O}$
Further Reactions of Haloalkanes

Unimolecular Substitution and Pathways of Elimination

We have learned that the $S_n2$ displacement process is an important reaction pathway for haloalkanes. But is it the only mechanism for displacement available? Or are there other, fundamentally different types of transformations that haloalkanes undergo? In this chapter, we shall see that haloalkanes can indeed follow reaction pathways other than $S_n2$ displacement, especially if the haloalkanes are tertiary or secondary. In fact, bimolecular substitution is only one of four possible modes of reaction. The other three modes are unimolecular substitution and two types of elimination processes. The elimination processes give rise to double bonds through loss of HX and serve as our introduction into the preparation of multiply bonded organic compounds.

7-1 Solvolysis of Tertiary and Secondary Haloalkanes

We have learned that the rate of the $S_n2$ reaction diminishes drastically when the reacting center changes from primary to secondary to tertiary. These observations, however, pertain only to bimolecular substitution. Secondary and tertiary halides do undergo substitution, but by another mechanism. In fact, these substrates transform readily, even in the presence of weak nucleophiles, to give substitution products.

For example, when 2-bromo-2-methylpropane ( tert-butyl bromide) is mixed with water, it is rapidly converted into 2-methyl-2-propanol ( tert-butyl alcohol) and hydrogen bromide. Water is the nucleophile here, even though it is poor in this capacity. Such a transformation, in which a substrate undergoes substitution by solvent molecules, is called solvolysis, such as methanolation, ethanolysis, and so on. When the solvent is water, the term hydrolysis is applied.

An Example of Solvolysis: Hydrolysis

We can now look at an example of solvolysis. Consider the reaction of 2-bromo-2-methylpropane ( tert-butyl bromide) with water. The reaction is relatively fast, and produces 2-methyl-2-propanol ( tert-butyl alcohol) and hydrogen bromide as products.

Medicinal chemists use many reactions to explore structure-activity relationships in physiologically active compounds. Above, the bromocyclohexyl substituent to a $\beta$-lactam is converted to a cyclohexenyl group by elimination of HBr. $\beta$-Lactams are four-membered ring amides featured in the structure of many antibiotics, such as penicillin and cephalosporin, and their modification is essential in combating drug resistance. The photo shows Petri dish cultures of two strains of Staphylococcus aureus bacteria (opaque and grey), an organism that causes boils, abscesses, and urinary tract infections. At left, one bacterial strain shows sensitivity to penicillin (white pellet) as indicated by the clear zone of inhibited growth around it. At right, a second strain of bacteria shows resistance to the drug and its growth is not inhibited.
2-Bromopropane is hydrolyzed similarly, albeit much more slowly, whereas 1-bromopropane, bromoethane, and bromomethane are *unchanged* under these conditions.

**Hydrolysis of a Secondary Haloalkane**

\[
\begin{align*}
\text{CH}_3 \text{Br} + \text{H}_2\text{O} & \rightarrow \text{CH}_3 \text{OH} + \text{HBr} \\
2\text{-Bromopropane} & \rightarrow 2\text{-Propanol} \\
(\text{Isopropyl bromide}) & \rightarrow (\text{Isopropyl alcohol})
\end{align*}
\]

Solvolysis also takes place in alcohol solvents.

**Solvolysis of 2-Chloro-2-methylpropane in Methanol**

\[
\begin{align*}
\text{CH}_3 \text{CCl} + \text{CH}_3\text{OH} & \rightarrow \text{CH}_3 \text{COCH}_3 + \text{HCl} \\
2\text{-Chloro-} & \text{2-methylpropane} \rightarrow 2\text{-Methoxy-} \\
& \text{2-methylpropane}
\end{align*}
\]

The relative rates of reaction of 2-bromopropane and 2-bromo-2-methylpropane with water to give the corresponding alcohols are shown in Table 7-1 and are compared with the corresponding rates of hydrolysis of their unbranched counterparts. Although the process gives the products expected from an $S_N2$ reaction, the order of reactivity is *reversed* from that found under typical $S_N2$ conditions. Thus, primary halides are very slow in their reactions with water, secondary halides are more reactive, and tertiary halides are about 1 million times as fast as primary ones.

These observations suggest that the mechanism of solvolysis of secondary and, especially, tertiary haloalkanes *must be different* from that of bimolecular substitution. To understand the details of this transformation, we shall use the same methods that we used to study the $S_N2$ process: kinetics, stereochemistry, and the effect of substrate structure and solvent on reaction rates.

**Exercise 7-1**

Whereas compound A (shown in the margin) is completely stable in ethanol, B is rapidly converted into another compound. Explain.

**7-2 Unimolecular Nucleophilic Substitution**

In this section, we shall learn about a new pathway for nucleophilic substitution. Recall that the $S_N2$ reaction

- Has second-order kinetics
- Generates products stereospecifically with inversion of configuration
- Is fastest with halomethanes and successively slower with primary and secondary halides
- Does not take place with tertiary substrates at all
In contrast, solvolyses

- Follow a first-order rate law
- Are not stereospecific
- Are characterized by the opposite order of reactivity

Let us see how these findings can be accommodated mechanistically.

**Solvolysis follows first-order kinetics**

In Chapter 6, the kinetics of reaction between halomethanes and nucleophiles revealed a bimolecular transition state: The rate of the $S_{N2}$ reaction is proportional to the concentration of both ingredients. Similar studies have been carried out by varying the concentrations of 2-bromo-2-methylpropane and water in formic acid (a polar solvent of very low nucleophilicity) and measuring the rates of solvolysis. The results of these experiments show that the rate of hydrolysis of the bromide is proportional to the concentration of only the starting halide, not the water.

$$Rate = k[(CH_3)_3CBr] \text{ mol L}^{-1} \text{ s}^{-1}$$

What does this observation mean? First, it is clear that the haloalkane has to undergo some transformation on its own before anything else takes place. Second, because the final product contains a hydroxy group, water (or, in general, any nucleophile) must enter the reaction, but at a later stage and not in a way that will affect the rate law. The only way to explain this behavior is to postulate that any steps that follow the initial reaction of the halide are relatively fast. In other words, the observed rate is that of the slowest step in the sequence: the rate-determining step. It follows that only those species taking part in the transition state of this step enter into the rate expression: in this case, only the starting haloalkane.

In analogy, think of the rate-determining step as a bottleneck. Imagine a water hose with several attached clamps restricting the flow (Figure 7-1). We can see that the rate at which the water will spew out of the end is controlled by the narrowest constriction. If we were to reverse the direction of flow (to model the reversibility of a reaction), again the rate of flow would be controlled by this point. Such is the case in transformations consisting of more than one step—for example, solvolysis. What, then, are the steps in our example?

![Figure 7-1](image)

**The mechanism of solvolysis includes carbocation formation**

The hydrolysis of 2-bromo-2-methylpropane is said to proceed by unimolecular nucleophilic substitution, abbreviated $S_{N1}$. The number 1 indicates that only one molecule, the haloalkane, participates in the rate-determining step: The rate of the reaction does not depend on the concentration of the nucleophile. The mechanism consists of three steps.
Step 1. The rate-determining step is the dissociation of the haloalkane to an alkyl cation and bromide.

\[
\ce{CH3CH2CH2CH2Br + \text{water} \rightarrow \ce{CH3CH2CH2CH3} + \ce{Br^-}}
\]

This conversion is an example of heterolytic cleavage. The hydrocarbon product contains a positively charged central carbon atom attached to three other groups and bearing only an electron sextet. Such a structure is called a **carbocation**.

Step 2. The 1,1-dimethylethyl (tert-butyl) cation formed in step 1 is a powerful electrophile that is immediately trapped by the surrounding water. This process can be viewed as a nucleophilic attack by the solvent on the electron-deficient carbon.

\[
\ce{\text{tert-Butyl cation} + \text{water} \rightarrow \ce{CH3CH2CH2CH2OH}}
\]

The resulting species is an example of an **alkyloxonium ion**, the conjugate acid of an alcohol—in this case 2-methyl-2-propanol, the eventual product of the sequence.

Step 3. Like the hydronium ion, \(\text{H}_3\text{O}^+\), the first member of the series of oxonium ions, all alkylloxonium ions are strong acids. They are therefore readily deprotonated by the water in the reaction medium to furnish the final alcohol.

---

*aIndeed, IUPAC recommends the use of the name oxonium ion instead hydronium ion for \(\text{H}_3\text{O}^+\).*
Figure 7-2 compares the potential-energy diagrams for the S_N2 reaction of chloromethane with hydroxide ion and the S_N1 reaction of 2-bromo-2-methylpropane with water. The S_N1 diagram exhibits three transition states, one for each step in the mechanism. The first has the highest energy—and thus is rate determining—because it requires the separation of opposite charges.

**Exercise 7-2**

Using the bond-strength data in Table 3-1, calculate the \( \Delta H^\circ \) for the hydrolysis of 2-bromo-2-methylpropane to 2-methyl-2-propanol and hydrogen bromide. **Caution:** Don’t get confused by the ionic mechanism of these reactions. The \( \Delta H^\circ \) is a measure of the thermicity of the overall transformation, regardless of mechanism (Section 2-1).
All three steps of the mechanism of solvolysis are reversible. The overall equilibrium can be driven in either direction by the suitable choice of reaction conditions. Thus, a large excess of nucleophilic solvent ensures complete solvolysis. In Chapter 9, we shall see how this reaction can be reversed to permit the synthesis of tertiary haloalkanes from alcohols.

**In Summary** The kinetics of haloalkane solvolysis lead us to a three-step mechanism. The crucial, rate-determining step is the initial dissociation of a leaving group from the starting material to form a carbocation. Because only the substrate molecule participates in the rate-limiting step, this process is called *unimolecular nucleophilic substitution*, $S_N^1$. Let us now see what other experimental observations can tell us about the $S_N^1$ mechanism.

### 7-3 Stereochemical Consequences of $S_N^1$ Reactions

The proposed mechanism of unimolecular nucleophilic substitution has predictable stereochemical consequences because of the structure of the intermediate carbocation. To minimize electron repulsion, the positively charged carbon assumes trigonal planar geometry, the result of $sp^2$ hybridization (Sections 1-3 and 1-8). Such an intermediate is therefore achiral (make a model). Hence, starting with an optically active secondary or tertiary haloalkane in which the stereocenter bears the departing halogen, under conditions favorable for $S_N^1$ reaction we should obtain racemic products (Figure 7-3). This result is, in fact, observed in many solvolyses. In general, the formation of racemic products from optically active substrates is strong evidence for the intermediate being a symmetrical, achiral species, such as a carbocation.

![Figure 7-3](image)

**Figure 7-3** The mechanism of hydrolysis of (S)-(1-bromoethyl)benzene explains the stereochemistry of the reaction. Initial ionization furnishes a planar, achiral carbocation. This ion, when trapped with water, yields racemic alcohol.

### Exercise 7-3

(R)-3-Bromo-3-methylhexane loses its optical activity when dissolved in nitromethane, a highly polar but nonnucleophilic solvent. Explain by a detailed mechanism. **(Caution:** When writing mechanisms, use “arrow pushing” to depict electron flow; write out every step separately; formulate complete structures, including charges and relevant electron pairs; and draw explicit reaction arrows to connect starting materials or intermediates with their respective products. Don’t use shortcuts, and don’t be sloppy!)
Exercise 7-4

**Working with the Concepts: Stereochemical Consequences of SN1 Displacement**

Gentle warming of (2R,4R)-2-iodo-4-methylhexane in methanol gives two stereoisomeric methyl ethers. How are they related to each other? Explain mechanistically.

**Strategy**
The substrate is secondary; therefore, substitution can proceed by either the SN1 or the SN2 mechanism. Let’s consider the reaction conditions to see which is more likely and what its consequences will be.

**Solution**
- The reaction takes place in methanol, CH₃OH, a poor nucleophile (disfavoring SN2) but a very polar, protic solvent, well suited for dissociation of secondary and tertiary haloalkanes into ions (favoring SN1).
- Dissociation of the excellent leaving group I⁻ from C2 gives a trigonal planar carbocation. Methanol may attack from either face (compare mechanism steps 1 and 2 in Section 7-2), giving two stereoisomeric oxonium ions. The positively charged oxygen makes the attached hydrogen very acidic; after proton loss, two stereoisomeric ethers result (mechanism step 3 in Section 7-2; see also Figure 7-3). We have here another example of solvolysis (specifically, methanolysis), because the nucleophile is the solvent (methanol).

(Caution! When describing the SN1 mechanism, avoid the following two very common errors: (1) Do not dissociate CH₃OH to give methoxide (CH₃O⁻) and a proton before bonding with the cationic carbon. Methanol is a weak acid whose dissociation is thermodynamically not favored. (2) Do not dissociate CH₃OH to give a methyl cation and hydroxide ion. Although the presence of the OH functional group in alcohols may remind you of the formulas of inorganic hydroxides, alcohols are not sources of hydroxide ion.)
- The two stereoisomeric ether products are diastereomers; 2S,3R and 2R,3R. At the reaction site, C2, both R and S configurations result from the two possible pathways of methanol attack, a and b. At C3 a stereocenter where no reaction occurs, the original R configuration remains unchanged.

Exercise 7-5

**Try It Yourself**

Hydrolysis of molecule A (shown in the margin) gives two alcohols. Explain.
7-4 Effects of Solvent, Leaving Group, and Nucleophile on Unimolecular Substitution

As in $S_N2$ reactions, varying the solvent, the leaving group, and the nucleophile greatly affects unimolecular substitution.

Polar solvents accelerate the $S_N1$ reaction

Heterolytic cleavage of the C–X bond in the rate-determining step of the $S_N1$ reaction entails a transition-state structure that is highly polarized (Figure 7-4), leading eventually to two fully charged ions. In contrast, in a typical $S_N2$ transition state, charges are not created; rather, they are dispersed (see Figure 6-4).

Because of this polar transition state, the rate of an $S_N1$ reaction increases as solvent polarity is increased. The effect is particularly striking when the solvent is changed from aprotic to protic. For example, hydrolysis of 2-bromo-2-methylpropane is much faster in pure water than in a 9:1 mixture of acetone and water. The protic solvent accelerates the $S_N1$ reaction because it stabilizes the transition state shown in Figure 7-4 by hydrogen bonding with the leaving group. Remember that, in contrast, the $S_N2$ reaction is accelerated in polar *aprotic* solvents, mainly because of a solvent effect on the reactivity of the nucleophile.

The solvent nitromethane, CH$_3$NO$_2$ (see Table 6-5), is both highly polar and virtually nonnucleophilic. Therefore, it is useful in studies of $S_N1$ reactions with nucleophiles other than solvent molecules.

The $S_N1$ reaction speeds up with better leaving groups

Because the leaving group departs in the rate-determining step of the $S_N1$ reaction, it is not surprising that the rate of the reaction increases as the leaving-group ability of the departing group improves. Thus, tertiary iodoalkanes more readily undergo solvolysis than do the corresponding bromides, and bromides are, in turn, more reactive than chlorides. Sulfonates are particularly prone to departure.

**Relative Rate of Solvolysis of RX (R = Tertiary Alkyl)**

\[ X = -\text{OSO}_2R' > -\text{I} > -\text{Br} > -\text{Cl} \]
The strength of the nucleophile affects the product distribution but not the reaction rate

Does changing the nucleophile affect the rate of $S_N1$ reaction? The answer is no. Recall that, in the $S_N2$ process, the rate of reaction increases significantly as the nucleophilicity of the attacking species improves. However, because the rate-determining step of unimolecular substitution does not include the nucleophile, changing its structure (or concentration) does not alter the rate of disappearance of the haloalkane. Nevertheless, when two or more nucleophiles compete for capture of the intermediate carbocation, their relative strengths and concentrations may greatly affect the product distribution.

For example, hydrolysis of a solution of 2-chloro-2-methylpropane gives the expected 2-methyl-2-propanol (tert-butyl alcohol), with a rate constant $k_1$. Quite a different result is obtained when the same experiment is carried out in the presence of the soluble salt calcium formate: 1,1-Dimethylethyl formate (tert-butyl formate) replaces the alcohol as the product, but the reaction still proceeds at exactly the same rate $k_1$. In this case, formate ion, a better nucleophile than water, wins out in competition for bonding to the intermediate carbocation. The rate of disappearance of the starting material is determined by $k_1$ (regardless of the product eventually formed), but the relative yields of the products depend on the relative reactivities and concentrations of the competing nucleophiles.

\end{align*}
\]

### Exercise 7-6

**Working with the Concepts: Nucleophile Competition**

A solution of 1,1-dimethylethyl (tert-butyl) methanesulfonate in polar aprotic solvent containing equal amounts of sodium fluoride and sodium bromide produces 75% 2-fluoro-2-methylpropane and only 25% 2-bromo-2-methylpropane. Explain. (Hint: Refer to Section 6-8 and Problem 58 in Chapter 6 for information regarding relative nucleophilic strengths of the halide ions in aprotic solvents.)

**Strategy**

The substrate is tertiary; therefore, substitution can proceed only via the $S_N1$ mechanism. Equal amounts of the two nucleophiles are present, but the two substitution products do not form in equivalent yields. The explanation must lie in a difference in nucleophile strength and rate of carbocation trapping under the reaction conditions.

**Solution**

- Hydrogen bonding is absent in polar aprotic solvents, so nucleophilicity is determined by polarizability and basicity.
- Bromide, the larger ion, is more polarizable, but fluoride is the stronger base (see either Table 2-2 or 6-4). Which effect wins? They are closely balanced, but the table in Problem 6-58 provides the answer: In DMF (Table 6-5), Cl$^-$, the stronger base, is about twice as nucleophilic as Br$^-$. Fluoride is even more basic; consequently, it wins out over other halide ions in attacking the carbocation intermediate.
Further Reactions of Haloalkanes

In Summary

We have seen further evidence supporting the SN1 mechanism for the reaction of tertiary (and secondary) haloalkanes with certain nucleophiles. The stereochemistry of the process, the effects of the solvent and the leaving-group ability on the rate, and the absence of such effects when the strength of the nucleophile is varied, are consistent with the unimolecular route.

7-5 Effect of the Alkyl Group on the SN1 Reaction: Carbocation Stability

What is so special about tertiary haloalkanes that they undergo conversion by the SN1 pathway, whereas primary systems follow SN2? How do secondary haloalkanes fit into this scheme? Somehow, the degree of substitution at the reacting carbon must control the pathway followed in the reaction of haloalkanes (and related derivatives) with nucleophiles. We shall see that only secondary and tertiary systems can form carbocations. For this reason, tertiary halides, whose steric bulk prevents them from undergoing SN2 reactions, transform solely by the SN1 mechanism, primary haloalkanes only by SN2, and secondary haloalkanes by either route, depending on conditions.

Carbocation stability increases from primary to secondary to tertiary

We have learned that primary haloalkanes undergo only bimolecular nucleophilic substitution. In contrast, secondary systems often transform through carbocation intermediates and tertiary systems always do. The reasons for this difference are twofold. First, steric hindrance increases along the series, thereby slowing down SN2. Second, increasing alkyl substitution stabilizes carbocation centers. Only secondary and tertiary cations are energetically feasible under the conditions of the SN1 reaction.

Relative Stability of Carbocations

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_2^+ & < \text{CH}_3\text{CH}_2^+\text{CHCH}_3 & < & (\text{CH}_3)_3^+ \\
\text{Primary} & < & \text{Secondary} & < & \text{Tertiary}
\end{align*}
\]

Increasing carbocation stability

Now we can see why tertiary haloalkanes undergo solvolysis so readily. Because tertiary carbocations are more stable than their less substituted relatives, they form more easily. But what is the reason for this order of stability?

Hyperconjugation stabilizes positive charge

Note that the order of carbocation stability parallels that of the corresponding radicals. Both trends have their roots in the same phenomenon: hyperconjugation. Recall from Section 3-2 that hyperconjugation is the result of overlap of a p orbital with a neighboring bonding molecular orbital, such as that of a C–H or a C–C bond. In a radical, the p orbital is singly filled; in a carbocation, it is empty. In both cases, the alkyl group donates electron density...
to the electron-deficient center and thus stabilizes it. Figure 7-5 compares the orbital pictures of the methyl and 1,1-dimethylethyl (tert-butyl) cations and depicts the electrostatic potential maps of the methyl, ethyl, 1-methylethyl (isopropyl), and 1,1-dimethylethyl cations. Figure 7-6 shows the structure of the tertiary butyl system, which is stabilized enough to be isolated and characterized by X-ray diffraction measurements.

**Secondary systems undergo both \( S_N1 \) and \( S_N2 \) reactions**

As you will have gathered from the preceding discussion, secondary haloalkanes exhibit the most varied substitution behavior. Both \( S_N2 \) and \( S_N1 \) reactions are possible: Steric hindrance slows but does not preclude bimolecular nucleophilic attack. At the same time, unimolecular dissociation becomes competitive because of the relative stability of secondary carbocations. The pathway chosen depends on the reaction conditions: the solvent, the leaving group, and the nucleophile.

If we use a substrate carrying a very good leaving group, a poor nucleophile, and a polar protic solvent (\( S_N1 \) conditions), then unimolecular substitution is favored. If we employ a high concentration of a good nucleophile, a polar aprotic solvent, and a haloalkane bearing a reasonable leaving group (\( S_N2 \) conditions), then bimolecular substitution predominates. Table 7-2 summarizes our observations regarding the reactivity of haloalkanes toward nucleophiles.

![Figure 7-5](image-url) (A) The partial orbital picture of the methyl cation reveals why it cannot be stabilized by hyperconjugation. (B) In contrast, the 1,1-dimethylethyl (tert-butyl) cation benefits from three hyperconjugative interactions. The electrostatic potential maps of the (C) methyl, (D) ethyl, (E) 1-methylethyl (isopropyl), and (F) 1,1-dimethylethyl (tert-butyl) cations show how the initially strongly electron-deficient (blue) central carbon increasingly loses its blue color along the series because of increasing hyperconjugation.

![Figure 7-6](image-url) X-ray crystal structure determination for the 1,1-dimethylethyl (tert-butyl) cation. The four carbons lie in a plane with 120° C–C–C bond angles, consistent with sp\(^2\) hybridization at the central carbon. The C–C bond length is 1.44 Å, shorter than normal single bonds (1.54 Å), a consequence of hyperconjugative overlap.

\text{R} & \quad \text{I} & \quad + \quad \text{CH}_3\text{OH} & \quad \text{R} & \quad \text{CH}_3 & \quad \text{O} & \quad \text{R} & \quad \text{S} \\
\end{align*}
\]

**Strategy**

Both reactions have secondary substrates with good leaving groups, giving the options of substitution by either an SN1 or an SN2 pathway. As we did in Exercise 7-4, let’s look at the nucleophiles and solvents in each case.

**Solution**

- In reaction (a), cyanide ion, CN\textsuperscript{-}, is a good nucleophile (Table 6-7), and acetone is a polar aprotic solvent, a combination that favors the SN2 mechanism. Backside attack occurs, leading to inversion at the site of displacement (see Figure 6-4).
- In reaction (b), methanol, CH\textsubscript{3}OH, is both the solvent and the nucleophile. As in Exercise 7-4, we have the conditions for solvolysis via the SN1 mechanism, leading to both enantiomeric ether products.

**Exercise 7-9**

Try It Yourself

Would treatment of R-2-chlorobutane with aqueous ammonia be a good synthetic method for the preparation of R-2-butanolamine, R-CH\textsubscript{2}CH\textsubscript{2}CH(NH\textsubscript{2})CH\textsubscript{3}? Why or why not? Can you think of a better route?

---

The first five sections of this chapter have given us the background for understanding how the SN1 mechanism takes place and what factors favor its occurrence. It is useful to keep in mind that two conditions must be satisfied before dissociation of a carbon–halogen bond into ions can occur: The carbon atom must be secondary or tertiary so that the carbocation has sufficient thermodynamic stability to form, and the reaction must take place in a polar solvent capable of interacting with and stabilizing both positive and
negative ions. Nevertheless, carbocations are common intermediates that will appear in the reactions of many of the compound classes that we will study in the chapters to come.

**Which is “greener”: \( S_N1 \) or \( S_N2 \)?**

The contrast between the stereochemical outcomes of the \( S_N1 \) and \( S_N2 \) mechanisms directly affects the comparative utility of the two processes in synthesis. The \( S_N2 \) process is *stereo-specific*: Reaction of a single stereoisomeric substrate gives a single stereoisomeric product (Section 6-6). In contrast, virtually all reactions that proceed via the \( S_N1 \) mechanism at a stereocenter give mixtures of stereoisomers. And it gets worse: The chemistry of carbocations, the intermediates in all \( S_N1 \) reactions, is complex. As we shall see in Chapter 9, these species are prone to rearrangements, frequently resulting in complicated collections of products. In addition, carbocations undergo another important transformation to be described next: *loss of a proton* to furnish a double bond.

In the final analysis, \( S_N1 \) reactions, unlike \( S_N2 \) processes, are of limited use in synthesis because they fail the first two criteria of “green” reactions (see Chemical Highlight 3-1): They are poor in atom efficiency and wasteful overall, because they tend to lead to mixtures of stereoisomeric substitution products as well as other organic compounds. \( S_N2 \) is “greener.”
In Summary Tertiary haloalkanes are reactive in the presence of nucleophiles even though they are too sterically hindered to undergo $S_n2$ reactions: The tertiary carbocation is readily formed because it is stabilized by hyperconjugation. Subsequent trapping by a nucleophile, such as a solvent (solvolysis), results in the product of nucleophilic substitution. Primary haloalkanes do not react in this manner: The primary cation is too highly energetic (unstable) to be formed in solution. The primary substrate follows the $S_n2$ route. Secondary systems are converted into substitution products through either pathway, depending on the nature of the leaving group, the solvent, and the nucleophile.

7-6 Unimolecular Elimination: E1

We know that carbocations are readily attacked by nucleophiles at the positively charged carbon. However, this is not their only mode of reaction. A competing alternative is deprotonation by the nucleophile acting as a base, furnishing a new class of compounds, the alkenes. This process is possible because the proton neighboring the positive charge is unusually acidic.

Starting from a haloalkane, the overall transformation constitutes the removal of HX with the simultaneous generation of a double bond. The general term for such a process is elimination, abbreviated E.

Eliminations can take place by several mechanisms. Let us first establish the mechanism that is followed in solvolysis.

When 2-bromo-2-methylpropane is dissolved in methanol, it disappears rapidly. As expected, the major product, 2-methoxy-2-methylpropane, arises by solvolysis. However, there is also a significant amount of another compound, 2-methylpropene, the product of elimination of HBr from the original substrate. Thus, in competition with the $S_n1$ process, which leads to displacement of the leaving group, another mechanism transforms the tertiary halide, giving rise to the alkene. What is this mechanism? Is it related to the $S_n1$ reaction?

Once again we turn to a kinetic analysis and find that the rate of alkene formation depends on the concentration of only the starting halide; the reaction is first order. Because they are unimolecular, eliminations of this type are labeled E1. The rate-determining step in the E1 process is the same as that in $S_n1$ reactions: dissociation to a carbocation. This intermediate then has a second pathway at its disposal along with nucleophilic
trapping: loss of a proton from a carbon adjacent to the one bearing the positive charge.

Competition Between E1 and SN1 in the Methanolysis of 2-Bromo-2-methylpropane

\[
\begin{align*}
(\text{CH}_3)_2\text{CBr}: & \quad \text{E1} \quad \text{H}_3\text{C} - \text{C} - \text{H} + \text{:Br}^- \\
(\text{CH}_3)_2\text{C} & \quad \text{CH}_3 + \text{:Br}^- \\
\rightarrow & \quad \text{CH}_3 \quad \text{CH}_3
\end{align*}
\]

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH}_3 + \text{H}^+ + \text{:Br}^- \\
\text{H}_3\text{C} & \quad \text{C} = \text{C} + \text{H}^+ + \text{:Br}^- \\
\text{H}_3 & \quad \text{OCH}_3 + \text{H}^+ + \text{:Br}^- \\
\end{align*}
\]

20% 2-Methylpropene
80% 2-Methoxy-2-methylpropane

How exactly is the proton lost? Figure 7-7 depicts this process with orbitals. Although we often show protons that evolve in chemical processes by using the notation H\(^+\), “free” protons do not participate under the conditions of ordinary organic reactions. A Lewis base typically removes the proton (Section 2-2). In aqueous solution, water plays this role, giving H\(_3\)O\(^+\); here, the proton is carried off by CH\(_3\)OH as CH\(_3\)OH\(^+\), an alklyloxonium ion. The carbon left behind rehybridizes from sp\(^3\) to sp\(^2\). As the C–H bond breaks, its electrons shift to overlap in a \(\pi\) fashion with the vacant \(p\) orbital at the neighboring cationic center. The result is a hydrocarbon containing a double bond: an alkene. The complete mechanism is shown on the following page.

**Figure 7-7** The alkene-forming step in unimolecular elimination (E1): deprotonation of a 1,1-dimethylethyl (tert-butyl) cation by the solvent methanol. In an orbital description of proton abstraction, an electron pair on the oxygen atom in the solvent attacks a hydrogen on a carbon adjacent to that bearing the positive charge. The proton is transferred, leaving an electron pair behind. As the carbon rehybridizes from \(sp^3\) to \(sp^2\), these electrons redistribute over the two \(p\) orbitals of the new double bond.
Chapter 7
Further Reactions of Haloalkanes

The E1 Reaction Mechanism

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \rightleftharpoons \text{CH}_3\text{CH}_2\text{CH}_2\text{Br}^+ + \text{Br}^- \]

\[ + \text{H}_2\text{C}=\text{C}=\text{CH}_2 \rightarrow \text{H}_2\text{C}=\text{C}=\text{CH}_3 + \text{H}^+ \text{OCH}_3 \]

Any hydrogen positioned on any carbon next to the center bearing the leaving group can participate in the E1 reaction. The 1,1-dimethylethyl (tert-butyl) cation has nine such hydrogens, each of which is equally reactive. In this case, the product is the same regardless of the identity of the proton lost. In other cases, more than one product may be obtained. These pathways will be discussed in more detail in Chapter 11.

The E1 Reaction Can Give Product Mixtures

\[ (\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}(_\text{3})\text{CH}_3 \rightleftharpoons (\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}(_\text{3})\text{CH}_3) + \text{H}^+ \text{OCH}_3 \]

\[ + \text{CH}_3\text{CH}_2\text{CH}(_\text{2})\text{CH}(_\text{3})\text{CH}_3 + \text{CH}_3\text{CH}_2\text{CH}(_\text{3})\text{CH}_2\text{CH}(_\text{3})\text{CH}_2\text{CH}(_\text{3})\text{CH}_3 \]

The nature of the leaving group should have no effect on the ratio of substitution to elimination, because the carbocation formed is the same in either case. This is indeed observed (Table 7-3). The product ratio may be affected by the addition of base, but at low base concentration this effect is usually small. Recall that strong bases are usually strong nucleophiles as well (Section 6-8), so addition of a base will generally not greatly favor deprotonation of the carbocation at the expense of nucleophilic attack, and the ratio of E1 to S\text{N}1 products remains approximately constant. Indeed, elimination by the E1 mechanism is usually no more than a minor side reaction accompanying S\text{N}1 substitution.

Is there a way to make elimination the major outcome, to give alkenes as major products? Yes: By using high concentrations of strong base, the proportion of elimination rises dramatically. This effect does not arise from a change in the E1:S\text{N}1 ratio, however. Instead, a new mechanistic pathway for elimination is responsible. The next section describes this process.

**Exercise 7-10**

When 2-bromo-2-methylpropane is dissolved in aqueous ethanol at 25°C, a mixture of (CH\text{3})\text{3COCH}_2\text{CH}_3 (30%), (CH\text{3})\text{3COH} (60%), and (CH\text{3})\text{2C}==\text{CH}_2 (10%) is obtained. Explain.

**In Summary** Carbocations formed in solvolysis reactions are not only trapped by nucleophiles to give S\text{N}1 products but also deprotonated in an elimination (E1) reaction. In this process, the nucleophile (usually the solvent) acts as a base.

---

*This notation indicates that the elements of the acid have been removed from the starting material. In reality, the proton ends up protonating a Lewis base. This symbolism will be used occasionally in other elimination reactions in this book.*

7-7 Bimolecular Elimination: E2

In addition to $\text{S}_\text{N}2$, $\text{S}_\text{N}1$, and E1 reactions, there is a fourth pathway by which haloalkanes may react with nucleophiles that are also strong bases: elimination by a bimolecular mechanism. This method is the one employed when alkene formation is the desired outcome.

Strong bases effect bimolecular elimination

The preceding section taught us that unimolecular elimination may compete with substitution. However, a dramatic change of the kinetics is observed at higher concentrations of strong base. The rate of alkene formation becomes proportional to the concentrations of both the starting halide and the base: The kinetics of elimination are now second order and the process is called bimolecular elimination, abbreviated E2.

**Kinetics of the E2 Reaction of 2-Chloro-2-methylpropane**

$$\text{(CH}_3\text{)}_2\text{CCl} + \text{Na}^+\text{OH} \xrightarrow{k} \text{CH}_2\text{=C(CH}_3\text{)}_2 + \text{NaCl} + \text{H}_2\text{O}$$

Rate = $k[(\text{CH}_3\text{)}_2\text{CCl}][\text{OH}] \text{ mol L}^{-1} \text{s}^{-1}$

What causes this change in mechanism? Strong bases (such as hydroxide, $\text{HO}^-$, and alkoxides, $\text{RO}^-$) can attack haloalkanes before carbocation formation. The target is a hydrogen on a carbon atom next to the one carrying the leaving group. This reaction pathway is not restricted to tertiary halides, although in secondary and primary systems it must compete with the $\text{S}_\text{N}2$ process. Section 7-8 will describe the conditions under which $\text{S}_\text{N}2$ or E2 reaction predominates with these substrates.

**Exercise 7-11**

What products do you expect from the reaction of bromocyclohexane with hydroxide ion?

**Exercise 7-12**

Give the products (if any) of the E2 reaction of the following substrates: $\text{CH}_3\text{CH}_2\text{I}; \text{CH}_3\text{I}; (\text{CH}_3\text{)}_2\text{CCl}; (\text{CH}_3\text{)}_3\text{CCH}_2\text{I}$.

E2 reactions proceed in one step

The bimolecular elimination mechanism consists of a single step. The bonding changes that occur in its transition state are shown here with electron-pushing arrows; in Figure 7-8, they are shown with orbitals. Three changes take place:

1. Deprotonation by the base
2. Departure of the leaving group
3. Rehybridization of the reacting carbon centers from $sp^3$ to $sp^2$ to furnish the two $p$ orbitals of the emerging double bond

**The E2 Reaction Mechanism**

All three changes take place simultaneously: The E2 is a one-step, concerted process.
Further Reactions of Haloalkanes

Chapter 7

Figure 7-8 Orbital description of the E2 reaction of 2-chloro-2-methylpropane with hydroxide ion.

Notice that the E1 (Figure 7-7) and E2 mechanisms are very similar, differing only in the sequence of events. In the bimolecular reaction, proton abstraction and leaving-group departure are simultaneous, as depicted in the transition state above (for a Newman projection, see margin). In the E1 process, the halide leaves first, followed by an attack by the base. A good way of thinking about the difference is to imagine that the strong base participating in the E2 reaction is more aggressive. It does not wait for the tertiary or secondary halide to dissociate but attacks the substrate directly.

Experiments elucidate the detailed structure of the E2 transition state

What is the experimental evidence in support of a one-step process with a transition state like that depicted in Figure 7-8? There are three pieces of relevant information. First, the second-order rate law requires that both the haloalkane and the base take part in the rate-determining step. Second, better leaving groups result in faster eliminations. This observation implies that the bond to the leaving group is partially broken in the transition state.

Newman Projection of E2 Transition State

Relative Reactivity in the E2 Reaction

RI > RBr > RCl > RF

Exercise 7-13

Explain the result in the reaction shown below.

The third observation not only strongly suggests that both the C–H and the C–X bonds are broken in the transition state, it also describes their relative orientation in space when this event takes place. Figure 7-8 illustrates a characteristic feature of the E2 reaction: its stereochemistry. The substrate is pictured as reacting in a conformation that places the breaking C–H and C–X bonds in an anti relation. How can we establish the structure of the transition state with such precision? For this purpose, we can use the principles of conformation and stereochemistry. Treatment of cis-1-bromo-4-(1,1-dimethylethyl)cyclohexane with strong base leads to rapid bimolecular elimination to the corresponding alkene. In contrast,
under the same conditions, the trans isomer reacts only very slowly. Why? When we exam-
ise the most stable chair conformation of the cis compound, we find that two hydrogens are
located anti to the axial bromine substituent. This geometry is very similar to that required
by the E2 transition state, and consequently elimination is easy. Conversely, the trans system
has no C–H bonds aligned anti to the equatorial leaving group (make a model). E2 elimina-
tion in this case would require either ring-flip to a diaxial conformer (see Section 4-4) or
removal of a hydrogen gauche to the bromine, both of which are energetically costly. The
latter would be an example of an elimination proceeding through an unfavorable syn transi-
tion state (syn, Greek, together). We shall return to E2 elimination in Chapter 11.

**Anti Elimination Occurs Readily for cis- but Not for trans-1-Bromo-4-(1,1-dimethylethyl)cyclohexane**

![Model Building](image)

**Exercise 7-14**

**Working with the Concepts: Elimination Rates and Mechanisms**

The rate of elimination of cis-1-bromo-4-(1,1-dimethylethyl)cyclohexane is proportional to the
centration of both substrate and base, but that of the trans isomer is proportional only to the
centration of the substrate. Explain.

**Strategy**

In this problem we are given rate information that we need to explain. Throughout Chapters 6 and
7 we have seen how reaction kinetics can help define mechanism. Apply the lessons: Consider the
kinetic order of each reaction and the consequences of the corresponding mechanism.

**Solution**

- Because the base-promoted elimination of cis-1-bromo-4-(1,1-dimethylethyl)cyclohexane occurs
  with a rate proportional to both substrate and base, it must be following the E2 pathway.
- The E2 reaction strongly favors an anti orientation of the leaving group with respect to the
  proton being removed. The graphic (above, left) shows that this orientation is already present in
  the most stable chair conformation of the substrate molecule. Thus the E2 mechanism readily
  occurs, with the base removing an H (blue) and initiating simultaneous expulsion of Br (green).
- In contrast, in the trans isomer (graphic, above right) the best conformation places the Br equatorial;
  the C–Br bond is anti to two C–C bonds of the cyclohexane ring (blue). No hydrogen on either
  adjacent carbon is anti with respect to the Br. E2 cannot readily occur from this conformation.
- For the trans isomer to undergo easy E2 reaction, it would first have to undergo ring-flip in order
  for the Br to become axial. The energy of this ring-flip is prohibitively unfavorable, however,
  because the result would be a very high-energy conformation with the bulky tertiary butyl group
  also in an axial position (see Table 4-3).
In Summary

Strong bases react with haloalkanes not only by substitution, but also by elimination. The kinetics of these reactions are second order, an observation that points to a bimolecular mechanism. An anti transition state is preferred, in which the base abstracts a proton at the same time as the leaving group departs.

Competition Between Substitution and Elimination: Structure Determines Function

The multiple reaction pathways—SN2, SN1, E2, and E1—that haloalkanes may follow in the presence of nucleophiles may seem confusing. Given the many parameters that affect the relative importance of these transformations, are there some simple guidelines that might allow us to predict, at least roughly, what the outcome of any particular reaction will be? The answer is a cautious yes. This section will explain how consideration of base strength and steric bulk of the reacting species can help us decide whether substitution or elimination will predominate. We shall see that variation of these parameters may even permit control of the reaction pathway.

Weakly basic nucleophiles give substitution

Good nucleophiles that are weaker bases than hydroxide give good yields of SN2 products with primary and secondary halides and of SN1 products with tertiary substrates. Examples include I-, Br-, RS-, N3-, RCOO-, and PR3. Thus, 2-bromopropane reacts with both iodide and acetate ions cleanly through the SN2 pathway, with virtually no competing elimination.
Weak nucleophiles such as water and alcohols react at appreciable rates only with secondary and tertiary halides, substrates capable of following the S\textsubscript{N}1 pathway. Unimolecular elimination is usually only a minor side reaction.

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \xrightarrow{\text{H}_2\text{O}, \text{CH}_3\text{OH, 80}^\circ\text{C}} \text{CH}_3\text{CH}_2\text{CH}_2\text{OCH}_2\text{CH}_3 \quad 85\% \quad \text{CH}_3\text{CH}==\text{CH}_2\text{CH}_3 \quad 15\%$$

**Strongly basic nucleophiles give more elimination as steric bulk increases**

We have seen (Section 7-7) that strong bases may give rise to elimination through the E2 pathway. Is there some straightforward way to predict how much elimination will occur in competition with substitution in any particular situation? Yes, but other factors need to be considered. Let us examine the reactions of sodium ethoxide, a strong base, with several halides, measuring the relative amounts of ether and alkene produced in each case.

Reactions of simple primary halides with strongly basic nucleophiles give mostly S\textsubscript{N}2 products. As steric bulk is increased around the carbon bearing the leaving group, substitution is retarded relative to elimination because an attack at carbon is subject to more steric hindrance than is an attack on hydrogen. Thus, branched primary substrates give about equal amounts of S\textsubscript{N}2 and E2 reaction, whereas E2 is the major outcome with secondary substrates.
The $S_N2$ mechanism is not an option for tertiary halides. $S_N1$ and $E1$ pathways compete under neutral or weakly basic conditions. However, high concentrations of strong base give exclusively $E2$ reaction.

**Sterically hindered basic nucleophiles favor elimination**

We have seen that primary haloalkanes react by substitution with good nucleophiles, including strong bases. The situation changes when the steric bulk of the nucleophile hinders attack at the electrophilic carbon. In this case, elimination may predominate, even with primary systems, through deprotonation at the less hindered periphery of the molecule.

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} \xrightarrow{\text{(CH}_3\text{)}_3\text{CO K}^+, (\text{CH}_3\text{)}_3\text{COH} \text{HBr}} \text{CH}_3\text{CH}_2\text{CH}=\text{CH}_2 + \text{CH}_3\text{CH}_2\text{CH}_2\text{OC(CH}_3)_3
\]

85% 15%

Two examples of sterically hindered bases that are frequently employed in eliminations are potassium tert-butoxide and lithium diisopropylamide (LDA). The first contains a tertiary alkyl group on oxygen; the second has two secondary alkyl groups on nitrogen. For use in such reactions, these bases are frequently dissolved in their conjugate acids, 2-methyl-2-propanol (tert-butyl alcohol) and 1-methyl-$N$-(1-methylethyl)ethanamine (diisopropylamine), respectively.

**In Summary** We have identified three principal factors that affect the competition between substitution and elimination: basicity of the nucleophile, steric hindrance in the haloalkane, and steric bulk around the nucleophilic (basic) atom.

**Factor 1.** Base strength of the nucleophile

<table>
<thead>
<tr>
<th>Weak Bases</th>
<th>Strong Bases</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\text{H}_2\text{O}^<em>$, ROH$^</em>$, PR$_3$, halides, $\text{RS}^-$, $\text{N}_3^-$, NC$^-$, RCOO$^-$</td>
<td>HO$^-$, RO$^-$, $\text{H}_2\text{N}^-$, R$_2$N$^-$</td>
</tr>
<tr>
<td>Substitution more likely</td>
<td>Likelihood of elimination increased</td>
</tr>
</tbody>
</table>

$^*$Reacts only with $S_N1$ substrates; no reaction with simple primary or methyl halides.
Factor 2. Steric hindrance around the reacting carbon

<table>
<thead>
<tr>
<th>Sterically Unhindered</th>
<th>Sterically Hindered</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary haloalkanes</td>
<td>Branched primary, secondary, tertiary haloalkanes</td>
</tr>
<tr>
<td>Substitution more likely</td>
<td>Likelihood of elimination increased</td>
</tr>
</tbody>
</table>

Factor 3. Steric hindrance in the nucleophile (strong base)

<table>
<thead>
<tr>
<th>Sterically Unhindered</th>
<th>Sterically Hindered</th>
</tr>
</thead>
<tbody>
<tr>
<td>HO⁻, CH₃O⁻, CH₂CH₂O⁻, H₂N⁻</td>
<td>(CH₃)₂CO⁻, [(CH₃)₂CH]₂N⁻</td>
</tr>
<tr>
<td>Substitution may occur</td>
<td>Elimination strongly favored</td>
</tr>
</tbody>
</table>

For simple predictive purposes, we assume that each of these factors is of equal importance in determining the ratio of elimination to substitution. Thus, “the majority rules.” This method of analysis is quite reliable. Verify that it applies to the examples of this section and the summary section that follows.

Exercise 7-16

Which nucleophile in each of the following pairs will give a higher elimination:substitution product ratio in reaction with 1-bromo-2-methylpropane?

(a) N(CH₃)₃, P(CH₃)₃  
(b) H₂N⁻, (CH₃CH)₂N⁻  
(c) I⁻, Cl⁻

Exercise 7-17

In all cases where substitution and elimination compete, higher reaction temperatures lead to greater proportions of elimination products. Thus, the amount of elimination accompanying hydrolysis of 2-bromo-2-methylpropane doubles as the temperature is raised from 25 to 65°C, and that from reaction of 2-bromopropane with ethoxide rises from 80% at 25°C to nearly 100% at 55°C. Explain.

7-9 Summary of Reactivity of Haloalkanes

Table 7-4 summarizes the substitution and elimination chemistry of primary, secondary, and tertiary haloalkanes. Each entry presents the major mechanism(s) observed for a given combination of substrate and nucleophile type.

Primary Haloalkanes. Unhindered primary alkyl substrates always react in a bimolecular way and almost always give predominantly substitution products, except when sterically

| Table 7-4 Likely Mechanisms by Which Haloalkanes React with Nucleophiles (Bases) |
|------------------------|-------------------------------|------------------------|------------------------|
| Type of haloalkane     | Poor nucleophile (e.g., H₂O) | Weakly basic, good nucleophile (e.g., I⁻) | Strongly basic, unhindered nucleophile (e.g., CH₃O⁻) | Strongly basic, hindered nucleophile (e.g., (CH₃)₂CO⁻) |
| Methyl                 | No reaction                  | S₉₂                    | S₉₂                    | S₉₂                    |
| Primary Unhindered     | No reaction                  | S₉₂                    | S₉₂                    | E₂                     |
| Branch                 | No reaction                  | S₉₂                    | E₂                     | E₂                     |
| Secondary              | Slow S₉₁, E₁                 | S₉₂                    | E₂                     | E₂                     |
| Tertiary               | S₉₁, E₁                      | S₉₁, E₁                | E₂                     | E₂                     |
hindered strong bases, such as potassium tert-butoxide, are employed. In these cases, the S_N2 pathway is slowed down sufficiently for steric reasons to allow the E2 mechanism to take over. Another way of reducing substitution is to introduce branching. However, even in these cases, good nucleophiles still furnish predominantly substitution products. Only strong bases, such as alkoxides, RO^-, or amides, R_2N^-, tend to react by elimination.

**Exercise 7-18**

Write the structure of the major organic product of the reaction of 1-bromopropane with (a) NaCN in acetone; (b) NaOCH_3 in CH_3OH; (c) (CH_3)_2COK in (CH_3)_3COH.

**Exercise 7-19**

Write the structure of the major organic product of the reaction of 1-bromo-2-methylpropane with (a) NaI in acetone; (b) NaOCH_2CH_3 in CH_3CH_2OH.

Primary (and methyl) haloalkanes react so exceedingly slowly with poor nucleophiles that for practical purposes we consider the combination to give “no reaction.”

**Secondary Haloalkanes.** Secondary alkyl systems undergo, depending on conditions, both eliminations and substitutions by either possible pathway: uni- or bimolecular. Good nucleophiles favor S_N2, strong bases result in E2, and weakly nucleophilic polar media give mainly S_N1 and E1.

**Exercise 7-20**

Write the structure of the major organic product of the reaction of 2-bromopropane with (a) CH_3CH_2OH; (b) NaSCH_3 in CH_3CH_2OH; (c) NaOCH_2CH_3 in CH_3CH_2OH.

**Tertiary Haloalkanes.** Tertiary systems eliminate (E2) with concentrated strong base and are substituted in nonbasic media (S_N1). Bimolecular substitution is not observed, but elimination by E1 accompanies S_N1.

**Exercise 7-21**

Write the structure of the major organic product of the reaction of (a) 2-bromo-2-methylbutane with water in acetone; (b) 3-chloro-3-ethylpentane with NaOCH_3 in CH_3OH.

**Exercise 7-22**

Predict which reaction in each of the following pairs will have a higher E2:E1 product ratio and explain why.

(a) CH_3CH_2CHBr \[\xrightarrow{\text{CH}_3\text{OH}}\] ? \hfill (CH_3)CHCHBr \[\xrightarrow{\text{CH}_3\text{OH, Na}^+}\] ?

(b) I \[\xrightarrow{\text{CH}_3\text{CHN}^+, \text{CH}_3\text{CHNH}}\] ? \hfill \[\text{Nitromethane}\] ?
THE BIG PICTURE

We have completed our study of haloalkanes by describing three new reaction pathways—SN1, E1, and E2—that are available to this class of compounds, in addition to the SN2 process. We see now that details can make a big difference! Small changes in substrate structure can completely alter the course followed by the reaction of a haloalkane with a nucleophile. Similarly, correctly identifying a reaction product may require that we be able to assign both nucleophile and base strength to a reagent.

The final two sections in this chapter showed how the interplay of these factors affects the outcome of a reaction. However, learning to solve problems of this type correctly requires the use of accurate information. Therefore, we make the following study suggestion: Practice solving problems first with your textbook and your class notes open, so that you can find the correct, applicable information as you are trying to devise a solution. Remember, much of the problem solving you will be doing throughout this course will require extrapolation from examples presented to you in various contexts. If you are comfortable studying in small groups, propose reaction problems to one another, and analyze their components in order to determine what process or processes are likely to occur.

Where do we go from here? We next examine compounds containing polar carbon–oxygen single bonds, comparing them with polar carbon–halogen bonds. The alcohols will be first; they add the feature of a polar O–H bond as well. Over the next two chapters we shall see that some of the conversions of these and related compounds follow very similar mechanistic pathways, as do the reactions of haloalkanes. Such parallels between the structures of functional groups and the mechanisms of their reactions provide a useful framework for comprehending the extensive body of information in organic chemistry.

CHAPTER INTEGRATION PROBLEMS

7-23. Consider the reaction shown below. Will it proceed by substitution or by elimination? What factors determine the most likely mechanism? Write the expected product and the mechanism by which it forms.

\[
\begin{align*}
\text{CH}_3\text{CH}_3\text{Cl} & \xrightarrow{\text{NaOCH}_2\text{CH}_3, \text{CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{CHCH}_3 \\
\end{align*}
\]

SOLUTION

The fact that the compound is cyclic does not change how we approach the problem. The substrate is secondary because the leaving group is attached to a secondary carbon. The nucleophile (ethoxide ion, derived from NaOCH\(_2\)CH\(_3\)) is a good one, but, like hydroxide and methoxide (see Table 6-4), it is also a strong base. Based on the evaluation criteria in Sections 7-8 and 7-9, the combination of a secondary substrate and a strongly basic nucleophile will favor elimination by the E2 pathway (Table 7-4). This mechanism has specific requirements with regard to the relative geometric arrangement of the leaving group and the hydrogen being removed by the base: They must possess an anti conformation with respect to the carbon–carbon bond between them (Section 7-7). In order to prepare a reasonable structural representation of the molecule, we must make use of what we learned in Chapter 4 (Section 4-4) about conformations of substituted cyclohexanes. The best available shape is the chair shown below, in which two of the substituents, including the bulky 1-methylethyl (isopropyl) group, are equatorial. Note that the leaving group is axial, and one of the neighboring carbons possesses an axial hydrogen, positioned in the required orientation anti to the chlorine:
We draw curved arrows appropriate to the one-step E2 mechanism, arriving at the product structure shown, a cyclic alkene, with the double bond located in the indicated position. The methyl group on the alkene carbon moves into the plane of the double bond (recall from Section 1-8 that alkene carbons exhibit trigonal planar geometry—sp$^2$ hybridization). Notice that the remaining two alkyl groups, which started cis, remain cis with respect to each other, because no chemical change occurred to the ring carbons on which they were located.

**Avoid the very common error** of removing a hydrogen from the wrong carbon atom in an E2 process. In the correct mechanism the hydrogen comes off a carbon atom adjacent to that bearing the leaving group; never from the same carbon.

### 7-24. a.

2-Bromo-2-methylpropane (tert-butyl bromide) reacts readily in nitromethane with chloride and iodide ions.

1. Write the structures of the substitution products, and write the complete mechanism by which one of them is formed.
2. Assume equal concentrations of all reactants, and predict the relative rates of these two reactions.
3. Which reaction will give more elimination? Write its mechanism.

#### SOLUTION

1. We begin by analyzing the participating species and then recognizing just what kind of reaction is likely to take place. The substrate is a haloalkane with a good leaving group attached to a tertiary carbon. According to Table 7-4, displacement by the S$_{N}$2 mechanism is not an option, but S$_{N}$1, E1, and E2 processes are possibilities. Chloride and iodide are good nucleophiles and weak bases, suggesting that substitution should predominate to give (CH$_3$)$_3$CCl and (CH$_3$)$_3$CI as the products, respectively (Section 7-8). The mechanism (S$_{N}$1) is as shown in Section 7-2 except that, subsequent to initial ionization of the C–Br bond to give the carbocation, halide ion attacks at carbon to give the final product directly. The very polar nitromethane is a good solvent for S$_{N}$1 reactions (Section 7-4).

2. We learned in Section 7-4 that different nucleophilic power has no effect on the rates of unimolecular processes. The rates should be (and, experimentally, are) identical.

3. This part requires a bit more thought. According to Table 7-4 and Section 7-8, elimination by the E1 pathway always accompanies S$_{N}$1 displacement. However, increasing the base strength of the nucleophile may “turn on” the E2 mechanism, increasing the proportion of elimination product. Referring to Tables 6-4 and 6-7, we see that chloride is more basic (and less nucleophilic) than iodide. More elimination is indeed observed with chloride than with iodide. The mechanism is as shown in Figure 7-7, with chloride acting as the base to remove a proton from the carbocation.

#### b.

The table in the margin presents data for the reactions that take place when the chloro compound shown here is dissolved in acetone containing varying quantities of water and sodium azide, NaN$_3$:

| H$_2$O % | [N$_3$]$^-$ % | RN$_3$ % | $k_{rel}$

*Too fast to measure.

In the table, H$_2$O% is the percentage of water by volume in the solvent, [N$_3$]$^-$ is the initial concentration of sodium azide, RN$_3$% is the percentage of organic azide in the product mixture (the remainder is the alcohol), and $k_{rel}$ is the relative rate constant for the reaction, derived from the rate at which the starting material is consumed. The initial concentration of substrate is 0.04 M in all experiments. Answer the following questions.

1. Describe and explain the effects of changing the percentage of H$_2$O on the rate of the reaction and on the product distribution.
2. Do the same for the effects of changing [N$_3$]$^-$]. Additional information: The reaction rates shown are the same when other ions—for example, Br$^-$ or I$^-$ —are used instead of azide.
SOLUTION

1. We begin by examining the data in the table, specifically rows 2–5, which compare reactions in the presence of different amounts of water at constant azide concentration. The rate of substitution increases rapidly as the proportion of water goes up, but the ratio of the two products stays the same: 60% azide and 40% alcohol. These two results suggest that the only effect of increasing the amount of water is to make the solvent environment more polar, thereby speeding up the initial ionization of the substrate. Even when the proportion of water is only 10%, it is present in great excess and is trapping carbocations as fast as it can, relative to the rate at which azide ion reacts with the same intermediates (Section 7-2).

2. We note from rows 1 and 2 in the table that the reaction rate rises by about 50% when NaN₃ is added. Without further information, we might assume that this effect is a consequence of the occurrence of the Sₘ₂ mechanism. Were that to be the case, however, other anions should affect the rate differently. However, we were told that bromide and iodide, far more powerful nucleophiles, affect the measured rate in exactly the same way as does azide. We can explain this observation only by assuming that displacement is entirely by the Sₘ₁ mechanism, and added ions affect the rate only by increasing the polarity of the solution and speeding up ionization (Section 7-4).

In rows 5–8 of the table, we note that increasing the amount of azide ion increases the amount of azide-containing product that is formed. At the higher concentrations, azide, a better nucleophile than water, is better able to compete for reaction with the carbocation intermediate.

New Reactions

1. Bimolecular Substitution—Sₘ₂ (Sections 6-2 through 6-9, 7-5)

Primary and secondary substrates only

\[
\text{H}_2\text{C} - \text{C} - \text{I} \quad \text{H}^+ \quad \text{Nu}^- \quad \text{Nu}^- \quad \text{C} - \text{H} \quad \text{CH}_3 \quad + \quad \text{I}^- \\
\text{CH}_3\text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3
\]

Direct backside displacement with 100% inversion of configuration

2. Unimolecular Substitution—Sₘ₁ (Sections 7-1 through 7-5)

Secondary and tertiary substrates only

\[
\text{CH}_3 \quad \text{Br} \quad \text{Br} \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{C} - \text{Nu}^- \quad \text{C} - \text{Nu}^- \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3
\]

Through carbocation: Chiral systems are racemized

3. Unimolecular Elimination—E₁ (Section 7-6)

Secondary and tertiary substrates only

\[
\text{CH}_3 \quad \text{C} - \text{Cl} \quad \text{Cl} \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{C} - \text{B}^- \quad \text{C} - \text{B}^- \quad \text{CH}_2 \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3
\]

Through carbocation

4. Bimolecular Elimination—E₂ (Section 7-7)

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{I} \quad \text{B}^- \quad \text{CH}_2\text{CH}\text{CH}_2\text{I} \quad \text{CH}_2\text{CH}\text{CH}_2\text{I} \quad \text{CH}_2\text{CH}\text{CH}_2\text{I} \quad + \quad \text{BH} \quad + \quad \text{I}^- \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{I} \quad \text{B}^- \quad \text{CH}_2\text{CH}\text{CH}_2\text{I} \quad \text{CH}_2\text{CH}\text{CH}_2\text{I} \quad \text{CH}_2\text{CH}\text{CH}_2\text{I} \quad + \quad \text{BH} \quad + \quad \text{I}^- \\
\]

Simultaneous elimination of leaving group and neighboring proton

Important Concepts

1. Secondary haloalkanes undergo slow and tertiary haloalkanes undergo fast unimolecular substitution in polar media. When the solvent serves as the nucleophile, the process is called solvolysis.

2. The slowest, or rate-determining, step in unimolecular substitution is dissociation of the C–X bond to form a carbocation intermediate. Added strong nucleophile changes the product but not the reaction rate.
3. Carbocations are stabilized by hyperconjugation: Tertiary are the most stable, followed by secondary. Primary and methyl cations are too unstable to form in solution.

4. Racemization often results when unimolecular substitution takes place at a chiral carbon.

5. Unimolecular elimination to form an alkene accompanies substitution in secondary and tertiary systems.

6. High concentrations of strong base may bring about bimolecular elimination. Expulsion of the leaving group accompanies removal of a hydrogen from the neighboring carbon by the base. The stereochemistry indicates an anti conformational arrangement of the hydrogen and the leaving group.

7. Substitution is favored by unhindered substrates and small, less basic nucleophiles.

8. Elimination is favored by hindered substrates and bulky, more basic nucleophiles.

Problems

25. What is the major substitution product of each of the following solvolysis reactions?

![Reaction Diagram](attachment:image1)

26. For each reaction presented in Problem 25, write out the complete, step-by-step mechanism using curved-arrow notation. Be sure to show each individual step of each mechanism separately, and show the complete structures of the products of that step before going on to the next.

27. Write the two major substitution products of the reaction shown in the margin. (a) Write a mechanism to explain the formation of each of them. (b) Monitoring the reaction mixture reveals that an isomer of the starting material is generated as an intermediate. Draw its structure and explain how it is formed.

28. Give the two major substitution products of the following reaction.

![Reaction Diagram](attachment:image2)

29. How would each reaction in Problem 25 be affected by the addition of each of the following substances to the solvolysis mixture?

(a) H₂O  
(b) KI
(c) NaN₃  
(d) CH₃CH₂OCH₂CH₃ (Hint: Low polarity.)

30. Rank the following carbocations in decreasing order of stability.

![Carbocation Diagram](attachment:image3)
31. Rank the compounds in each of the following groups in order of decreasing rate of solvolysis in aqueous acetone.

(a) \( \text{CH}_3 \text{CH}_2 \text{CH}_2 \text{CH}_2 \text{Cl} \)
(b) \( \text{CH}_3 \text{CH}_2 \text{CH}_2 \text{CH}_3 \)
(c) \( \text{CH}_2 \text{CH}_2 \text{CH}_2 \text{Cl} \)

32. Give the products of the following substitution reactions. Indicate whether they arise through the \( S_N 1 \) or the \( S_N 2 \) process. Formulate the detailed mechanisms of their generation.

(a) \( \text{(CH}_3\text{)}_2\text{CHOSO}_2\text{CF}_3 \xrightarrow{\text{CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{Br} \)
(b) \( \text{CH}_3\text{CH}_2\text{CHClCH}_2\text{CH}_3 \)
(c) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \xrightarrow{(\text{C}_6\text{H}_5\text{)}_3\text{P, DMSO NaI, acetone}} \text{CH}_3\text{Cl} \)

33. Give the product of each of the following substitution reactions. Which of these transformations should proceed faster in a polar, aprotic solvent (such as acetone or DMSO) than in a polar, protic solvent (such as water or \( \text{CH}_3\text{OH} \))? Explain your answer on the basis of the mechanism that you expect to be operating in each case.

(a) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} + \text{Na}^+ \text{CN} \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CN}^- \)
(b) \( \text{(CH}_3\text{)}_2\text{CHCH}_2\text{I} + \text{Na}^+ \text{N}_3^- \rightarrow \text{(CH}_3\text{)}_2\text{CHCH}_2\text{N}_3^- \)
(c) \( \text{(CH}_3\text{)}_2\text{CBr} + \text{HSCCH}_3 \rightarrow \text{(CH}_3\text{)}_2\text{CBrCHCH}_3 \)
(d) \( \text{(CH}_3\text{)}_2\text{CHOSO}_2\text{CH}_3 + \text{HOCH(CH}_3\text{)}_2 \rightarrow \text{(CH}_3\text{)}_2\text{CHOSO}_2\text{CH}_3 \)

34. Propose a synthesis of \( \text{(R)}\text{-CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} \), starting from \( \text{(R)}\text{-2-chlorobutane} \).

35. Two substitution reactions of \( \text{(S)}\text{-2-bromobutane} \) are shown here. Show their stereochemical outcomes.

\[ \text{(S)-CH}_3\text{CH}_2\text{CHBrCH}_3 \xrightarrow{\text{HCOH}} \text{(S)-CH}_3\text{CH}_2\text{CHBrCH}_3 \]

36. Propose a stereocontrolled synthesis of \( \text{cis-1-acetoxy-3-methylcyclopentane} \) (margin), starting from \( \text{trans-1-chloro-3-methylcyclopentane} \).

37. The two seemingly similar reactions shown below differ in their outcomes.

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} \xrightarrow{\text{NaOH, CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH} \]
\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} \xrightarrow{\text{NaSH, CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{SH} \]

The first proceeds in high yield. The yield of the product in the second, however, is diminished by the formation of \( \text{(CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{S)}_2 \) in substantial quantities. Discuss the formation of this by-product mechanistically, and explain why it occurs in the second case but not in the first.

38. Write all possible E1 products of each reaction in Problem 25.

39. Formulate the complete step-by-step mechanisms for all the E1 processes that you identified in Problem 38.
40. Write the products of the following elimination reactions. Specify the predominant mechanism (E1 or E2) and formulate it in detail.

(a) \((\text{CH}_3\text{CH}_2)\text{CBr}\) \(\xrightarrow{\text{NaNH}_2, \text{NH}_3}\) \((\text{CH}_3\text{CH}_2)\text{CBr}\) 
(b) \((\text{CH}_3\text{CH}_2)\text{CCH}_2\text{Cl}\) \(\xrightarrow{\text{KOC(CH}_3)_3, (\text{CH}_3)_3\text{COH}}\) \((\text{CH}_3\text{CH}_2)\text{CCH}_2\text{Cl}\) 

(c) \(\text{Br}\) \(\text{CH}_2\text{CH}_3\) \(\xrightarrow{\text{Excess KOH, CH}_3\text{CH}_2\text{OH}}\) \(\text{H}_3\text{C}\) 
(d) \((\text{CH}_3\text{CH}_2)\text{Br}\) \(\xrightarrow{\text{NaNH}_2, \text{liquid NH}_3}\) \((\text{CH}_3\text{CH}_2)\text{Br}\)

41. From the list of reagents (a)–(f) below, choose all those that are most likely to give primarily
(i) \(\text{SN}_2\) reaction with primary RX; (ii) \(\text{E}_2\) reaction with primary RX; (iii) \(\text{SN}_2\) reaction with secondary RX; (iv) \(\text{E}_2\) reaction with secondary RX.

(a) \(\text{NaSCH}_3\) in \(\text{CH}_3\text{OH}\)  
(b) \(\text{CH}_3\text{CH}_2\text{COH}Li\) in \((\text{CH}_3)_2\text{COH}\)
(c) \(\text{NaNH}_2\) in liquid \(\text{NH}_3\)  
(d) \(\text{KCN}\) in \(\text{DMSO}\)
(e) \(\text{Li}\) in \(\text{NH}_3\)  
(f) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{CONa}\) in \(\text{DMF}\)

42. Predict the major product(s) that should form from reaction between 1-bromobutane and each of the following substances. By which reaction mechanism is each formed — \(\text{SN}_1\), \(\text{SN}_2\), \(\text{E}_1\), or \(\text{E}_2\)? If it appears that a reaction will either not take place or be exceedingly slow, write “no reaction.” Assume that each reagent is present in large excess. The solvent for each reaction is given.

(a) \(\text{KCl}\) in \(\text{DMF}\)  
(b) \(\text{KI}\) in \(\text{DMF}\)
(c) \(\text{KCl}\) in \(\text{CH}_3\text{NO}_2\)
(d) \(\text{NH}_3\) in \(\text{CH}_3\text{CH}_2\text{OH}\)
(e) \(\text{NaOCH}_2\text{CH}_3\) in \(\text{CH}_3\text{CH}_2\text{OH}\)
(f) \(\text{CH}_3\text{CO}_2\text{H}\)

43. Predict the major product(s) and mechanism(s) for reaction between 2-bromobutane (sec-butyl bromide) and each of the reagents in Problem 42.

44. Predict the major product(s) and mechanism(s) for reaction between 2-bromo-2-methylpropane (tert-butyl bromide) and each of the reagents in Problem 42.

45. Three reactions of 2-chloro-2-methylpropane are shown here. (a) Write the major product of each transformation. (b) Compare the rates of the three reactions. Assume identical solution polarities and reactant concentrations. Explain mechanistically.

\[(\text{CH}_3)_3\text{CCl} \xrightarrow{\text{H}_2\text{S, CH}_3\text{OH}} \text{H}_2\text{S, CH}_3\text{OH}\]
\[(\text{CH}_3)_3\text{CCl} \xrightarrow{O \xrightarrow{\text{CH}_3\text{CO}^-\text{K}^+, \text{CH}_3\text{OH}}} \text{CH}_3\text{CO}^-\text{K}^+, \text{CH}_3\text{OH}\]
\[(\text{CH}_3)_3\text{CCl} \xrightarrow{\text{CH}_3\text{O}^-\text{K}^+, \text{CH}_3\text{OH}} \text{CH}_3\text{O}^-\text{K}^+, \text{CH}_3\text{OH}\]

46. Give the major product(s) of the following reactions. Indicate which of the following mechanism(s) is in operation: \(\text{SN}_1\), \(\text{SN}_2\), \(\text{E}_1\), or \(\text{E}_2\). If no reaction takes place, write “no reaction.”

(a) \(\text{CH}_2\text{Cl}\) \(\xrightarrow{\text{KOC(CH}_3)_3, (\text{CH}_3)_3\text{COH}}\) \(\text{F}\)  
(b) \(\text{CH}_3\text{CHCH}_2\text{CH}_3\) \(\xrightarrow{\text{KBr, acetone}}\) \(\text{F}\)
(c) \(\text{H}_2\text{C}\) \(\xrightarrow{\text{H}_2\text{O}}\) \(\text{I}\)  
(d) \(\text{NaNH}_2\) in liquid \(\text{NH}_3\)
47. Fill in the blanks in the following table with the major product(s) of the reaction of each haloalkane with the reagents shown.

<table>
<thead>

48. Indicate the major mechanism(s) (simply specify Sₘ₂, Sₘ₁, E₂, or E₁) required for the formation of each product that you wrote in Problem 47.

49. For each of the following reactions, indicate whether the reaction would work well, poorly, or not at all. Formulate alternative products, if appropriate.

(a) CH₃CH₂CH₂Br → CH₃CH₂CH₂CH₃
(b) CH₃CH₂CH₂Cl → CH₃CH₂CH₂OCH₃
(c) CH₃CH₂CH₂OH → CH₃CH₂CH₂OCH₃
(d) CH₃COH → CH₃COH
(e) CH₃I → CH₃OCH₃
(f) CH₃CH₂CH₂Br → CH₃CH₂CH₂N₃
(g) (CH₃)₂CCl → (CH₃)₂Cl
(h) (CH₃)₂CO → (CH₃)₂COCH₂⁺ + I⁻
50. Propose syntheses of the following molecules from the indicated starting materials. Make use of any other reagents or solvents that you need. In some cases, there may be no alternative but to employ a reaction that results in a mixture of products. If so, use reagents and conditions that will maximize the yield of the desired material (compare Problem 53 in Chapter 6).

(a) \( \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \), from butane
(b) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{I} \), from butane
(c) \( (\text{CH}_3)_3\text{COCH}_3 \), from methane
(d) Cyclohexene, from cyclohexane and 2-methylpropane
(e) Cyclohexanol, from cyclohexane
(f) \( \begin{array}{c} \text{S} \\ \text{S} \end{array} \), from 1,3-dibromopropane

51. \([1\text{-Bromo-1-methyl}\text{ethyl}]\text{benzene}, \) shown in the margin, undergoes solvolysis in a unimolecular, strictly first-order process. The reaction rate for \([\text{RBr}] = 0.1 \text{ M RBr}\) in 9:1 acetone:water is measured to be \(2 \times 10^{-2} \text{ mol L}^{-1}\text{s}^{-1}\). (a) Calculate the rate constant \(k\) from these data. What is the product of this reaction? (b) In the presence of 0.1 M LiCl, the rate is found to increase to \(4 \times 10^{-4} \text{ mol L}^{-1}\text{s}^{-1}\), although the reaction still remains strictly first order. Calculate the new rate constant \(k_{\text{LiCl}}\) and suggest an explanation. (c) When 0.1 M LiBr is present instead of LiCl, the measured rate drops to \(1.6 \times 10^{-4} \text{ mol L}^{-1}\text{s}^{-1}\). Explain this observation, and write the appropriate chemical equations to describe the reactions.

52. In this chapter we have encountered many examples of \(S_N1\) solvolysis reactions, all of which proceed according to the following scheme:

\[
\begin{align*}
\text{R} & \xrightarrow{\text{Rate}_1 = k_1[RX]} \text{X}^- + \text{R}^+ \\
\text{R} & \xrightarrow{\text{Rate}_2 = k_2[R^{-}][\text{Nu}]} \text{OH}_2
\end{align*}
\]

Loss of a proton gives the final product. Although there is considerable evidence for the intermediacy of a carbocation, it is not directly observed normally because its combination with a nucleophile is so rapid. Recently, examples of \(S_N1\) solvolyses have been found that give rise to very unusual observations. One example is

Upon mixing the colorless substrate and solvent, a reddish-orange color is observed immediately, signaling the formation of an intermediate carbocation. This color fades over a period of about a minute, and analysis of the solution reveals the presence of the final product in 100% yield. (a) There are two reasons for the buildup of a detectable concentration of carbocation in this case. One is that the carbocation derived from dissociation of this particular substrate is unusually stable (for reasons we will explore in Chapter 22). The other is that the solvent (2,2,2-trifluoroethanol) is an unusually poor nucleophile, even compared with ordinary alcohols such as ethanol. Suggest an explanation for the poor nucleophilicity of the solvent. (b) What can you say about the relative rates of the two steps (\(\text{rate}_1\) and \(\text{rate}_2\)), and how do they compare to those in the usual \(S_N1\) reaction mechanism? (c) How might increasing carbocation stability and decreasing solvent nucleophilicity affect the relative magnitudes of \(\text{rate}_1\) and \(\text{rate}_2\) in an \(S_N1\) process? (d) Write the complete mechanism for the reaction above.

53. Match each of the following transformations to the correct reaction profile shown here, and draw the structures of the species present at all points on the energy curves marked by capital letters.
54. Formulate the structure of the most likely product of the following reaction of 4-chloro-4-methyl-1-pentanol in neutral polar solution.

\[ (\text{CH}_3)\text{CCH}_2\text{CH}_2\text{CH}_2\text{OH} \xrightarrow{\text{HCl}} \text{C}_6\text{H}_{12}\text{O} \]

In strongly basic solution, the starting material again converts into a molecule with the molecular formula C_6H_{12}O, but with a completely different structure. What is it? Explain the difference between the two results.

55. The following reaction can proceed through both E1 and E2 mechanisms.

\[ \text{C}_6\text{H}_5\text{CH}_2\text{CCl} \xrightarrow{\text{NaOCH}_3, \text{CH}_3\text{OH}} \text{C}_6\text{H}_5\text{CH} = \text{C} + \text{C}_6\text{H}_5\text{CH}_2\text{CC} = \text{CH}_2 \]

The E1 rate constant \( k_{E1} \) = \( 1.4 \times 10^{-4} \text{ s}^{-1} \) and the E2 rate constant \( k_{E2} \) = \( 1.9 \times 10^{-4} \text{ L mol}^{-1} \text{ s}^{-1} \); 0.02 M haloalkane. (a) What is the predominant elimination mechanism with 0.5 M NaOCH_3? (b) What is the predominant elimination mechanism with 2.0 M NaOCH_3? (c) At what concentration of base does exactly 50% of the starting material react by an E1 route and 50% by an E2 pathway?

56. The compound below is an example of a methyl ester. Methyl esters react with lithium iodide to give lithium carboxylate salts. The solvent in this example is pyridine (margin).

\[ \text{Pyridine} \]

Suggest several experiments that would allow you to determine the likely mechanism of this process.
57. **CHALLENGE** Ethers containing the 1,1-dimethylethyl (tert-butyl) group are readily cleaved with dilute, strong acid, as shown in the example below.

\[
\begin{align*}
\text{CF}_3\text{CO}_2\text{H}, \text{H}_2\text{O} & \rightarrow \text{CH}_3\text{OH} + \text{H}_2\text{C}=\text{CH}_2
\end{align*}
\]

Suggest a plausible mechanism for this process. What role might the strong acid play?

58. Give the mechanism and major product for the reaction of a secondary haloalkane in a polar aprotic solvent with the following nucleophiles. The \( pK_a \) value of the conjugate acid of the nucleophile is given in parentheses.

(a) \( \text{N}_3^- \) (4.6)  
(b) \( \text{H}_2\text{N}^- \) (35)  
(c) \( \text{NH}_3 \) (9.5)  
(d) \( \text{HSe}^- \) (3.7)  
(e) \( \text{F}^- \) (3.2)  
(f) \( \text{C}_6\text{H}_5\text{O}^- \) (9.9)  
(g) \( \text{PH}_3 \) (−12)  
(h) \( \text{NH}_2\text{OH} \) (6.0)  
(i) \( \text{NCS}^- \) (0.7)

59. Cortisone is an important steroidal anti-inflammatory agent. Cortisone can be synthesized efficiently from the alkene shown here.

Of the following three chlorinated compounds, two give reasonable yields of the alkene shown above by E2 elimination with base, but one does not. Which one does not work well, and why? What does it give during attempted E2 elimination? (Hint: Consider the geometry of each system.)

60. **CHALLENGE** The chemistry of derivatives of trans-decalin is of interest because this ring system is part of the structure of steroids. Make models of the brominated systems (i and ii) to help you answer the following questions.

(a) One of the molecules undergoes E2 reaction with \( \text{NaOCH}_2\text{CH}_3 \) in \( \text{CH}_3\text{CH}_2\text{OH} \) considerably faster than does the other. Which molecule is which? Explain. (b) The following deuterated analogs of systems i and ii react with base to give the products shown.
Specify whether anti or syn eliminations have taken place. Draw the conformations that the molecules must adopt for elimination to occur. Does your answer to (b) help you in solving (a)?

Team Problem

61. Consider the general substitution-elimination reactions of the bromoalkanes.

\[ \text{RBr} \xrightarrow{\text{Nu/base}} \text{RNu} + \text{alkene} \]

How do the reaction mechanisms and product formation differ when the structure of the substrate and reaction conditions change? To begin to unravel the nuances of bimolecular and unimolecular substitution and elimination reactions, focus on the treatment of bromoalkanes A through D under conditions (a) through (e). Divide the problem evenly among yourselves so that each of you tackles the questions of reaction mechanism(s) and qualitative distribution of product(s), if any. Reconvene to discuss your conclusions and come to a consensus. When you are explaining a reaction mechanism to the rest of the team, use curved arrows to show the flow of electrons. Label the stereochemistry of starting materials and products as R or S, as appropriate.

(a) NaN_3, DMF  (b) LDA, DMF  (c) NaOH, DMF  (d) CH_3CO^-Na^+, CH_3COH  (e) CH_3OH

Preprofessional Problems

62. Which of the following haloalkanes will undergo hydrolysis most rapidly?
(a) (CH_3)_3CF  (b) (CH_3)_3CCl  (c) (CH_3)_3CBr  (d) (CH_3)_3CI

63. The reaction

\[ (\text{CH}_3)_3\text{CCl} \xrightarrow{\text{CHO}} \text{H}_3\text{C} - \text{C} = \text{CH}_2 \]

is an example of which of the following processes?
(a) E1  (b) E2  (c) S_N1  (d) S_N2
64. In this transformation,

\[ A \xrightarrow{\text{H}_2\text{O, acetone}} \text{CH}_3\text{CH}_2\text{C(CH}_3\text{)}_2\text{OH} \]

what is the best structure for \( A \)?

(a) BrCH\(_2\)CH\(_2\)CH(CH\(_3\))\(_2\)  
(b) CH\(_3\)CH\(_2\)CBr  
(c) CH\(_3\)CH\(_2\)CH  
(d) CH\(_3\)CHCH(CH\(_3\))\(_2\)  

65. Which of the following isomeric carbocations is the most stable?

(a)  
(b)  
(c)  
(d)  

66. Which reaction intermediate is involved in the following reaction?

\[ \text{2-Methylbutane} \xrightarrow{\text{Br}_2, \text{hv}} \text{2-bromo-3-methylbutane (not the major product)} \]

(a) A secondary radical  
(b) A tertiary radical  
(c) A secondary carbocation  
(d) A tertiary carbocation
What is your first thought when you hear the word “alcohol”? Undoubtedly, whether pleasant or not, it is connected in some way to ethanol, which is the alcohol in alcoholic beverages. The euphoric effects of (limited) ethanol consumption have been known and purposely used for thousands of years. This is perhaps not surprising, because ethanol is naturally generated by the fermentation of carbohydrates. For example, the addition of yeast to an aqueous sugar solution leads to the evolution of CO₂ and the formation of ethanol.

\[
\text{C}_6\text{H}_{12}\text{O}_6 \xrightarrow{\text{Yeast enzymes}} 2 \text{CH}_3\text{CH}_2\text{OH} + 2 \text{CO}_2
\]

Fermentation is currently employed on a large scale to supply the vast quantities of ethanol needed as a renewable “green” fuel source, so-called bioethanol or, as a 10% additive to gasoline, gasohol. A variety of feed stocks, such as sugar cane, corn, switchgrass, and straw, can be converted quite efficiently to ethanol in this way (see Chemical Highlight 3-1). Worldwide production in 2008 was estimated at 15 billion gallons.

Ethanol is a member of a large family of compounds called **alcohols**. This chapter introduces you to some of their chemistry. From Chapter 2, we know that alcohols have carbon backbones bearing the substituent OH, the **hydroxy**

- Water
- Methanol (An alcohol)
- Methoxymethane (Dimethyl ether) (An ether)
functional group. Alcohols may be viewed as derivatives of water in which one hydrogen has been replaced by an alkyl group. Replacement of the second hydrogen gives an ether (Chapter 9). The hydroxy function is readily converted to other functional groups, such as the C=C double bond in alkenes (Chapters 7, 9, and 11) or the C=O bond in aldehydes and ketones (this chapter and Chapter 17).

Alcohols are abundant in nature and varied in structure (see, e.g., Section 4-7). Simple alcohols are used as solvents; others aid in the synthesis of more complex molecules. They are a good example of how functional groups shape the structure and function of organic compounds.

Our discussion begins with the naming of alcohols, followed by a brief description of their structures and other physical properties, particularly in comparison with those of the alkanes and haloalkanes. Finally, we examine the preparation of alcohols, which will introduce our first study of strategies for efficiently synthesizing new organic compounds.

8-1 Naming the Alcohols

Like other compounds, alcohols may have both systematic and common names. Systematic nomenclature treats alcohols as derivatives of alkanes. The ending -e of the alkane is replaced by -ol. Thus, an alkane is converted into an alkanol. For example, the simplest alcohol is derived from methane: methanol. Ethanol stems from ethane, propanol from propane, and so on. In more complicated, branched systems, the name of the alcohol is based on the longest chain containing the OH substituent—not necessarily the longest chain in the molecule.

To locate positions along the chain, number each carbon atom beginning from the end closest to the OH group. The names of other substituents along the chain can then be added to the alkanol stem as prefixes. Complex alkyl appendages are named according to the IUPAC rules for hydrocarbons (Section 2-5), and enantiomers according to the $R,S$ rules (Section 5-4). When there is more than one hydroxy substituent along the alkane stem, the molecule is called a diol, triol, and so on.

Cyclic alcohols are called cycloalkanols. Here the carbon carrying the functional group automatically receives the number 1.

When named as a substituent, the OH group is called hydroxy. This occurs when a functional group taking higher precedence, such as in hydroxycarboxylic acids, is present. Like haloalkanes, alcohols can be classified as primary, secondary, or tertiary.
Exercise 8-1

Draw the structures of the following alcohols: (a) (S)-3-methyl-3-hexanol; (b) trans-2-bromocyclopentanol; (c) 2,2-dimethyl-1-propanol (neopentyl alcohol).

Exercise 8-2

Name the following compounds.

(a) CH₃CH₂CH(CH₃)CH₂OH
(b) CH₃CH₂OH
(c) CH₃CHCHCH₂OH

In common nomenclature, the name of the alkyl group is followed by the word alcohol, written separately. Common names are found in the older literature; although it is best not to use them, we should be able to recognize them.

In Summary

Alcohols can be named as alkanols (IUPAC) or alkyl alcohols. In IUPAC nomenclature, the name is derived from the chain bearing the hydroxy group, whose position is given the lowest possible number.

8-2 Structural and Physical Properties of Alcohols

The hydroxy functional group strongly shapes the physical characteristics of the alcohols. It affects their molecular structure and allows them to enter into hydrogen bonding. As a result, it raises their boiling points and increases their solubilities in water.

The structure of alcohols resembles that of water

Figure 8-1 shows how closely the structure of methanol resembles those of water and of methoxymethane (dimethyl ether). In all three, the bond angles reflect the effect of electron repulsion and increasing steric bulk of the substituents on the central oxygen. Although it is not strictly correct (see Exercise 1-17), you can think of the oxygen as sp³ hybridized, as in ammonia and methane (Section 1-8), with nearly tetrahedral bond angles around the hetero-atom. The two lone electron pairs are then placed into two nonbonding sp³ hybrid orbitals.

The O–H bond is considerably shorter than the C–H bond, in part because of the high electronegativity of oxygen relative to that of carbon. Remember that electronegativity (Table 1-2) determines how tightly nuclei hold all their surrounding electrons, including the bonding electrons. Consistent with this bond shortening is the order of bond strengths: \( \Delta H_{\text{O-H}} = 104 \text{ kcal mol}^{-1} (435 \text{ kJ mol}^{-1}) \); \( \Delta H_{\text{C-H}} = 98 \text{ kcal mol}^{-1} (410 \text{ kJ mol}^{-1}) \).

The electronegativity of oxygen causes an unsymmetrical distribution of charge in alcohols. This effect polarizes the O–H bond so that the hydrogen has a partial positive charge and gives rise to a molecular dipole (Section 1-3), similar to that observed for water.
Chapter 8
Hydroxy Functional Group: Alcohols

The consequences of polarization are seen clearly in the electrostatic potential maps of water and methanol.

Bond and Molecular Dipoles of Water and Methanol

![Figure 8-1](image)
The similarity in structure of water, methanol, and methoxymethane.

Water clusters in the gas phase have been analyzed by physical chemists. This picture (courtesy of Professor Richard Saykally) shows the lowest-energy structure of the water hexamer against a background of the structure of ice. The yellow lines depict hydrogen bonds.

Hydrogen bonding raises the boiling points and water solubilities of alcohols

In Section 6-1 we invoked the polarity of the haloalkanes to explain why their boiling points are higher than those of the corresponding nonpolar alkanes. The polarity of alcohols is similar to that of the haloalkanes. Does this mean that the boiling points of haloalkanes and alcohols correspond? Inspection of Table 8-1 shows that they do not: Alcohols have unusually high boiling points, much higher than those of comparable alkanes and haloalkanes.

The explanation lies in hydrogen bonding. Hydrogen bonds may form between the oxygen atoms of one alcohol molecule and the hydroxy hydrogen atoms of another. Alcohols build up an extensive network of these interactions (Figure 8-2). Although hydrogen bonds are longer and much weaker \(DH^\circ \approx 5-6 \text{ kcal mol}^{-1} (21-25 \text{ kJ mol}^{-1})\) than the covalent O–H linkage \(DH^\circ = 104 \text{ kcal mol}^{-1}\), so many of them form that their combined strength makes it difficult for molecules to escape the liquid. The result is a higher boiling point.

</table>
The effect is even more pronounced in water, which has two hydrogens available for hydrogen bonding (see Figure 8-2). This phenomenon explains why water, with a molecular weight of only 18, has a boiling point of 100°C. Without this property, water would be a gas at ordinary temperatures. Considering the importance of water in all living organisms, imagine how the absence of liquid water would have affected the development of life on our planet.

Hydrogen bonding in water and alcohols is responsible for another property: Many alcohols are appreciably water soluble (Table 8-1). This behavior contrasts with that of the nonpolar alkanes, which are poorly solvated by this medium. Because of their characteristic insolubility in water, alkanes are said to be hydrophobic (hydro, Greek, water; phobos, Greek, fear). So are most alkyl chains. The hydrophobic effect has its origin in two phenomena. First, dissolution of alkyl chains in water requires breaking up the hydrogen-bonded network of the solvent. Second, the alkyl moieties can self-aggregate by London forces (Section 2-6).

In contrast to the hydrophobic behavior of alkyl groups, the OH group and other polar substituents, such as COOH and NH₂, are hydrophilic: They enhance water solubility.

As the values in Table 8-1 show, the larger the alkyl (hydrophobic) part of an alcohol, the lower its solubility in water. At the same time, the alkyl part increases the solubility of the alcohol in nonpolar solvents (Figure 8-3). The “waterlike” structure of the lower alcohols, particularly methanol and ethanol, makes them excellent solvents for polar compounds and even salts. It is not surprising, then, that alcohols are popular protic solvents in the S_N2 reaction (Section 6-8).
In Summary The oxygen in alcohols (and ethers) is tetrahedral and sp³ hybridized. The covalent O–H bond is shorter and stronger than the C–H bond. Because of the electronegativity of the oxygen, alcohols exhibit appreciable molecular polarity, as do water and ethers. The hydroxy hydrogen enters into hydrogen bonding with other alcohol molecules. These properties lead to a substantial increase in the boiling points and in the solubilities of alcohols in polar solvents relative to those of the alkanes and haloalkanes.

8-3 Alcohols as Acids and Bases

Many applications of the alcohols depend on their ability to act both as acids and as bases. (See the review of these concepts in Section 2-2.) Thus, deprotonation gives alkoxide ions. We shall see how structure affects pKₐ values. The lone electron pairs on oxygen render alcohols basic as well, and protonation results in alkyloxonium ions.

The acidity of alcohols resembles that of water

The acidity of alcohols in water is expressed by the equilibrium constant \( K \).

\[
\begin{align*}
\text{ROH} & \rightleftharpoons \text{RO}^- + \text{H}_3\text{O}^+ \\
K &= \frac{[\text{RO}^-][\text{H}_3\text{O}^+]}{[\text{ROH}]} \text{ mol L}^{-1}
\end{align*}
\]

Making use of the constant concentration of water (55 mol L⁻¹; Section 2-2), we derive a new equilibrium constant \( K_a \).

\[
K_a = K[H_2O] = \frac{[\text{H}_3\text{O}^+][\text{RO}^-]}{[\text{ROH}]} \text{ mol L}^{-1}, \text{ and } pK_a = -\log K_a
\]

Table 8-2 lists the pKₐ values of several alcohols. A comparison of these values with those given in Table 2-2 for mineral and other strong acids shows that alcohols, like water, are fairly weak acids. Their acidity is far greater, however, than that of alkanes and haloalkanes.

Why are alcohols acidic, whereas alkanes and haloalkanes are not? The answer lies in the relatively strong electronegativity of the oxygen to which the proton is attached, which stabilizes the negative charge of the alkoxide ion.

To drive the equilibrium between alcohol and alkoxide to the side of the conjugate base, it is necessary to use a base stronger than the alkoxide formed (i.e., a base derived from a conjugate acid weaker than the alcohol; see also Section 9-1). An example is the reaction of sodium amide, NaNH₂, with methanol to furnish sodium methoxide and ammonia.

\[
\begin{align*}
\text{CH}_3\text{O}^- & + \text{Na}^+ \rightleftharpoons \text{CH}_3\text{O}^- + \text{Na}^+ \\
pK_a = 15.5
\end{align*}
\]

\[
\begin{align*}
\text{Sodium amide} & \rightleftharpoons \text{Sodium methoxide} \\
pK_a = 15.5 & \rightleftharpoons pK_a = 35
\end{align*}
\]

This equilibrium lies well to the right (\( K = 10^{15.5-15.5} = 10^{0} \)), because methanol is a much stronger acid than is ammonia, or, conversely, because amide is a much stronger base than is methoxide.

It is sometimes sufficient to generate alkoxides in less than stoichiometric equilibrium concentrations. For this purpose, we may add an alkali metal hydroxide to the alcohol.

\[
\text{CH}_3\text{CH}_2\text{O}^-\text{H}^+ + \text{Na}^+ + \text{OH}^- \rightleftharpoons K \text{CH}_3\text{CH}_2\text{O}^-\text{Na}^+ + \text{H}_2\text{O}
\]

\(pK_a = 15.9\)

\(pK_a = 15.7\)

With this base present, approximately half of the alcohol exists as the alkoxide, if we assume equimolar concentrations of starting materials. If the alcohol is the solvent (i.e., present in large excess), however, essentially all of the base exists in the form of the alkoxide.

### Exercise 8-3

**Working with the Concepts: Estimating Acid-Base Equilibria**

You want to prepare potassium methoxide by treatment of methanol with KCN. Will this procedure work?

**Strategy**

We need to visualize the desired reaction by writing it down. We then add to the equation the \(pK_a\) values of the acids on each side (consult Table 2-2 or 6-4, and Table 8-2). If the \(pK_a\) of the (conjugate) acid on the right is more than 2 units larger than that of methanol on the left, the equilibrium will lie >99% to the right \((K > 100)\).

**Solution**

- The equilibrium reaction and the associated \(pK_a\) values are

\[
\text{CH}_3\text{OH} + K^+ + \text{CN}^- \rightleftharpoons \text{CH}_3\text{O}^- + K^+ + \text{HCN}
\]

\(pK_a = 15.5\)

\(pK_a = 9.2\)

- The \(pK_a\) of HCN is 6.3 units smaller than that of methanol; it is a much stronger acid.
- The equilibrium will lie to the left; \(K = 10^{-6.3}\). This approach to preparing potassium methoxide will not work.

### Exercise 8-4

**Try It Yourself**

Which of the following bases are strong enough to cause essentially complete deprotonation of methanol? The \(pK_a\) of the conjugate acid is given in parentheses.

- (a) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{Li} (50)\);
- (b) \(\text{CH}_3\text{CO}_2\text{Na} (4.7)\);
- (c) \(\text{LiN}[\text{CH}(\text{CH}_3)_2]_2 \text{(LDA, 40)}\);
- (d) \(\text{KH} (38)\);
- (e) \(\text{CH}_3\text{SNa} (10)\).

**Steric disruption and inductive effects control the acidity of alcohols**

Table 8-2 shows an almost million-fold variation in the acidity of the alcohols. A closer look at the first column reveals that the acidity decreases (\(pK_a\) increases) from methanol to primary, secondary, and finally tertiary systems.

<table>
<thead>
<tr>
<th>Relative (pK_a) Values of Alcohols (in Solution)</th>
</tr>
</thead>
<tbody>
<tr>
<td>CH(_3)OH</td>
</tr>
<tr>
<td>Strongest acid</td>
</tr>
<tr>
<td>Increasing acidity</td>
</tr>
</tbody>
</table>

This ordering has been ascribed to steric disruption of solvation and to hydrogen bonding in the alkoxide (Figure 8-4). Because solvation and hydrogen bonding stabilize the negative charge on oxygen, interference with these processes leads to an increase in \(pK_a\).

The second column in Table 8-2 reveals another contribution to the \(pK_a\) of alcohols: The presence of halogens increases acidity. Recall that the carbon of the C–X bond is positively
polarized as a result of the high electronegativity of X (Sections 1-3 and 6-1). Electron withdrawal by the halogen also causes atoms farther away to be slightly positively charged. This phenomenon of transmission of charge, both negative and positive, through the $\sigma$ bonds in a chain of atoms is called an inductive effect. Here it stabilizes the negative charge on the alkoxide oxygen by electrostatic attraction. The inductive effect in alcohols increases with the number of electronegative groups but decreases with distance from the oxygen.

**Exercise 8-5**

Rank the following alcohols in order of increasing acidity.

![Figure 8-4](image)

The smaller methoxide ion is better solvated than is the larger tertiary butoxide ion. ($S =$ solvent molecules).

**Exercise 8-6**

Which side of the following equilibrium reaction is favored (assume equimolar concentrations of starting materials)?

$$\text{CH}_3\text{CO}^- + \text{CH}_3\text{OH} \rightleftharpoons \text{CH}_3\text{COH} + \text{CH}_3\text{O}^-$$

**The lone electron pairs on oxygen make alcohols weakly basic**

Alcohols may also be basic, although weakly so. Very strong acids are required to protonate the OH group, as indicated by the low $pK_a$ values (strong acidity) of their conjugate acids, the alkylloxonium ions (Table 8-3). Molecules that may be both acids and bases are called amphoteric (ampho, Greek, both).

The amphoteric nature of the hydroxy functional group characterizes the chemical reactivity of alcohols. In strong acids, they exist as alkylloxonium ions, in neutral media as alcohols, and in strong bases as alkoxides.

**Table 8-3**

Strong acid $\rightarrow$ Mild base $\rightarrow$ Strong base $\rightarrow$ Mild acid

![Diagram](image)
In Summary  Alcohols are amphoteric. They are acidic by virtue of the electronegativity of the oxygen and are converted into alkoxides by strong bases. In solution, the steric bulk of branching inhibits solvation of the alkoxide, thereby raising the $pK_a$ of the corresponding alcohol. Electron-withdrawing substituents close to the functional group lower the $pK_a$ by the inductive effect. Alcohols are also weakly basic and can be protonated by strong acids to furnish alkylxonium ions.

8-4 Industrial Sources of Alcohols: Carbon Monoxide and Ethene

Let us now turn to the preparation of alcohols. We start in this section with methods of special importance in industry. Subsequent sections address procedures that are used more generally in the synthetic laboratory to introduce the hydroxy functional group into a wide range of organic molecules.

Methanol is made on a multibillion-pound scale from a pressurized mixture of CO and H$_2$ called synthesis gas. The reaction involves a catalyst consisting of copper, zinc oxide, and chromium(III) oxide.

$$\text{CO} + 2\text{H}_2 \xrightarrow{\text{Cu-ZnO-Cr}_2\text{O}_3, 250^\circ\text{C}, 50-100\text{ atm}} \text{CH}_3\text{OH}$$

Changing the catalyst to rhodium or ruthenium leads to 1,2-ethanediol (ethylene glycol), an important industrial chemical that is the principal component of automobile antifreeze.

$$2\text{CO} + 3\text{H}_2 \xrightarrow{\text{Rh or Ru, pressure, heat}} \text{CH}_2-\text{CH}_2-\text{OH}$$

1,2-Ethanediol (Ethylene glycol)

Other reactions that would permit the selective formation of a given alcohol from synthesis gas are the focus of much current research, because synthesis gas is readily available by the gasification of coal or other biomass in the presence of water, or by the partial oxidation of methane.

$$\text{Coal} \xrightarrow{\text{Air, H}_2\text{O, }\Delta} x\text{CO} + y\text{H}_2 \xleftarrow{\text{Air}} \text{CH}_4$$

The methanol produced from synthesis gas costs only about $1 per gallon and, because its heat content is high [182.5 kcal mol$^{-1}$ (763.6 kJ mol$^{-1}$); compare values in Table 3-7], it has become the cornerstone of a methanol-based fuel strategy. A key development has been the methanol fuel cell, in which the electrons released upon the conversion of methanol to CO$_2$ are used to power cars and electronic devices, such as cell phones, laptop computers, and small power-generating units for domestic use.

Ethanol is prepared in large quantities by fermentation of sugars (see Chapter Opening) or by the phosphoric acid–catalyzed hydration of ethene (ethylene). The hydration (and other addition reactions) of alkenes are considered in detail in Chapter 12.

$$\text{CH}_2=\text{CH}_2 + \text{HOH} \xrightarrow{\text{H}_3\text{PO}_4, 300^\circ\text{C}} \text{CH}_2-\text{CH}_2-\text{OH}$$

In Summary The industrial preparation of methanol and 1,2-ethanediol proceeds by reduction of carbon monoxide with hydrogen. Ethanol is prepared by fermentation or the acid-catalyzed hydration of ethene (ethylene).

8-5 Synthesis of Alcohols by Nucleophilic Substitution

On a smaller than industrial scale, we can prepare alcohols from a wide variety of starting materials. For example, conversions of haloalkanes into alcohols by SN$_2$ and SN$_1$ processes featuring hydroxide and water, respectively, as nucleophiles were described in Chapters 6 and 7. These methods are not as widely used as one might think, however, because the
required halides are often accessible only from the corresponding alcohols (Chapter 9). They also suffer from the usual drawbacks of nucleophilic substitution: Bimolecular elimination can be a major side reaction of hindered systems, and tertiary halides form carbocations that may undergo E1 reactions. Some of these drawbacks are overcome by the use of polar, aprotic solvents (Table 6-5).

### Alcohols by Nucleophilic Substitution

![Chemical structure](image)

\[ \text{SN2} \]

92%

![Chemical structure](image)

\[ \text{H}_2\text{O}, \text{HMPA} \]

\[ \text{SN1} \]

92%

A way around the problem of elimination in \(\text{S}_{\text{N2}}\) reactions of oxygen nucleophiles with secondary or sterically encumbered, branched primary substrates is the use of less basic functional equivalents of water, such as acetate (Section 6-8). The resulting alkyl acetate (an ester) can then be converted into the desired alcohol by aqueous hydroxide. We shall consider this reaction, known as *ester hydrolysis*, in Chapter 20.

### Exercise 8-7

Show how you might convert the following haloalkanes into alcohols:
(a) Bromoethane; (b) chlorocyclohexane; (c) 3-chloro-3-methylpentane.

### Alcohols from Haloalkanes by Acetate Substitution—Hydrolysis

**Step 1.** Acetate formation (\(\text{S}_{\text{N2}}\) reaction)

\[ \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_2\text{Br} + \text{CH}_3\text{CO}^-\text{Na}^+ \xrightarrow{\text{DMF}, 80^\circ C} \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_2\text{OCCCH}_3 + \text{Na}^+\text{Br}^- \]

1-Bromo-3-methylpentane

95%

3-Methylpentyl acetate (An ester)

**Step 2.** Conversion into the alcohol (ester hydrolysis)

\[ \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_2\text{OCCCH}_3 + \text{Na}^+\text{OH}^- \xrightarrow{\text{H}_2\text{O}} \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_2\text{OH} \]

85%

3-Methyl-1-pentanol

**In Summary** Alcohols may be prepared from haloalkanes by nucleophilic substitution, provided the haloalkane is readily available and side reactions such as elimination do not interfere.
8-6 Synthesis of Alcohols: Oxidation–Reduction Relation Between Alcohols and Carbonyl Compounds

This section describes an important synthesis of alcohols: reduction of aldehydes and ketones. Later, we shall see that aldehydes and ketones may be converted into alcohols by addition of organometallic reagents, with resulting formation of a new carbon–carbon bond. Because of this versatility of aldehydes and ketones in synthesis, we shall also illustrate their preparation by oxidation of alcohols.

Oxidation and reduction have special meanings in organic chemistry

We can readily recognize inorganic oxidation and reduction processes as the loss and gain of electrons, respectively. With organic compounds, it is often less clear whether electrons are being gained or lost in a reaction. Hence, organic chemists find it more useful to define oxidation and reduction in other terms. A process that adds electronegative atoms such as halogen or oxygen to, or removes hydrogen from, a molecule constitutes an oxidation. Conversely, the removal of halogen or oxygen or the addition of hydrogen is defined as reduction. You can readily visualize this definition in the step-by-step oxidation of methane, CH₄, to carbon dioxide, CO₂.

**Step-by-Step Oxidation of CH₄ to CO₂**

\[
\text{CH}_4 \xrightarrow{+ \text{O}} \text{CH}_3\text{OH} \xrightarrow{-2\text{H}} \text{H}_2\text{C}==\text{O} \xrightarrow{+ \text{O}} \text{HCOH} \xrightarrow{-2\text{H}} \text{O}==\text{C}==\text{O}
\]

This definition of an oxidation-reduction relation allows us to relate alcohols to aldehydes and ketones. Addition of two hydrogen atoms to the double bond of a carbonyl group constitutes reduction to the corresponding alcohol. Aldehydes give primary alcohols; ketones give secondary alcohols. The reverse process, removal of hydrogen to furnish carbonyl compounds, is an example of oxidation. Together, these processes are referred to as redox reactions.

**The Redox Relation Between Alcohols and Carbonyl Compounds**

How are such processes carried out in the laboratory? The remainder of this section introduces the most common methods used to effect the reduction of carbonyl compounds and the oxidation of alcohols.

Alcohols can form by hydride reduction of the carbonyl group

Conceptually, the easiest way to reduce a carbonyl group would be to add hydrogen, H–H, across the carbon–oxygen double bond directly. Although this can be done, it requires high pressures and special catalysts. A more convenient way is a polar process, in which hydride ion, H⁻, and a proton, H⁺, are delivered to the double bond, either simultaneously or sequentially. The net result is the same, because H⁻ + H⁺ = H–H. How does this work in practice?

The electrons in the carbonyl group are not distributed evenly between the two component atoms. Because oxygen is more electronegative than carbon, the carbon of a carbonyl group is electrophilic and the oxygen is nucleophilic. This polarization can be represented...
Chapter 8
Hydroxy Functional Group: Alcohols

### Chemical Highlight 8-1: Biological Oxidation and Reduction

In biological systems, alcohols are metabolized by oxidation to carbonyl compounds. For example, ethanol is converted into acetaldehyde by the cationic oxidizing agent *nicotinamide adenine dinucleotide* (abbreviated as NAD$^+$; see Chemical Highlight 25-2). The process is catalyzed by the enzyme *alcohol dehydrogenase*. (This enzyme also catalyzes the reverse process, reduction of aldehydes and ketones to alcohols; see Problems 58 and 59 at the end of this chapter.) When the two enantiomers of 1-deuterioethanol are subjected to the enzyme, the biochemical oxidation is found to be stereospecific, NAD$^+$ removing only the hydrogen marked by the arrow in the first reaction below from C1 of the alcohol (Chemical Highlight 25-2).

Other alcohols are similarly oxidized biochemically. The relatively high toxicity of methanol (“wood alcohol”) is due largely to its oxidation to formaldehyde, which interferes specifically with a system responsible for the transfer of one-carbon fragments between nucleophilic sites in biomolecules.

![Formaldehyde](image)

The capability of alcohols to undergo enzymatic oxidation makes them important relay stations in metabolism. One of the functions of the metabolic degradation of the food we eat is its controlled “burning” (i.e., combustion; see Section 3-10) to release the heat and chemical energy required to run our bodies. Another function is the selective introduction of functional groups, especially hydroxy groups, into unfunctionalized parts of molecules—in other words, alkyl substituents. This process is called hydroxylation. The *cytochrome* proteins are crucial biomolecules that help to accomplish this task. These molecules are present in almost all living cells and emerged about 1.5 billion years ago, before the development of plants and animals as separate species. Cytochrome P-450 (see Section 22-9) uses O$_2$ to accomplish the direct hydroxylation of organic molecules. In the liver, this process serves to

by a charge-separated resonance form (Section 1-5). It is visualized in the electrostatic potential map of formaldehyde, H$_2$C$\equiv$O, in the margin.

**Polar Character of the Carbonyl Function**

\[
\begin{align*}
\text{Electrophilic} & \quad \longleftrightarrow \quad \text{Nucleophilic} \\
\begin{array}{c}
\overset{\delta^+}{C\equiv O} \\
\overset{\delta^-}{C\equiv O}
\end{array}
\end{align*}
\]

Therefore, it should be possible to add hydride to carbon and proton to oxygen, provided that suitable reagents containing nucleophilic hydrogen are available. Such reagents are sodium borohydride, Na$^+$$\cdot$BH$_4$, and lithium aluminum hydride, Li$^+$$\cdot$AlH$_4$. The anions in these species are electronically and structurally similar to methane (see Problem 1-23), but because boron and aluminum are to the left of carbon in the periodic table (Table 1-1), the anions are negatively charged. Therefore, the hydrogens are “hydridic” and capable of attacking the carbonyl carbon by transferring with their bonding electron pair to generate
detoxify substances that are foreign to the body (xenobiotic), many of which are the medicines that we take. Often, the primary effect of hydroxylation is simply to impart greater water solubility, thereby accelerating the excretion of a drug and thus preventing its accumulation to toxic levels.

Selective hydroxylation is important in steroid synthesis (Section 4-7). For example, progesterone is converted by triple hydroxylation at C17, C21, and C11 into cortisol. Not only does the protein pick specific positions as targets for introducing functional groups with complete stereoselectivity, it also controls the sequence in which these reactions take place. You can get an inkling of the origin of this selectivity when you inspect the cytochrome model shown on the opposite page.

The active site is an Fe atom tightly held by a strongly bound heme group (see Section 26-8) embedded in the cloak of a polypeptide (protein) chain. The Fe center binds O2 to generate an Fe–O2 species, which is then reduced to H2O and Fe=O. This oxide reacts as a radical (Section 3-4) with the R–H unit as shown, producing an Fe–OH intermediate in the presence of R⁻. The carbon-based radical then abstracts OH to furnish the alcohol.

The steric and electronic environment provided by the polypeptide mantle allows substrates, such as progesterone, to approach the active iron site only in very specific orientations, leading to preferential oxidation at only certain positions, such as C17, C21, and C11.

an alkoxide ion. You can visualize this transformation by pushing electrons starting from the B–H bond and ending at the carbonyl oxygen (see margin). In a separate (or simultaneous) process the alkoxide oxygen is protonated, either by solvent (alcohol in the case of NaBH₄), or by aqueous work-up (for LiAlH₄).
Note: The reduction of cyclobutanone introduces a short convention to describe several step sequences. In step 1, the starting material is reacted with LiAlH₄ in ethoxyethane (diethyl ether). In step 2, the product of this transformation is treated with aqueous acid. It is important to understand and use this convention correctly. For example, mixing the reagents of 1 and 2 will cause violent hydrolysis of LiAlH₄.

Examples of Hydride Reductions of Aldehydes and Ketones to Alcohols

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \xrightarrow{\text{NaBH}_4, \text{CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \]

Pentanal

\[ \text{NaBH}_4, \text{CH}_3\text{CH}_2\text{OH} \]

CH₃CH₂CH₂CH₂CH₂CH₃

85%

1-Pentanol

Exercise 8-8

Formulate all of the expected products of NaBH₄ reduction of the following compounds. (Hint: Remember the possibility of stereoisomerism.)

(a) \(\text{CH}_3\text{CCH}_2\text{CH}_2\text{CH}_2\text{CH}_3\)
(b) \(\text{CH}_3\text{CCH}_2\text{CH}_2\text{CH}_2\text{CH}_3\)
(c) \(\text{CH}_3\text{CCH}_2\text{CH}_2\text{CH}_3\)

Exercise 8-9

Because of electronic repulsion, nucleophilic attack on the carbonyl function does not occur perpendicular (90° angle) to the \(\pi\) bond, but at an angle (107°) away from the negatively polarized oxygen. Consequently, the nucleophile approaches the target carbon in relatively close proximity to its substituents. For this reason, hydride reductions can be stereoselective, with the delivery of hydrogen from the less hindered side of the substrate molecule. Predict the likely stereochemical outcome of the treatment of compound A with NaBH₄. (Hint: Draw the chair form of A.)

Why not use the simpler reagents LiH or NaH (Section 1-3) for such reductions? The reason is the reduced basicity of hydride in the form of BH₄⁻ and AlH₄⁻, as well as the higher solubility of the B and Al reagents in organic solvents. For example, free hydride ion is a powerful base that is instantly protonated by protic solvents [see Exercise 8-4(d)], but attachment to boron in BH₄⁻ moderates its reactivity considerably, thus allowing NaBH₄ to be used in solvents such as ethanol. In this medium, the reagent donates hydride to the carbonyl carbon with simultaneous protonation of the carbonyl oxygen by the solvent. The ethoxide generated from ethanol combines with the resulting BH₃ (which is electron deficient, with 6 electrons; see Section 1-8), giving ethoxyborohydride.

Mechanism of NaBH₄ Reduction

Electrophilic Nucleophilic

\[ \text{Na}^+ \text{H}_3\text{B} \xrightarrow{\text{H}^-} \text{H}^-\text{C} \xrightarrow{\text{O}} \text{H}^-\text{OCH}_2\text{CH}_3 \xrightarrow{\text{Na}^+ \text{H}_3\text{B}} \text{H}^-\text{C} \xrightarrow{\text{H}^-} + \text{Na}^+ \text{H}_3\text{BOCH}_2\text{CH}_3 \]

Ethanol solvent Product alcohol Sodium ethoxyborohydride
Alcohol synthesis by reduction can be reversed: chromium reagents

We have just learned how to make alcohols from aldehydes and ketones by reduction with hydride reagents. The reverse process is also possible: Alcohols may be oxidized to produce aldehydes and ketones. A useful reagent for this purpose is a transition metal in a high oxidation state: chromium(VI). In this form, chromium has a yellow-orange color. Upon exposure to an alcohol, the Cr(VI) species is reduced to the diagnostic deep green Cr(III) (see Chemical Highlight 8-2). The reagent is usually supplied as a dichromate salt (K₂Cr₂O₇ or Na₂Cr₂O₇) or as CrO₃. Oxidation of secondary alcohols to ketones is often carried out in aqueous acid, in which all of the chromium reagents generate varying amounts of chromic acid, H₂CrO₄, depending on pH.

**Exercise 8-10**

Formulate reductions that would give rise to the following alcohols: (a) 1-decanol; (b) 4-methyl-2-pentanol; (c) cyclopentylmethanol; (d) 1,4-cyclohexanediol.

**Alcohol synthesis by reduction can be reversed: chromium reagents**

We have just learned how to make alcohols from aldehydes and ketones by reduction with hydride reagents. The reverse process is also possible: Alcohols may be oxidized to produce aldehydes and ketones. A useful reagent for this purpose is a transition metal in a high oxidation state: chromium(VI). In this form, chromium has a yellow-orange color. Upon exposure to an alcohol, the Cr(VI) species is reduced to the diagnostic deep green Cr(III) (see Chemical Highlight 8-2). The reagent is usually supplied as a dichromate salt (K₂Cr₂O₇ or Na₂Cr₂O₇) or as CrO₃. Oxidation of secondary alcohols to ketones is often carried out in aqueous acid, in which all of the chromium reagents generate varying amounts of chromic acid, H₂CrO₄, depending on pH.
**CHEMICAL HIGHLIGHT 8-2**

**The Breath Analyzer Test**

The color change from Cr(VI) (orange) in the presence of alcohols to Cr(III) (green) is used in a preliminary determination of the ethanol level in the breath (and therefore blood) of suspected alcohol-intoxicated persons, especially drivers. (For the physiological effects of ethanol, see Section 9-11.) If this test is positive, it is taken as a justification by law enforcement officers to administer a more accurate blood or urine screening. It works because of the diffusion of blood alcohol through the lungs into the breath, with a measured distribution ratio of roughly 2100:1 (i.e., 2100 mL of breath contains as much ethanol as 1 mL of blood). In the simplest version of this test, the participant is asked to blow into a tube containing K$_2$Cr$_2$O$_7$ and H$_2$SO$_4$ supported on powdered silica gel (SiO$_2$) for a duration of 10–20 s (as indicated by the inflation of a plastic bag attached at the end of the tube). Any alcohol present in the breath is oxidized to acetic (ethanoic) acid, a reaction signaled by the progressive color change from orange to green along the tube, according to the following balanced equation.

$$2 \text{K}_2\text{Cr}_2\text{O}_7 + 8 \text{H}_2\text{SO}_4 + 3 \text{CH}_3\text{CH}_2\text{OH} \rightarrow 2 \text{Cr}_2(\text{SO}_4)_3 + 2 \text{K}_2\text{SO}_4 + 3 \text{CH}_3\text{COH} + 11 \text{H}_2\text{O}$$

If green develops beyond the halfway mark, a blood alcohol concentration greater than 0.08% is indicated, which is considered a criminal offense in many countries. A more sophisticated version of this simple procedure uses spectrophotometric techniques to quantify the extent of oxidation, the so-called breath analyzer test, and more recent developments include the use of mini–gas chromatographs, electrochemical analyzers, and infrared spectrometers (Section 11-8). Some people claim that a breath analyzer can be tricked into producing a “false negative” by smoking, chewing coffee beans, eating garlic, or ingesting chlorophyll preparations beforehand: These claims are false.

---

**Oxidation of a Secondary Alcohol to a Ketone with Aqueous Cr(VI)**

In water, primary alcohols tend to overoxidize to carboxylic acids, as shown for 1-propanol. The reason is that aldehydes in water are in equilibrium with the corresponding diols, derived by addition of water. One of the hydroxy functions of the diol then reacts further with the chromium reagent to the carboxylic acid. We shall discuss the hydration of aldehydes and ketones in Chapter 17.

In the absence of water, however, aldehydes are not susceptible to overoxidation. Therefore, a water-free form of Cr(VI) has been developed by reaction of CrO$_3$ with HCl, followed
by the addition of the organic base pyridine. The result is the oxidizing agent \textit{pyridinium chlorochromate}, abbreviated as pyH$^+$CrO$_3$Cl$^-$ or just PCC (margin), which gives excellent yields of aldehydes upon exposure to primary alcohols in dichloromethane solvent.

\[
\text{PCC Oxidation of a Primary Alcohol to an Aldehyde}
\]

\[
\text{CH}_3\text{(CH}_2\text{)}_3\text{CH}_2\text{OH} \xrightarrow{\text{pyH}^+\text{CrO}_3\text{Cl}^-\cdot\text{CH}_2\text{Cl}_2} \text{CH}_3\text{(CH}_2\text{)}_3\text{CHO} \quad 92\%
\]

PCC oxidation conditions are often also used with secondary alcohols, because the relatively nonacidic reaction conditions minimize side reactions (e.g., carbocation formation; Sections 7-2, 7-3, and 9-3) and often give better yields than does the aqueous chromate method. Tertiary alcohols are unreactive toward oxidation by Cr(VI) because they do not carry hydrogens next to the OH function and therefore cannot readily form a carbon–oxygen double bond.

**Exercise 8-11**

Formulate the product(s) of each of the following steps. What can you say about stereochemistry?

(a) \[
\text{(cis-4-Methylcyclohexanol)}
\]

(b) \[
\text{1. Excess LiAlH}_4 \\
\text{2. H}_2\text{O work-up} \\
\text{C}_7\text{H}_{16}\text{O}_2 \text{ (two alcohols)}
\]

(c) \[
\text{Optically active} \\
\text{Optically inactive}
\]

**Chromic esters are intermediates in alcohol oxidation**

What is the mechanism of the chromium(VI) oxidation of alcohols? The first step is formation of an intermediate called a \textit{chromic ester}; the oxidation state of chromium stays unchanged in this process.

**Chromic Ester Formation from an Alcohol**

\[
\text{RCH}_2\text{OH} + \text{HO}^{-\text{Cr(VI)}} + \text{OH}^{-} \rightleftharpoons \text{RCH}_2\text{O}^{-\text{Cr(VI)}} + \text{H}_2\text{O}
\]

The next step in alcohol oxidation is equivalent to an E2 reaction. Here water (or pyridine, in the case of PCC) acts as a mild base, removing the proton next to the alcohol oxygen. This proton is made unusually acidic by the electron-withdrawing power of the Cr(VI) (remember that it wants to become reduced!). HCrO$_3$ is an exceptionally good
leaving group, because the donation of an electron pair to chromium changes its oxidation state by two units, yielding Cr(IV).

**Aldehyde Formation from a Chromic Ester: an E2 Reaction**

\[
\begin{align*}
\text{R} & \quad \text{C} \quad \text{O} \quad \text{Cr(VI)} \\
\text{H} & \quad \text{H} \\
\text{H}_2\text{O} & \quad \text{O}_3\text{Cr(IV)}\text{H}
\end{align*}
\]

In contrast with the kinds of E2 reactions considered so far, this elimination furnishes a carbon–oxygen instead of a carbon–carbon double bond. The Cr(IV) species formed undergoes a redox reaction with itself to Cr(III) and Cr(V); the latter may function as an oxidizing agent independently. Eventually, all Cr(VI) is reduced to Cr(III).

**Exercise 8-12**

Formulate a synthesis of each of the following carbonyl compounds from the corresponding alcohol.

(a) \(\text{CH}_3\text{CH}_2\text{CCH(CH}_3)\text{H}\)   
(b) \(\text{HCH}_2\text{O}\)  
(c) \(\text{CH}_3\text{CH}_2\text{CH}_3\)

**In Summary** Reductions of aldehydes and ketones by hydride reagents constitute general syntheses of primary and secondary alcohols, respectively. The reverse reactions, oxidations of primary alcohols to aldehydes and secondary alcohols to ketones, are achieved with chromium(VI) reagents. Use of pyridinium chlorochromate (PCC) prevents overoxidation of primary alcohols to carboxylic acids.

**8-7 Organometallic Reagents: Sources of Nucleophilic Carbon for Alcohol Synthesis**

The reduction of aldehydes and ketones with hydride reagents is a useful way of synthesizing alcohols. This approach would be even more powerful if, instead of hydride, we could use a source of nucleophilic carbon. Attack by a carbon nucleophile on a carbonyl group would give an alcohol and simultaneously form a carbon–carbon bond. This kind of reaction—adding carbon atoms to a molecule—is of fundamental practical importance for synthesizing new compounds from simpler reactants.

To achieve such transformations, we need to find a way of making carbon-based nucleophiles, \(\text{R}^-\). This section describes how to reach this goal. Metals, particularly lithium and magnesium, act on haloalkanes to generate new compounds, called organometallic reagents, in which a carbon atom of an organic group is bound to a metal. These species are strong bases and good nucleophiles and as such are extremely useful in organic syntheses.

**Alkyl lithium and alkylmagnesium reagents are prepared from haloalkanes**

Organometallic compounds of lithium and magnesium are most conveniently prepared by direct reaction of a haloalkane with the metal suspended in ethoxyethane (diethyl ether) or oxacyclopentane (tetrahydrofuran, THF). The reactivity of the haloalkanes increases in the order Cl < Br < I; the relatively unreactive fluorides are not normally used as starting
Organomagnesium compounds, RMgX, are also called **Grignard reagents**, named after their discoverer, F. A. Victor Grignard.*

### Alkylithium Synthesis

\[
\text{CH}_3\text{Br} + 2\text{Li} \xrightarrow{(\text{CH}_3\text{CH}_2)\text{O}, 0^\circ - 10^\circ C} \text{CH}_3\text{Li} + \text{LiBr}
\]

**Methyl-lithium**

### AlkylMagnesium (Grignard) Synthesis

\[
\begin{align*}
\text{CH}_3\text{C} & \quad \text{CH}_3\text{I} \\
\text{H}_3\text{C} & \quad \text{H}
\end{align*}
\]

\[
\xrightarrow{\text{Mg, THF, 20}^\circ C}
\]

**1-Methylethylmagnesium iodide**

Alkylithium compounds and Grignard reagents are rarely isolated; they are formed in solution and used immediately in the desired reaction. Sensitive to air and moisture, they must be prepared and handled under rigorously air- and water-free conditions. Simple examples, such as methyllithium, methylmagnesium bromide, butyllithium, and others, are commercially available.

The formulas RLi and RMgX oversimplify the true structures of these reagents. Thus, as written, the metal ions are highly electron deficient. To make up the desired electron octet, they function as Lewis acids (Section 2-2) and attach themselves to the Lewis basic solvent molecules. For example, alkylmagnesium halides are stabilized by bonding to two ether molecules. The solvent is said to be **coordinated** to the metal. This coordination is rarely shown in equations, but it is crucial for the formation of the Grignard species.

### Grignard Reagents Are Coordinated to Solvent

\[
\begin{align*}
\text{R} - \text{X} & + \text{Mg} \xrightarrow{(\text{CH}_3\text{CH}_2)\text{O}} \text{X} & \quad \text{Mg} & \quad \text{R}^\bullet
\end{align*}
\]

**Methyllithium**

**Methylmagnesium chloride**

### The alkylmetal bond is strongly polar

Alkylithium and alkylmagnesium reagents have strongly polarized carbon–metal bonds; the strongly electropositive metal (Table 1-2) is the positive end of the dipole, as shown in the margin for CH3Li and CH3MgCl. The degree of polarization is sometimes referred to as “percentage of ionic bond character.” The carbon–lithium bond, for example, has about 40% ionic character and the carbon–magnesium bond 35%. Such systems react chemically as if they contained a negatively charged carbon. To symbolize this behavior, we can show the carbon–metal bond with a resonance form that places the full negative charge on the carbon atom: a **carbanion**. Carbanions, R^\bullet, are related to alkyl radicals, R^\bullet (Section 3-2), and carbocations, R^+ (Section 7-5), by successive removal of one electron. Because of charge repulsion, the carbon in carbanions assumes sp^3 hybridization and a tetrahedral structure (Exercise 1-16).

---

*Professor François Auguste Victor Grignard (1871–1935), University of Lyon, France, Nobel Prize 1912 (chemistry).
The preparation of alkylmetals from haloalkanes illustrates an important principle in synthetic organic chemistry: **reverse polarization.** In a haloalkane, the presence of the electronegative halogen turns the carbon into an electrophilic center. Upon treatment with a metal, the $\text{C}^\delta^+\text{-X}^\delta^-$ unit is converted into $\text{C}^\delta^-\text{-M}^\delta^+$. In other words, the direction of polarization is reversed. Reaction with a metal (metallation) has turned an electrophilic carbon into a nucleophilic center.

**The alkyl group in alkylmetals is strongly basic**

Carbanions are very strong bases. In fact, alkylmetals are much more basic than amides or alkoxides, because carbon is considerably less electronegative than either nitrogen or oxygen (Table 1-2) and much less capable of supporting a negative charge. Recall (Table 2-2, Section 2-2) that alkanes are extremely weak acids: The $pK_a$ of methane is estimated to be 50. It is not surprising, therefore, that carbanions are such strong bases: They are, after all, the conjugate bases of alkanes. Their basicity makes organometallic reagents moisture sensitive and incompatible with OH or similarly acidic functional groups. Therefore, it is impossible to make organolithium or Grignard species from haloalcohols or halocarboxylic acids. On the other hand, such alkylmetals can be used as efficient bases to turn alcohols into their corresponding alkoxides (see Section 8-3). The by-product is an alkane. The outcome of this transformation is predictable on purely electrostatic grounds.

**Alkoxide Formation with Methylithium**

$\text{(CH}_3\text{)}_3\text{CO}^{-} + \text{Li}^+ \rightarrow \text{(CH}_3\text{)}_3\text{CO} \text{- Li}^+$

$\text{1,1-Dimethylethanol} (\text{tert-Butylalcohol})$

$pK_a = 18$

Similarly, organometals hydrolyze with water—often violently—to produce a metal hydroxide and alkane.

**Hydrolysis of an Organometallic Reagent**

$\text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_2\text{MgBr} + \text{HOH} \rightarrow \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_2\text{H} + \text{BrMgOH}$

$\text{3-Methylpentylmagnesium bromide}$

$\text{3-Methylpentane}$

100%

The sequence Grignard (or alkylithium) formation, also called metallation, followed by hydrolysis converts a haloalkane into an alkane. A more direct way of achieving the same goal is the reaction of a haloalkane with the powerful hydride donor lithium aluminum hydride, an $\text{S}_2\text{2}$ displacement of halide by $\text{H}^-$. The less reactive $\text{NaBH}_4$ is incapable of performing this substitution.
Another useful application of metallation–hydrolysis is the introduction of hydrogen isotopes, such as deuterium, into a molecule by exposure of the organometallic compound to labeled water (see margin).

\[ \text{CH}_3\text{(CH}_2\text{)}_7\text{CH}_2\text{Br} \xrightarrow{\text{LiAIH}_4, (CH}_3\text{CH}_2\text{)}_2\text{O} \xrightarrow{-\text{LiBr}} \text{CH}_3\text{(CH}_2\text{)}_7\text{CH}_2\text{H} \]

1-Bromononane  Nonane

In Summary  Haloalkanes can be converted into organometallic compounds of lithium or magnesium (Grignard reagents) by reaction with the respective metals in ether solvents. In these compounds, the alkyl group is negatively polarized, a charge distribution opposite that found in the haloalkane. Although the alkyl–metal bond is to a large extent covalent, the carbon attached to the metal behaves as a strongly basic carbanion, exemplified by its ready protonation.

8-8 Organometallic Reagents in the Synthesis of Alcohols

Among the most useful applications of organometallic reagents of magnesium and lithium are those in which the negatively polarized alkyl group reacts as a nucleophile. Like the hydrides, these reagents can attack the carbonyl group of an aldehyde or ketone to produce an alcohol (upon aqueous work-up). The difference is that a new carbon–carbon bond is formed in the process.

Exercise 8-13

Working with the Concepts: Making a Deuterated Hydrocarbon

Show how you would prepare monodeuteriocyclohexane from cyclohexane.

Strategy

You are asked to replace one of the hydrogens in your starting material by deuterium. The best way to approach a solution to this problem is to work backward, that is, ask the question: What do I know about making a deuterated alkane?

The answer is given in the preceding paragraphs: You have learned two ways to convert a haloalkane into a deuterated alkane. The two reagents employed are LiAlD₄ or Mg, followed by D₂O. This problem requires one of these reagents and a halocyclohexane. How can you make a halocyclohexane from cyclohexane? The answer is in Chapter 3: radical halogenation.

Solution

Putting everything together, a possible solution scheme is

\[ \text{Br}_2, \text{hv} \xrightarrow{} \text{Br} \xrightarrow{} \text{Mg} \xrightarrow{} \text{MgBr} \xrightarrow{} \text{D}_2\text{O} \xrightarrow{} \text{D} \]

Exercise 8-14

Try It Yourself

You have a small amount of precious CD₃OH, but what you really need is completely deuterated CD₃OD. How can you make it?

Note: You may have noticed that we are beginning to apply our knowledge of organic chemistry to more complex problems. This process is not unlike learning a language: Each reaction may be viewed as part of the vocabulary, and now we are learning to form sentences. The “sentence” to be written here leads from cyclohexane to singly deuterated cyclohexane. We shall see in Section 8-9 that for our sentence to make sense, it is easiest to work backward from the product.
Following the flow of electrons can help us understand the reaction. In the first step, the nucleophilic alkyl group in the organometallic compound attacks the carbonyl carbon. As an electron pair from the alkyl group shifts to generate the new carbon–carbon linkage, it “pushes” two electrons from the double bond onto the oxygen, thus producing a metal alkoxide. The addition of a dilute aqueous acid furnishes the alcohol by hydrolyzing the metal–oxygen bond, another example of aqueous work-up.

The reaction of organometallic compounds with formaldehyde results in primary alcohols. In the electrostatic potential maps of the example below, the electron-rich (orange-red) carbon of the butylmagnesium bromide is seen to attack the electron-poor (blue) carbon of formaldehyde to give 1-pentanol.

However, aldehydes other than formaldehyde convert into secondary alcohols.
Ketones furnish tertiary alcohols.

**Exercise 8-15**

Write a synthetic scheme for the conversion of 2-bromopropane, \((\text{CH}_3\text{)}_2\text{CHBr}\), into 2-methyl-1-propanol, \((\text{CH}_3\text{)}_2\text{CHCH}_2\text{OH}\).

**Exercise 8-16**

Propose efficient syntheses of the following products from starting materials containing no more than four carbons.

(a) \(\text{CH}_3(\text{CH}_2)_4\text{OH}\)  
(b) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{CHCH}_2\text{CH}_3\)  
(c) \(\text{C}(\text{CH}_3)_3\)  
(d) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{CCH}_2\text{CH}_3\)

Although the nucleophilic addition of alkylithium and Grignard reagents to the carbonyl group provides us with a powerful C–C bond-forming transformation, nucleophilic attack is too slow on haloalkanes and related electrophiles, such as those encountered in Section 6-7. This kinetic problem is what enables us to make the organometallic reagents described in Section 8-7: The product alkylmetal does not attack the haloalkane from which it is made (Chemical Highlight 8-3).

**In Summary** Alkylithium and alkylmagnesium reagents add to aldehydes and ketones to give alcohols in which the alkyl group of the organometallic reagent has formed a bond to the original carbonyl carbon.

**8-9 Complex Alcohols: An Introduction to Synthetic Strategy**

The reactions introduced so far are part of the “vocabulary” of organic chemistry; unless we know the vocabulary, we cannot speak the language of organic chemistry. These reactions allow us to manipulate molecules and interconvert functional groups, so it is important to become familiar with these transformations—their types, the reagents used, the conditions under which they occur (especially when the conditions are crucial to the success of the process), and the limitations of each type.

This task may seem monumental, one that will require much memorization. But it is made easier by an understanding of the reaction mechanisms. We already know that reactivity can be predicted from a small number of factors, such as electronegativity, coulombic forces, and bond strengths. Let us see how organic chemists apply this understanding to devise useful synthetic strategies, that is, reaction sequences that allow the construction of a desired target in the minimum number of high-yielding steps.
**CHEMICAL HIGHLIGHT 8-3**

**Transition Metal-Catalyzed Cross-Coupling Reactions**

The general coupling reaction of a haloalkane, containing a positively polarized carbon, with an alkylmetal, containing a negatively polarized carbon, is quite exothermic.

\[
\begin{align*}
R^+X^- + R^-M^- & \rightarrow R^-R^+ + MX
\end{align*}
\]

Yet, in the case of Li and Mg, such couplings are either too slow at room temperature or lead to product mixtures on heating. As this process constitutes one of the most fundamental C–C bond-forming reactions, it is not surprising that synthetic chemists have devoted considerable effort to the solution of the problem, an effort that is ongoing. An early solution was provided by copper salts as catalysts. Catalysts enable reactions to proceed faster, through lower-energy transition states and mechanisms (Section 3-3).

The method has been applied on an industrial scale in the manufacture of muscalure, the sex attractant of the housefly. In conjunction with a toxic ingredient, it is used for pest control, particularly in poultry, swine, beef and dairy cattle facilities, and stables (see also Section 12-17).

The mechanism of these reactions proceeds through organocopper species, also called *cuprates* (see Section 18-10), which can be generated and used stoichiometrically, for example, from alkyllithium reagents.

Let us begin with a few examples in which we predict reactivity on mechanistic grounds. Then we shall turn to synthesis—the making of molecules. How do chemists develop new synthetic methods, and how can we make a “target” molecule as efficiently as possible? The two topics are closely related. The second, known as *total synthesis*, usually requires a series of reactions. In studying these tasks, therefore, we will also be reviewing much of the reaction chemistry that we have considered so far.

**Mechanisms help in predicting the outcome of a reaction**

First, recall how we predict the outcome of a reaction. What are the factors that let a particular mechanism go forward? Here are three examples.

**How to Predict the Outcome of a Reaction on Mechanistic Grounds**

**Example 1.** What happens when you add I\(^-\) to FCH\(_2\)CH\(_2\)Br?

\[
\begin{align*}
\text{IClCH}_2\text{CH}_2\text{Br} & \leftarrow \text{IClCH}_2\text{CH}_2\text{Br} \\
\text{FCH}_2\text{CH}_2\text{Br} & \rightarrow \text{FCH}_2\text{CH}_2\text{I}
\end{align*}
\]

*Explanation.* Bromide is a better leaving group than fluoride.
Example 2. How does a Grignard reagent add to a carbonyl group?

\[
2 \text{CH}_3\text{CH}_2\text{CH}_2\text{Li} + \text{CuI} \rightarrow (\text{CH}_3\text{CH}_2\text{CH}_2)_2\text{CuLi} + \text{LiI}
\]

Lithium dibutylcuprate

\[
\text{CH}_3\text{OCH}_2\text{CH}_2\text{O} + 3 (\text{CH}_3\text{CH}_2\text{CH}_2)_2\text{CuLi} \rightarrow \text{CH}_3\text{O}(\text{CH}_2)_2\text{CH}_3
\]

90%

More recently, a number of variations on this theme have been explored, employing M = Zn, Sn, Al, and others, in the presence of catalysts based on Ni, Pd, Fe, and Rh, just to name a few. The aim is to improve not only efficiency, but also functional group tolerance. For example, unlike alkyllithium and Grignard reagents, the corresponding Zn compounds do not attack carbonyl functions.

Example 3. What is the product of the radical bromination of methylcyclohexane?

Other bromides + \[\text{Br}_2, h_v\] Not formed

\[
\text{CH}_3
\]

\[
\text{CH}_2\text{Br}
\]

\[
\text{CH}_3, \text{H}_3
\]

\[
\text{Br}
\]
Explanation. The tertiary C–H bond is weaker than a primary or secondary C–H bond, and Br₂ is quite selective in radical halogenations.

**Exercise 8-17**

**Working with the Concepts: Using Mechanistic Knowledge to Predict the Outcome of a Reaction**

Predict and explain the outcome of the following reaction on mechanistic grounds.

\[ \text{CH}_2\text{Cl} \]
\[ \text{ClCH}_2\text{CH}_2\text{CH}_2\text{C(CH}_3)_2 + \text{NaOH} \xrightarrow{\text{H}_2\text{O}} \]

**Strategy**
The first step is to identify the functional sites in the two starting materials. Then you can list the possible modes of reactivity for these functional groups and sort out which ones best apply.

**Solution**
• The organic component is a dihaloalkane. Hence, it contains two reaction sites that might be subject to the chemistry described in Chapters 6 and 7: S_N2, S_N1, E2, and E1.
• The inorganic NaOH is a strong unhindered base and nucleophile. Inspection of Table 7-4 reveals that hydroxide attacks haloalkanes at primary centers to make alcohols by S_N2, but forms alkenes at more hindered (to nucleophilic attack) positions by E2.
• Turning to the haloalkane, one Cl resides at an unhindered primary center; it should be replaced by OH through S_N2. The second Cl is also bound to a primary carbon; however, it is sterically hindered by \( \beta \) branching. Such steric hindrance retards nucleophilic attack, resulting in favorable E2, but only in cases in which a \( \beta \) hydrogen is available for deprotonation. In the present case, the carbon is neopentyl-like and E2 is not possible. Therefore, no reaction occurs at this center. Consequently, the product is

\[ \text{HO} \quad \text{Cl} \]

**Exercise 8-18**

**Try It Yourself**

Predict and explain the outcome of the following reactions on mechanistic grounds.

(a) \[ \text{ClCH}_2\text{CH}_2\text{CH}_2\text{C(CH}_3)_2 + \text{CH}_3\text{CH}_2\text{OH} \xrightarrow{\cdot} \]

(b) \[ \text{HOCH}_2\text{CH}_2\text{CH}_2\text{C(CH}_3)_2 \xrightarrow{\text{PCC, CH}_2\text{Cl}_2} \]

**New reactions lead to new synthetic methods**

New reactions are found by design or by accident. For example, consider how two different students might discover the reactivity of a Grignard reagent with a ketone to give an alcohol. The first student, knowing about electronegativity and the electronic makeup of ketones, would predict that the nucleophilic alkyl group of the Grignard species should attach itself to the electrophilic carbonyl carbon. This student would be pleased by the successful outcome of the experiment, verifying chemical principles in practice. The second student, with less knowledge, might attempt to dilute a particularly concentrated solution of a Grignard reagent with what one might conceive to be a perfectly good polar solvent: acetone. A violent reaction would immediately reveal that this notion is incorrect, and further investigation would uncover the powerful potential of the reagent in alcohol synthesis.
When a reaction has been discovered, it is important to show its scope and its limitations. For this purpose, many different substrates are tested, side products (if any) noted, new functional groups subjected to the reaction conditions, and mechanistic studies carried out. Should these investigations prove the new reaction to be generally applicable, it is added as a new synthetic method to the organic chemist’s arsenal.

Because a reaction leads to a very specific change in a molecule, it is frequently useful to emphasize the general nature of this “molecular alteration.” A simple example is the addition of a Grignard or alkyllithium reagent to formaldehyde. What is the structural change in this transformation? A one-carbon unit is added to an alkyl group. The method is valuable because it allows a straightforward one-carbon extension, also called a homologation.

Even though our synthetic vocabulary at this stage is relatively limited, we already have quite a number of molecular alterations at our disposal. For example, bromoalkanes are excellent starting points for numerous transformations.

Each one of the products in the scheme can enter into further transformations of its own, thereby leading to more complicated products.

When we ask, “What good is a reaction? What sort of structures can we make by applying it?” we address a problem of synthetic methodology. Let us ask a different question. Suppose that we want to prepare a specific target molecule. How would we go about devising an efficient route to it? How do we find suitable starting materials? The problem with which we are dealing now is total synthesis.

Organic chemists want to make complex molecules for specific purposes. For example, certain compounds might have valuable medicinal properties but are not readily available from natural sources. Biochemists need a particular isotopically labeled molecule to trace metabolic pathways. Physical organic chemists frequently design novel structures to study. There are many reasons for the total synthesis of organic molecules.

Whatever the final target, a successful synthesis is characterized by brevity and high overall yield. The starting materials should be readily available, preferably commercially, and inexpensive. The principles of “green” chemistry need to be addressed (see Chemical Highlight 3-1), minimizing safety and environmental concerns, such as potentially dangerous reaction conditions and ingredients and the production of toxic waste.

**Retrosynthetic analysis simplifies synthesis problems**

Many compounds that are commercially available and inexpensive are also small, containing six or fewer carbon atoms. Therefore, the most frequent task facing the synthetic planner
is that of building up a larger, complicated molecule from smaller, simple fragments. The best approach to the preparation of the target is to work its synthesis backward on paper, an approach called \textit{retrosynthetic analysis} (\textit{retro}, Latin, backward). In this analysis, strategic carbon–carbon bonds \textit{in the target} are “broken” at points where bond formation seems possible. This way of thinking backward may seem strange to you at first, because you are accustomed to learning reactions in a forward way—for example, “A plus B gives C.” Retrosynthesis requires that you think of this process in the reverse manner—for example, “C is derived from A plus B” (recall Exercise 6-2, p. 220).

Why retrosynthesis? The answer is that, in any “building” of a complex framework from simple building blocks, the number of possibilities of adding pieces increases drastically when going forward and includes myriad “dead-end” options. In contrast, in working backward, complexity decreases and unworkable solutions are minimized. A simple analogy is a jigsaw puzzle: It is clearly easier to dismantle step by step than it is to assemble. For example, a retrosynthetic analysis of the synthesis of 3-hexanol from two three-carbon units would suggest its formation from a propyl organometallic compound and propanal.

\begin{center}
\textbf{Retrosynthetic Analysis of 3-Hexanol Synthesis from Two Three-Carbon Fragments}
\end{center}

\[
\begin{align*}
\text{Propylmagnesium bromide} & \quad \text{Propanal} \\
\text{Retrosynthetic Analysis} & \\
\text{OH} & \quad \text{O} \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{+CHCH}_2\text{CH}_3 & \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{MgBr} + \text{HCCH}_2\text{CH}_3
\end{align*}
\]

The double-shafted arrow indicates the so-called \textit{strategic disconnection}. We recognize that the bond “broken” in this analysis, that between C3 and C4 in the product, is one that we can construct by using a transformation that we know, CH$_3$CH$_2$CH$_2$MgBr + CH$_3$CH$_2$CHO. In this case, only one reaction is necessary to achieve the connection; in others, it might require several steps.

Why not pick the other possible C–C disconnection, namely, that between C4 and C5? In our example, this strategy is perfectly reasonable and would require the starting materials butanal and ethylmagnesium bromide. In general, however, retrosynthetic disconnections should be made to provide molecular pieces that are as equally sized as possible. Therefore, our first analysis is superior.

\begin{center}
\textbf{Retrosynthetic Disconnection of 3-Hexanol at C4–C5}

\end{align*}
\]

\[
\begin{align*}
\text{OH} & \quad \text{O} \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{CHCH}_2\text{CH}_3 & \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CHCH}_2\text{CH}_3
\end{align*}
\]

\*Pioneered by Professor Elias J. Corey (b. 1928), Harvard University, Nobel Prize 1990 (chemistry).
They are not as good as the first because they do not significantly simplify the target structure: No carbon–carbon bonds are “broken.”

**Retrosynthetic analysis aids in alcohol construction**

Let us apply retrosynthetic analysis to the preparation of a tertiary alcohol, 4-ethyl-4-nonanol. Because of their steric encumbrance and hydrophobic nature, this alcohol and its homologs have important industrial applications as cosolvents and additives in certain polymerization processes (Section 12-14). There are two steps to follow at each stage of the process. First, we identify all possible strategic disconnections, “breaking” all bonds that can be formed by reactions that we know. Second, we evaluate the relative merits of these disconnections, seeking the one that best simplifies the target structure. The strategic bonds in 4-ethyl-4-nonanol are those around the functional group. There are three disconnections leading to simpler precursors. Path a cleaves the ethyl group from C4, suggesting as the starting materials for its construction ethylmagnesium bromide and 4-nonanone. Cleavage b is an alternative possibility leading to a propyl Grignard reagent and 3-octanone as precursors. Finally, disconnection c reveals a third synthesis route derived from the addition of pentylmagnesium bromide to 3-hexanone.

**Partial Retrosynthetic Analysis of the Synthesis of 4-Ethyl-4-nonanol**

Evaluation reveals that pathway c is best: The necessary building blocks are almost equal in size, containing five and six carbons; thus, this disconnection provides the greatest simplification in structure.

**Exercise 8-19**

Apply retrosynthetic analysis to 4-ethyl-4-nonanol, disconnecting the carbon–oxygen bond. Does this lead to an efficient synthesis? Explain.

Can we pursue either of the fragments arising from disconnection by pathway c to even simpler starting materials? Yes; recall (Section 8-6) that ketones are obtained from the oxidation of secondary alcohols by Cr(VI) reagents. We may therefore envision preparation of 3-hexanone from the corresponding alcohol, 3-hexanol.
Because we earlier identified an efficient disconnection of 3-hexanol into two three-carbon fragments, we are now in a position to present our complete synthetic scheme:

**Synthesis of 4-Ethyl-4-nonanol**

\[
\begin{align*}
\text{Propanal} & \xrightarrow{1. \text{CH}_3\text{CH}_2\text{CH}_2\text{MgBr}, (\text{CH}_3\text{CH}_2)_2\text{O}, 2. \text{H}^+, \text{H}_2\text{O}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \\
\text{3-Hexanone} & \xrightarrow{1. \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{MgBr}, (\text{CH}_3\text{CH}_2)_2\text{O}, 2. \text{H}^+, \text{H}_2\text{O}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

This example illustrates a very powerful general sequence for the construction of complex alcohols: first, Grignard or organolithium addition to an aldehyde to give a secondary alcohol; then oxidation to a ketone; and finally, addition of another organometallic reagent to give a tertiary alcohol.

**Exercise 8-20**

**Working with the Concepts: Working Backward Through Retrosynthesis**

Write a retrosynthetic analysis of 3-cyclobutyl-3-heptanol from starting materials containing four carbons or less.

**Strategy**

We apply the steps discussed for retrosynthetic analysis: Identify all possible strategic disconnections, then evaluate the relative merits of these disconnections. In this case, our evaluation has to take into account the restriction that starting materials contain four carbons or less.

**Solution**

- Applying what we have learned so far, we can dissect the product retrosynthetically in three possible ways: \(a\), \(b\), and \(c\).

\[\text{MgBr}\]

\[
\begin{align*}
\text{MgBr} & \xrightarrow{a} \text{CH}_3\text{CH}_{2}\text{CH}_2\text{CH}_3 \\
\text{MgBr} & \xrightarrow{b} \text{CH}_3\text{CH}_{2}\text{CH}_2\text{CH}_3 \\
\text{MgBr} & \xrightarrow{c} \text{CH}_3\text{CH}_{2}\text{CH}_2\text{CH}_3
\end{align*}
\]

- All of them break down the target into smaller fragments, but none of these schemes provides fragments of the stipulated size: four carbons or less. Thus, the resulting ketones contain seven or
Watch out for pitfalls in planning syntheses

There are several considerations to keep in mind when practicing synthetic chemistry that will help to avoid designing unsuccessful or low-yielding approaches to a target molecule.

First, try to minimize the total number of transformations required to convert the initial starting material into the desired product.

This point is so important that, in some cases, it is worthwhile to accept a low-yield step if it allows a significant shortening of the synthetic sequence. For example (with the assumption that all starting materials are of comparable cost), a seven-step synthesis in which each step has an 85% yield is inferior to a four-step synthesis with three yields at 95% and one at 45%. The overall efficiency in the first sequence comes to \((0.85 \times 0.85 \times 0.85 \times 0.85 \times 0.85 \times 0.85 \times 0.85) \times 100 = 32\%\), whereas the second synthesis, in addition to being three steps shorter, gives \((0.95 \times 0.95 \times 0.95 \times 0.45) \times 100 = 39\%\).

In these examples, all steps take place consecutively, a procedure called linear synthesis. In general, it is better to approach complex targets through two or more concurrent routes, as long as the overall number of steps is the same, a strategy described as convergent synthesis. Although a simple overall-yield calculation is not possible for a convergent strategy, you can readily convince yourself of its increased efficiency by comparing the actual amounts of starting materials required by the two approaches to make the same amount of product. In the following example, 10 g of a product H is prepared first in three steps (50% each) by a linear sequence A \(\rightarrow\) B \(\rightarrow\) C \(\rightarrow\) H and second by a convergent one starting from D and F, respectively, through E and G. If we assume (for the sake of
simplicity) that the molecular weights of these compounds are all the same, the first preparation requires 80 g of starting materials and the second only (a combined) 40 g.

\[
\begin{align*}
A & \xrightarrow{50\%} B & C & \xrightarrow{50\%} H \\
80 \text{ g} & \quad 40 \text{ g} & 20 \text{ g} & \quad 10 \text{ g}
\end{align*}
\]

Linear synthesis of H

\[
\begin{align*}
D & \xrightarrow{50\%} E & \xrightarrow{50\%} H \\
20 \text{ g} & \quad 10 \text{ g} & \quad 10 \text{ g}
\end{align*}
\]

Convergent synthesis of H

Second, do not use reagents whose molecules have functional groups that would interfere with the desired reaction.

For example, treating a hydroxyaldehyde with a Grignard reagent leads to an acid-base reaction that destroys the organometallic reagent, and not to carbon–carbon bond formation.

\[
\begin{align*}
\text{HOCH}_2\text{CH}_2\text{CH} & \xrightarrow{\text{X}} \text{HOCH}_2\text{CH}_2\text{CH} + \text{CH}_3\text{MgBr} \\
\text{CH}_3
\end{align*}
\]

\[
\begin{align*}
\text{BrMgOCH}_2\text{CH}_2\text{CH} & + \text{CH}_3 \\
\text{O} & \quad \text{H}
\end{align*}
\]

A possible solution to this problem would be to add two equivalents of Grignard reagent: one to react with the acidic hydrogen as shown, the other to achieve the desired addition to the carbonyl group. Another solution is to “protect” the hydroxy function in the form of an ether. We will encounter this strategy in Section 9-8.

Do not try to make a Grignard reagent from a bromoketone. Such a reagent is not stable and will, as soon as it is formed, decompose by reacting with its own carbonyl group (in the same or another molecule). We will learn how to protect a carbonyl function in Section 17-8.

Third, take into account any mechanistic and structural constraints affecting the reactions under consideration.

For example, radical brominations are more selective than chlorinations. Keep in mind the structural limitations on nucleophilic reactions, and do not forget the lack of reactivity of the 2,2-dimethyl-1-halopropanes. Although sometimes difficult to recognize, many haloalkanes have such hindered structures and are similarly unreactive. Nevertheless, such systems do form organometallic reagents and may be further functionalized in this manner. For example, treatment of the Grignard reagent made from 1-bromo-2,2-dimethylpropane with formaldehyde leads to the corresponding alcohol.

\[
\begin{align*}
\text{(CH}_3\text{)}_3\text{CCH}_2\text{Br} & \xrightarrow{1. \text{ Mg}} \xrightarrow{2. \text{ CH}_3=\text{O}} \xrightarrow{3. \text{ H}^+\text{, H}_2\text{O}} \text{(CH}_3\text{)}_3\text{CCH}_2\text{CH}_2\text{OH} \\
1\text{-Bromo-2,2-dimethylpropane} & \quad \text{3,3-Dimethyl-1-butanol}
\end{align*}
\]
Tertiary haloalkanes, if incorporated into a more complex framework, also are sometimes difficult to recognize. Remember that tertiary halides do not undergo S_N2 reactions but eliminate in the presence of bases.

Expertise in synthesis, as in many other aspects of organic chemistry, develops largely from practice. Planning the synthesis of complex molecules requires a review of the reactions and mechanisms covered in earlier sections. The knowledge thus acquired can then be applied to the solution of synthetic problems.

**THE BIG PICTURE**

Where do we stand now, and where do we go from here? With Chapter 8, we have begun to discuss a second important functional class of compounds after the haloalkanes, namely, the alcohols. We used the haloalkanes to introduce two major mechanistic pathways: radical reactions (in order to make haloalkanes; Chapter 3) and ionic pathways (to demonstrate their reactivity in substitution and elimination, Chapters 6 and 7). In contrast, we have used the alcohols to introduce new types of reactions: oxidations, reductions, and organometallic additions to aldehydes and ketones. This discussion has allowed us to examine the idea of how to plan a synthesis. It requires us to start with a given product and work backward (retrosynthetic analysis) to determine what reactants and what kind of reaction conditions we need to obtain this product. As we proceed through the course and build up our knowledge of families of compounds and their chemistry, we shall keep returning to synthetic strategies as a way of classifying and applying this information.

This chapter and the next follow the format we shall use to present all future functional groups: (a) how to name them; (b) a description of their structures and general properties; (c) how to synthesize them; and (d) what kinds of reactions they undergo and how we can apply these reactions in various ways.

**CHAPTER INTEGRATION PROBLEMS**

8-22. Tertiary alcohols are important additives in some industrial processes utilizing Lewis acidic metal compounds (Section 2-2) as catalysts. The alcohol provides the metal with a sterically protecting and hydrophobic environment (see Figure 8-3; see also Chemical Highlight 8-1), which ensures solubility in organic solvents, longer lifetimes, and selectivity in substrate activation. Preparation of these tertiary alcohols typically follows the synthetic principles outlined in Section 8-9.

Starting from cyclohexane and using any other building blocks containing four or fewer carbons, in addition to any necessary reagents, formulate a synthesis of tertiary alcohol A.

**SOLUTION**

Before we start a random trial-and-error approach to solving this problem, it is better to take an inventory of what is given. First, we are given cyclohexane, and we note that this unit shows up as a substituent in tertiary alcohol A. Second, a total of seven additional carbons appears in the product, so our synthesis will require some additional stitching together of smaller fragments because we cannot
use compounds containing more than four carbons. Third, target A is a tertiary alcohol, which should be amenable to the retrosynthetic analysis introduced in Section 8-9 (M = metal):

Approach \( a \) is clearly the one of choice because it breaks up tertiary alcohol A into evenly sized fragments B and C.

Having chosen route \( a \) as the most suitable way to find direct precursors to A, we proceed to work backward further: What are the appropriate precursors to B and C, respectively? Compound B is readily traced by retrosynthesis to our starting hydrocarbon, cyclohexane: The precursor to the organometallic compound B must be a halocyclohexane, which in turn can be made from cyclohexane by free-radical halogenation:

Ketone C must be broken into two smaller components. The best breakdown would be a “four + three” carbon combination: It is the most evenly sized solution, and it suggests the use of cyclobutyl intermediates. Because the only C–C disconnection that we know at this stage is that of alcohols, the first retrosynthetic step from C is its precursor alcohol (plus a chromium oxidant). Further retrosynthesis then provides the required starting pieces D and E.

Now we can write the detailed synthetic scheme in a forward mode, with cyclohexane and pieces D and E as our starting materials:

A final note: In this and subsequent synthetic exercises in this book, retrosynthetic analysis requires that you have command of all reactions not only in a forward fashion (i.e., starting material + reagent \( \rightarrow \) product) but also in reverse (i.e., product \( \leftarrow \) starting material + reagent). The two sets address two different questions. The first asks: What are all the possible products that I can make from my starting material in the presence of all the reagents that I know? The second asks: What are all
the conceivable starting materials that, with the appropriate reagents, will lead to my product? The two types of schematic summaries of reactions that you will see at the end of this and subsequent chapters emphasize this point.

8-23. In this chapter we introduced redox reactions interconverting alcohols with aldehydes and ketones. The reagents employed were Cr(VI) (in the form of chromates, for example Na₂Cr₂O₇) and H⁻ (in the form of NaBH₄ and LiAlH₄). Organic chemists usually don’t worry about the inorganic products of such processes, because they are routinely discarded. However, for the purposes of electron bookkeeping (and in experimental recipes), it is useful (essential) to write balanced equations, showing how much of any given starting material is “going into” the reaction and how much of any possible product is “coming out.” Most of you have dealt with the problem of balancing equations in introductory chemistry, but usually only for redox exchanges between metals. Can you balance the following general oxidation of a primary alcohol to an aldehyde?

\[
\text{RCH}_2\text{OH} + \text{H}_2\text{SO}_4 + \text{Na}_2\text{Cr}_2\text{O}_7 \rightarrow \text{RCH} + \text{Cr}_2(\text{SO}_4)_3 + \text{Na}_2\text{SO}_4 + \text{H}_2\text{O}
\]

SOLUTION
It is best to think of this transformation as two separate reactions taking place simultaneously: (1) the oxidation of the alcohol, (2) the reduction of the Cr(VI) species to Cr(III). These two parts are called **half-reactions**. In water, which is the common solvent for this and similar redox processes, we balance the half-reactions by

- **a.** treating any hydrogen atoms consumed or produced as H³O⁺ (or, for simplicity, H⁺),
- **b.** treating any oxygen atoms consumed or produced as H₂O (in acidic solutions) or OH⁻ (in basic solution),
- **c.** adding electrons explicitly to the side deficient in negative charge.

Let us apply these guidelines to equation (1), which can be thought of as the removal of two hydrogens from the alcohol. These hydrogens are written as protons on the product side (rule a), charge-balanced by two added electrons (rule c):

\[
\text{RCH}_2\text{OH} \rightarrow \text{RCH} + 2 \text{H}^+ + 2 \text{e}^-
\]  

(1)

Turning to the half-reaction of the chromium species, we know that \( \text{Cr}_2\text{O}_7^{2⁻} \) is changed to (two) Cr³⁺ ions:

\[
\text{Cr}_2\text{O}_7^{2⁻} \rightarrow 2 \text{Cr}^{3⁺}
\]

We note that seven oxygen atoms need to appear on the right side; rule (b) stipulates seven molecules of H₂O:

\[
\text{Cr}_2\text{O}_7^{2⁻} \rightarrow 2 \text{Cr}^{3⁺} + 7 \text{H}_2\text{O}
\]

This change requires that 14 hydrogens be added to the left side; rule (a) says 14 H⁺ atoms:

\[
14 \text{H}^+ + \text{Cr}_2\text{O}_7^{2⁻} \rightarrow 2 \text{Cr}^{3⁺} + 7 \text{H}_2\text{O}
\]

Is the charge balanced? No, rule (c) tells us to add six electrons to the left side, resulting in balanced equation (2).

\[
14 \text{H}^+ + \text{Cr}_2\text{O}_7^{2⁻} + 6 \text{e}^- \rightarrow 2 \text{Cr}^{3⁺} + 7 \text{H}_2\text{O}
\]  

(2)

Inspection of the two half-reactions shows that, as written, (1) generates 2e⁻ (an oxidation, Section 8-6) and (2) consumes 6e⁻ (a reduction, Section 8-6). Since a chemical equation does not show electrons, we need to balance the production and consumption of electrons. We do this by simply multiplying (1) by 3:

\[
3 \text{RCH}_2\text{OH} \rightarrow 3 \text{RCH} + 6 \text{H}^+ + 6 \text{e}^-
\]  

(3)
We now combine the two balanced half-reactions by adding them to each other, that is, (3) + (2), a procedure that cancels out the electrons to give equation (4).

\[
\begin{align*}
3 \text{RCH}_2\text{OH} & \rightarrow 3 \text{RCH} + 6 \text{H}^+ + 6 \text{e}^- \quad (3) \\
14 \text{H}^+ + \text{Cr}_2\text{O}_7^{2-} + 6 \text{e}^- & \rightarrow 2 \text{Cr}^{3+} + 7 \text{H}_2\text{O} \quad (2)
\end{align*}
\]

\[
3 \text{RCH}_2\text{OH} + 14 \text{H}^+ + \text{Cr}_2\text{O}_7^{2-} \rightarrow 3 \text{RCH} + 6 \text{H}^+ + 2 \text{Cr}^{3+} + 7 \text{H}_2\text{O} \quad (4)
\]

In this form, (4) contains H⁺ on both sides. We can simplify it by removing the “excess” H⁺ to furnish equation (5).

\[
3 \text{RCH}_2\text{OH} + 8 \text{H}^+ + \text{Cr}_2\text{O}_7^{2-} \rightarrow 3 \text{RCH} + 2 \text{Cr}^{3+} + 7 \text{H}_2\text{O} \quad (5)
\]

Finally, we add nonreacting “spectator ions” of this reaction to show the proper stoichiometry in equation (6).

\[
3 \text{RCH}_2\text{OH} + 4 \text{H}_2\text{SO}_4 + \text{Na}_2\text{Cr}_2\text{O}_7 \rightarrow 3 \text{RCH} + \text{Cr}_2(\text{SO}_4)_3 + \text{Na}_2\text{SO}_4 + 7 \text{H}_2\text{O} \quad (6)
\]

The balanced equation (6) very nicely reveals why the reaction is run in acidic medium: H₂SO₄ is consumed. It also highlights the oxidizing power of dichromate: One mole is sufficient to effect the oxidation of three moles of alcohol.

**New Reactions**

1. **Acid-Base Properties of Alcohols (Section 8-3)**

   \[ \text{RO}^- + \text{H}^+ \leftrightarrow \text{ROH} \]

   **Acidity:** RO⁻ → HO⁻ → H₂N⁻ → H₃C⁻

   **Basicity:** RO⁻ < HO⁻ < H₂N⁻ < H₃C⁻

2. **Nucleophilic Displacement of Halides and Other Leaving Groups by Hydroxide (Section 8-5)**

   \[ \text{RCH}_2\text{X} + \text{HO}^- \rightarrow \text{RCH}_2\text{OH} + \text{X}^- \]

   **X = halide, sulfonate**

   **Primary, secondary (tertiary undergoes elimination)**

   \[ \begin{align*}
   \text{RCH}_2\text{X} + \text{CH}_2\text{CO}^- & \rightarrow \text{RCHOCCH}_3 \\
   \text{R'CHX} + \text{H}_2\text{O} & \rightarrow \text{R'COH}
   \end{align*} \]

   **Best method for tertiary**
3. Reduction of Aldehydes and Ketones by Hydrides (Section 8-6)

\[
\begin{align*}
\text{Aldehyde} & \quad \text{Primary alcohol} & \quad \text{Ketone} & \quad \text{Secondary alcohol} \\
\ce{RCH(OH)} & \quad \ce{CH3CH2OH} & \quad \ce{O} & \quad \ce{NaBH4, CH3CH2OH} & \quad \ce{RCH2OH} \\
\ce{RCH(OH)} & \quad \ce{CH3CH2OH} & \quad \ce{O} & \quad \ce{NaBH4, CH3CH2OH} & \quad \ce{RCH2OH} \\
\end{align*}
\]

Oxidation of Alcohols

4. Chromium Reagents (Section 8-6)

\[

**Important Concepts**

1. Alcohols are **alkanols** in IUPAC nomenclature. The stem containing the functional group gives the alcohol its name. Alkyl and halo substituents are added as prefixes.

2. Like water, alcohols have a **polarized** and short O–H bond. The hydroxy group is **hydrophilic** and enters into hydrogen bonding. Consequently, alcohols have unusually high boiling points and, in many cases, appreciable water solubility. The alkyl part of the molecule is **hydrophobic**.

3. Again like water, alcohols are **amphoteric**: They are both acidic and basic. Complete deprotonation to an **alkoxide** takes place with bases whose conjugate acids are considerably weaker than the alcohol. Protonation gives an **alkyloxonium ion**. In solution, the order of acidity is **primary**, **secondary**, **tertiary** alcohol. Electron-withdrawing substituents increase the acidity (and reduce the basicity).

4. The conversion of the electrophilic alkyl group in a haloalkane, C\(_{d1}\)–X\(_{d2}\), into its nucleophilic analog in an **organometallic compound**, C\(_{d}–M_{d1}\), is an example of **reverse polarization**.

5. The carbon atom in the **carbonyl group**, C\(\equiv\)O, of an aldehyde or a ketone is electrophilic and therefore subject to attack by nucleophiles, such as hydride in **hydride reagents** or alkyl in organometallic compounds. Subsequent to aqueous work-up, the products of such transformations are alcohols.

6. The **oxidation** of alcohols to aldehydes and ketones by chromium(VI) reagents opens up important synthetic possibilities based on further reactions with organometallic reagents.

7. **Retrosynthetic analysis** aids in planning the synthesis of complex organic molecules by identifying strategic bonds that may be constructed in an efficient sequence of reactions.

**Problems**

24. Name the following alcohols according to the IUPAC nomenclature system. Indicate stereochemistry (if any) and label the hydroxy groups as primary, secondary, or tertiary.

(a) \(\text{CH}_3\text{CH}_2\text{CHCH}_3\)\(\text{OH}\)
(b) \(\text{CH}_3\text{CHCH}_2\text{CHCH}_2\text{CH}_3\)\(\text{Br}\)\(\text{OH}\)
(c) \(\text{HOCH}_2\text{CH(CH}_2\text{CH}_2\text{CH}_3)_2\)
(d) \(\text{H}_2\text{C}–\text{CHCl}–\text{OH}\)
(e) \(\text{CH}_3\text{CH}_3\)\(\text{CH}_2\text{OH}\)
(f) \(\text{OH}\)\(\text{HOH}\)\(\text{Br}\)
(g) \(\text{C(CH}_2\text{OH})_4\)

25. Draw the structures of the following alcohols. (a) 2-(Trimethylsilyl)ethanol; (b) 1-methylcyclopropanol; (c) 3-(1-methylethyl)-2-hexanol; (d) \(\text{R}\)-2-pentanol; (e) 3,3-dibromocyclohexanol.

26. Rank each group of compounds in order of increasing boiling point. (a) Cyclohexane, cyclohexanol, chlorocyclohexane; (b) 2,3-dimethyl-2-pentanol, 2-methyl-2-hexanol, 2-heptanol.

27. Explain the order of water solubilities for the compounds in each of the following groups. (a) Ethanol > chloroethane > ethane; (b) methanol > ethanol > 1-propanol.

28. 1,2-Ethanediol exists to a much greater extent in the **gauche** conformation than does 1,2-dichloroethane. Explain. Would you expect the **gauche**: **anti** conformational ratio of 2-chloroethanol to be similar to that of 1,2-dichloroethane or more like that of 1,2-ethanediol?

29. The most stable conformation of **trans**-1,2-cyclohexanediol is the chair in which both hydroxy groups are equatorial. (a) Draw the structure or, better yet, make a model of the compound in this conformation. (b) Reaction of this diol with the chlorosilane \(\text{R}_3\text{SiCl}\), \(\text{R} = (\text{CH}_3)_2\text{CH}\) (isopropyl), gives the corresponding disilyl ether shown in the margin. Remarkably, this transformation causes the chair to flip, giving a conformation where both silyl ether groups are in **axial** positions. Explain this observation by means of either structural drawings or models.
30. Rank the compounds in each group in order of decreasing acidity.

(a) \( \text{CH}_3\text{CHClCH}_2\text{OH}, \text{CH}_3\text{CHBrCH}_2\text{OH}, \text{BrCH}_2\text{CH}_2\text{OH} \)
(b) \( \text{CH}_3\text{CCl}_2\text{CH}_2\text{OH}, \text{CCl}_3\text{CH}_2\text{OH}, (\text{CH}_3)_2\text{CClCH}_2\text{OH} \)
(c) \( (\text{CH}_3)_2\text{CHOH}, (\text{CF}_3)_2\text{CHOH}, (\text{CCl}_3)_2\text{CHOH} \)

31. Write an appropriate equation to show how each of the following alcohols acts as, first, a base, and, second, an acid in solution. How do the base and acid strengths of each compare with those of methanol? (a) \((\text{CH}_3)_2\text{CHOH}\); (b) \(\text{CH}_3\text{CHFCH}_2\text{OH}\); (c) \(\text{CCl}_3\text{CH}_2\text{OH}\).

32. Given the \(\text{pK}_a\) values of \(-2.2\) for \(\text{CH}_3\text{OH}_2\) and \(15.5\) for \(\text{CH}_3\text{OH}\), calculate the pH at which (a) methanol will contain exactly equal amounts of \(\text{CH}_3\text{OH}_2\) and \(\text{CH}_3\text{O}^-\); (b) \(50\%\) \(\text{CH}_3\text{OH}\) and \(50\%\) \(\text{CH}_3\text{OH}_2\) will be present; (c) \(50\%\) \(\text{CH}_3\text{OH}\) and \(50\%\) \(\text{CH}_3\text{O}^-\) will be present.

33. Do you expect hyperconjugation to be important in the stabilization of alkyloxonium ions (e.g., \(\text{ROH}_2\), \(\text{R}_2\text{OH}\))? Explain your answer.

34. Evaluate each of the following possible alcohol syntheses as being good (the desired alcohol is the major or only product), not so good (the desired alcohol is a minor product), or worthless. (Hint: Refer to Section 7-9 if necessary.)

(a) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl} \xrightarrow{\text{H}_2\text{O}, \text{CH}_3\text{CH}_3} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}\)
(b) \(\text{CH}_3\text{OSO}_2\xrightarrow{\text{CH}_3\text{CH}_2\text{OH}, \Delta, \text{H}_2\text{O}} \text{CH}_3\text{OH}\)
(c) \(\text{CH}_3\text{CHCH}_3\xrightarrow{\text{H}_2\text{O}, \Delta, \text{CH}_3\text{CHCH}_3} \text{CH}_3\text{CHCHCH}_2\text{CH}_3\)
(d) \(\text{CH}_3\text{CHCHCH}_2\text{CH}_3\xrightarrow{\text{H}_2\text{O}, \Delta} \text{CH}_3\text{CHCHCH}_2\text{CH}_3\)
(e) \(\text{CH}_3\text{CHCH}_2\text{Cl}\xrightarrow{\text{H}_2\text{O}, \Delta} \text{CH}_3\text{CHCH}_2\text{OH}\)
(f) \(\text{CH}_3\text{CHCH}_2\text{Cl}\xrightarrow{\text{H}_2\text{O}, \Delta} \text{CH}_3\text{CHCH}_2\text{OH}\)
(g) \(\text{H}_3\text{CBr}\xrightarrow{\text{H}_2\text{O}, \Delta} \text{H}_3\text{COH}\)
(h) \(\text{CH}_3\text{CHCH}_2\text{Cl}\xrightarrow{\text{H}_2\text{O}, \Delta} \text{CH}_3\text{CHCH}_2\text{OH}\)

35. For every process in Problem 34 that gives the designated product in poor yield, suggest a superior method if possible.

36. Give the major product(s) of each of the following reactions. Aqueous work-up steps (when necessary) have been omitted.

(a) \(\text{CH}_3\text{CH}==\text{CHCH}_3\xrightarrow{\text{H}_2\text{PO}_4, \text{H}_2\text{O}, \Delta} \) (Hint: See Section 8-4.)
(b) \(\text{CH}_3\text{CHCH}_2\text{CH}_2\text{CH}_3\xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O} 2. \text{H}_2\text{O}, \Delta} \)
(c) \(\text{CH}_3\text{CHCH}_2\text{CH}_2\text{CH}_3\xrightarrow{\text{NaBH}_4, \text{CH}_3\text{CH}_2\text{OH}} \)
(d) \(\text{Br}\xrightarrow{\text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O}} \)
(e) \(\text{CH}_3\text{CHCH}_2\text{CH}_2\text{CH}_3\xrightarrow{\text{NaBH}_4, \text{CH}_3\text{CH}_2\text{OH}} \)

37. What is the direction of the following equilibrium? (Hint: The \(\text{pK}_a\) for \(\text{H}_2\) is about 38.)

\[ \text{H}^- + \text{H}_2\text{O} \Leftrightarrow \text{H}_2 + \text{HO}^- \]
38. Formulate the product of each of the following reactions. The solvent in each case is (CH₃CH₂)₂O.

(a) \( \text{CH}_3\text{CH} \xrightarrow{\text{LiAlD}_4} \text{H}^-, \text{H}_2\text{O} \)  
(b) \( \text{CH}_3\text{CH} \xrightarrow{\text{LiAlH}_4} \text{D}^-, \text{D}_2\text{O} \)  
(c) \( \text{CH}_3\text{CH}_2\text{I} \xrightarrow{\text{LiAlD}_4} \)

39. Write out a mechanism for every reaction depicted in Problem 38.

40. Give the major product(s) of each of the following reactions [after work-up with aqueous acid in (d), (f), and (h)].

(a) \( \text{CH}_3\text{CH}_2\text{CHCH}_3 \xrightarrow{\text{Mg}, \text{(CH}_3\text{CH}_2\text{)}_2\text{O}} \text{Cl} \)  
(b) Product of (a) \( \xrightarrow{\text{D}_2\text{O}} \)  
(c) \( \text{Br} \xrightarrow{\text{Li}, \text{(CH}_3\text{CH}_2\text{)}_2\text{O}} \)  
(d) Product of (c)  
(e) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} + \text{Mg} \xrightarrow{(\text{CH}_3\text{CH}_2\text{)}_2\text{O}} \)  
(f) Product of (e) + \( \text{C}_6\text{H}_5\text{CHO} \)  
(g) \( \text{Br} \xrightarrow{2\text{Li}, (\text{CH}_3\text{CH}_2\text{)}_2\text{O}} \)  
(h) 2 mol product of (g) + 1 mol \( \text{CH}_3\text{CCH}_2\text{CH}_2\text{CCH}_3 \)

41. The common practice of washing laboratory glassware with acetone can lead to unintended consequences. For example, a student plans to carry out the preparation of methylmagnesium iodide, \( \text{CH}_3\text{MgI} \), which he will add to benzaldehyde, \( \text{C}_6\text{H}_5\text{CHO} \). What compound is he intending to synthesize after aqueous work-up? Using his freshly washed glassware, he carries out the procedure and finds that he has produced an unexpected tertiary alcohol as a product. What substance did he make? How did it form?

42. Which of the following halogenated compounds can be used successfully to prepare a Grignard reagent for alcohol synthesis by subsequent reaction with an aldehyde or ketone? Which ones cannot and why?

(a) \( \text{Br} \xrightarrow{\text{Cl}} \text{C}_6\text{H}_5\text{CH}_3 \)  
(b) \( \text{Cl} \xrightarrow{\text{O}} \text{C}_6\text{H}_5\text{CH}_3 \)  
(c) \( \text{I} \xrightarrow{\text{O}} \text{C}_6\text{H}_5\text{CH}_3 \)  
(d) \( \text{H} \xrightarrow{\text{O}} \text{C}_6\text{H}_5\text{CH}_3 \)  
(e) \( \text{H} \xrightarrow{\text{Br}} \text{C}_6\text{H}_5\text{CH}_3 \)  

(Hint: See Problem 49 in Chapter 1.)

43. Give the major product(s) of each of the following reactions (after aqueous work-up). The solvent in each case is ethoxyethane (diethyl ether).

(a) \( \text{MgBr} + \text{HCH} \)  
(b) \( \text{CH}_3\text{CHCH}_2\text{MgCl} + \text{CH}_3\text{CH} \)  
(c) \( \text{C}_6\text{H}_5\text{CH}_2\text{Li} + \text{C}_6\text{H}_6\text{CH} \)  
(d) \( \text{MgBr} + \text{C}_6\text{H}_5\text{CH}_3 \)  
(e) \( \text{MgCl} + \text{CH}_3\text{CHCH}_2\text{CH}_3 \)

44. For each reaction presented in Problem 43, write out the complete, step-by-step mechanism using curved-arrow notation. Include the aqueous acid work-up.
45. Write the structures of the products of reaction of ethylmagnesium bromide, CH₃CH₂MgBr, with each of the following carbonyl compounds. Identify any reaction that gives more than one stereoisomeric product, and indicate whether you would expect the products to form in identical or in differing amounts.

(a) 

(b) 

(c) 

(d) 

(e) 

(f) 

(g) 

(h) 

(i) 

(j) 

46. Give the expected major product of each of the following reactions. PCC is the abbreviation for pyridinium chlorochromate (Section 8-6).

(a) CH₃CH₂CH₂OH → Na₂Cr₂O₇, H₂SO₄, H₂O

(b) (CH₃)₂CHCH₂OH → PCC, CH₂Cl₂

(c) CH₂OH → Na₂Cr₂O₇, H₂SO₄, H₂O

(d) PCC, CH₂Cl₂

(e) PCC, CH₂Cl₂

47. Write out a mechanism for every reaction depicted in Problem 46.

48. Give the expected major product of each of the following reaction sequences. PCC refers to pyridinium chlorochromate.

(a) (CH₃)₂CHOH → 1. CrO₃, H₂SO₄, H₂O → 2. CH₃CH₂MgBr, (CH₃CH₂)₂O → 3. H⁺, H₂O → 4. \(\text{Li}, (\text{CH}_3\text{CH}_2)\text{O}\) → 5. H⁺, H₂O

(b) CH₃CH₂CH₂CH₂Cl → 1. \(\text{OH}, \text{H}_2\text{O}\) → 2. PCC, CH₂Cl₂ → 3. \(\text{Li}, (\text{CH}_3\text{CH}_2)\text{O}\) → 4. H⁺, H₂O

(c) Product of (b) → 1. CrO₃, H₂SO₄, H₂O → 2. \(\text{LiAIH}_4, (\text{CH}_3\text{CH}_2)\text{O}\) → 3. H⁺, H₂O

49. Unlike Grignard and organolithium reagents, organometallic compounds of the most electropositive metals (Na, K, etc.) react rapidly with haloalkanes. As a result, attempts to convert RX into RNa or RK by reaction with the corresponding metal lead to alkanes by a reaction called Wurtz coupling.

\[2 \text{RX} + 2 \text{Na} \rightarrow \text{R–R} + 2 \text{NaX}\]

which is the result of

\[\text{R–X} + 2 \text{Na} \rightarrow \text{R–Na} + \text{NaX}\]

followed rapidly by

\[\text{R–Na} + \text{R–X} \rightarrow \text{R–R} + \text{NaX}\]

When it was still in use, the Wurtz coupling reaction was employed mainly for the preparation of alkanes by the coupling of two identical alkyl groups (e.g., equation 1 below). Suggest a
reason why Wurtz coupling might not be a useful method for coupling two different alkyl groups (equation 2).

\[
\begin{align*}
2 \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} + 2 \text{Na} & \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 + 2 \text{NaCl} \\
\text{CH}_3\text{CH}_2\text{Cl} + \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} + 2 \text{Na} & \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 + 2 \text{NaCl}
\end{align*}
\]

50. The reaction of two equivalents of Mg with 1,4-dibromobutane produces compound A. The reaction of A with two equivalents of CH₃CHO (acetaldehyde), followed by work-up with dilute aqueous acid, produces compound B, having the formula C₈H₁₈O₂. What are the structures of A and B?

51. Suggest the best synthetic route to each of the following simple alcohols, using in each case a simple alkane as your initial starting molecule. What are some disadvantages of beginning syntheses with alkanes?

(a) Methanol  (b) Ethanol  (c) 1-Propanol  
(d) 2-Propanol  (e) 1-Butanol  (f) 2-Butanol  
(g) 2-Methyl-2-propanol

52. For each alcohol in Problem 51, suggest (if possible) a synthetic route that starts with, first, an aldehyde and, second, a ketone.

53. Outline the best method for preparing each of the following compounds from an appropriate alcohol.

(a)  
(b) CH₃CH₂CH₂CH₂COOH  
(c)  
(d) CH₃CHCCH₃  
(e) CH₃CH

54. Suggest three different syntheses of 2-methyl-2-hexanol. Each route should utilize one of the following starting materials. Then use any number of steps and any other reagents needed.

(a)  
(b)  
(c)  

55. Devise three different syntheses of 3-octanol starting with (a) a ketone; (b) an aldehyde; (c) an aldehyde different from that employed in (b).

56. Fill in the missing reagent(s) needed to convert each molecule into the next one pictured in the synthetic scheme below. If a transformation requires more than one step, number the reagents for the individual steps sequentially.

57. Waxes are naturally occurring esters (alkyl alkanoates) containing long, straight alkyl chains. Whale oil contains the wax 1-hexadecyl hexadecanoate, as shown in the margin. How would you synthesize this wax, using an S₂₂ reaction?

58. The reduced form of the coenzyme nicotinamide adenine dinucleotide (NAD⁺, Chemical Highlight 8-1) is abbreviated NADH. In the presence of a variety of enzyme catalysts, it acts as a biological hydride donor, capable of reducing aldehydes and ketones to alcohols, according to the general formula

\[
\text{RCR} + \text{NADH} + \text{H}^+ \xrightarrow{\text{Enzyme}} \text{RCHR} + \text{NAD}^+
\]
The COOH functional group of carboxylic acids is not reduced. Write the products of the NADH reduction of each of the molecules below.

- **(a)** \( \text{CH}_3\text{CH}_2\text{OH} + \text{NADH} \) \( \xrightarrow{\text{Alcohol dehydrogenase}} \) Alcohol dehydrogenase

- **(b)** \( \text{CH}_3\text{COCH}_2\text{H} + \text{NADH} \) \( \xrightarrow{\text{Lactate dehydrogenase}} \) Lactic acid

- **(c)** \( \text{HOOCCH}_2\text{CH}_2\text{COOH} + \text{NADH} \) \( \xrightarrow{\text{Malate dehydrogenase}} \) Malic acid

59. Reductions by NADH (Problem 58) are stereospecific, with the stereochemistry of the product controlled by an enzyme (see Chemical Highlight 8-1). The common forms of lactate and malate dehydrogenases produce exclusively the \( S \) stereoisomers of lactic and malic acids, respectively. Draw these stereoisomers.

60. Chemically modified steroids have become increasingly important in medicine. Give the possible product(s) of the following reactions. In each case, identify the major stereoisomer formed on the basis of delivery of the attacking reagent from the less hindered side of the substrate molecule. (Hint: Make models and refer to Section 4-7.)

61. Why do the two reactions shown in Problem 60 both require the use of excess \( \text{CH}_3\text{MgI} \) and \( \text{CH}_3\text{Li} \), respectively? How many equivalents of the organometallic reagents are needed in each case? What are the products of the reaction at each functionalized site in each molecule?

**Team Problem**

62. Your team has been asked to devise a synthesis of the tertiary alcohol 2-cyclohexyl-2-butanol, \( \text{A} \). Your laboratory is well stocked with the usual organic and inorganic reagents and solvents. An inventory check reveals that there are many appropriate bromoalkanes and alcohols on hand. As a group, analyze alcohol \( \text{A} \) retrosynthetically and propose all possible strategic disconnections. Check the inventory to see if a particular route is feasible in terms of available starting materials. Then divide the proposed routes evenly among yourselves to evaluate the merits or pitfalls of these strategies. Write a detailed synthetic plan based on your chosen retrosynthesis for the synthesis of 2-cyclohexyl-2-butanol. Reconvene to defend or reject these plans. Finally, take into consideration the prices of your starting materials. Which one of your routes to \( \text{A} \) is the cheapest?

Preprofessional Problems

63. A compound known to contain only C, H, and O gives the following upon microanalysis (atomic weights: C = 12.0, H = 1.00, O = 16.0): 52.1% C, 13.1% H. It is found to have a boiling point of 78°C. Its structure is

(a) CH₃OCH₃   (b) CH₃CH₂OH   (c) HOCH₂CH₂CH₂OH
(d) HOCH₂CH₂CH₂OH   (e) none of these

64. The compound whose structure is (CH₃)₂CHCH₂CH₂CH₂CH₃ is best named (IUPAC):

(a) 2-methyl-4-hexanol   (b) 5-methyl-3-hexanol
(c) 1,4,4-trimethyl-2-butanol   (d) 1-isopropyl-2-hexanol

65. In this transformation, what is the best structure for “A”?

66. Ester hydrolysis is best illustrated by

(a) CH₃OCCH₃ $\xrightarrow{H^+; H_2O}$ CH₃CH₂OH + CO   (b) CH₃OCCH₃ $\xrightarrow{H^+; H_2O}$ CH₃OH + HOCH₃
(c) CH₃OCH₂OH $\xrightarrow{H_2O}$ CH₃OH + H−C−H   (d) CH₃OH + CH₃CO₂H $\xrightarrow{H_2O}$ CH₃OCCH₃
Do you remember the fizzing that occurred when you (or your teacher) dropped a pellet of sodium into water? The violent reaction that you observed was due to the conversion of the metal and water into NaOH and H₂ gas. Alcohols, which can be regarded as “alkylated water” (Section 8-2), undergo the same reaction, albeit less vigorously, to give NaOR and H₂. This chapter will describe this and further transformations of the hydroxy substituent.

Figure 9-1 depicts a variety of reaction modes available to alcohols. Usually at least one of the four bonds marked a, b, c, or d is cleaved. In Chapter 8 we learned that oxidation to aldehydes and ketones breaks bonds a and d. We found that the use of this reaction in combination with additions of organometallic reagents provides us with the means of preparing alcohols of considerable structural diversity.

To further explore the reactions of alcohols, we start by reviewing their acidic and basic properties. Deprotonation at bond a furnishes alkoxides (Section 8-3), which are valuable both as strong bases and as nucleophiles (Section 7-8). Strong acids transform alcohols into alkylxonium ions (Section 8-3), converting OH (a poor leaving group) into H₂O (a good leaving group). Subsequently, bond b may break, thereby leading to substitution; or elimination can take place by cleavage of bonds b and c. We shall see that the carbocation intermediates arising from acid treatment of secondary and tertiary alcohols have a varied chemistry.

An introduction to the preparation of esters and their applications in synthesis is followed by the chemistry of ethers and sulfur compounds. Alcohols, ethers, and their sulfur analogs occur widely in nature and have numerous applications in industry and medicine.

Ethoxyethane (diethyl ether or simply “ether”) was discovered as an anesthetic in 1846, prompting a newspaper headline exclaiming “We have conquered pain.” The photo shows an ether inhaler from that period. It consists of a glass vessel that contains ether-soaked sponges, connected to a facemask by tubing. Apart from its flammability, ether is fairly safe, but has the undesirable postanesthetic effects of headaches and nausea. It has been superseded by a host of more effective pain killing drugs, but is still popular in some developing nations.
Chapter 9
Further Reactions of Alcohols and the Chemistry of Ethers

9-1 Reactions of Alcohols with Base: Preparation of Alkoxides

As described in Section 8-3, alcohols can be both acids and bases. In this section, we shall review the methods by which the hydroxy group of alcohols is deprotonated to furnish their conjugate bases, the alkoxides.

Strong bases are needed to deprotonate alcohols completely

To remove a proton from the OH group of an alcohol (Figure 9-1, cleavage of bond \( a \)), we must use a base stronger than the alkoxide. Examples include lithium diisopropylamide (Section 7-8), butyllithium (Section 8-7), and alkali metal hydrides (Section 8-6, Exercise 8-4), such as potassium hydride, KH. Such hydrides are particularly useful because the only by-product of the reaction is hydrogen gas.

Three Ways of Making Methoxide from Methanol

\[
\begin{align*}
\text{CH}_3\text{OH} & \quad \text{CH(CH}_3)_2 \quad \text{Li}^+ \quad \text{NCH(CH}_3)_2 \quad K = 10^{34.5} \\
\text{pK}_a = 15.5 & \quad \text{CH}_3\text{O}^- \quad \text{Li}^+ & \quad \text{CH(CH}_3)_2 \quad \text{pK}_a = 40 \\
\text{CH}_3\text{OH} & \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Li} \quad K = 10^{44.1} \\
\text{pK}_a = 15.5 & \quad \text{CH}_3\text{O}^- \quad \text{Li}^+ & \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{H} \quad \text{pK}_a = 50 \\
\text{CH}_3\text{OH} & \quad \text{K}^+ \quad \text{H}^- \quad K = 10^{12.5} \\
\text{pK}_a = 15.5 & \quad \text{CH}_3\text{O}^- \quad \text{K}^+ & \quad \text{H}^- \quad \text{pK}_a = 38
\end{align*}
\]
Alkali metals also deprotonate alcohols—but by reduction of H⁺

Another common way of obtaining alkoxides is by the reaction of alcohols with alkali metals, such as lithium. Such metals reduce water—in some cases, violently—to yield alkali metal hydroxides and hydrogen gas. When the more reactive metals (sodium, potassium, and cesium) are exposed to water in air, the hydrogen generated can ignite spontaneously or even detonate.

\[
2 \text{H}_2\text{O} + 2 \text{M (Li, Na, K, Cs)} \rightarrow 2 \text{M}^{+} \text{OH}^+ + \text{H}_2
\]

The alkali metals act similarly on the alcohols to give alkoxides, but the transformation is less vigorous. Here are two examples.

**Alkoxides from Alcohols and Alkali Metals**

\[
\begin{align*}
2 \text{CH}_3\text{CH}_2\text{OH} + 2 \text{Na} & \rightarrow 2 \text{CH}_3\text{CH}_2\text{O}^-\text{Na}^+ + \text{H}_2 \\
2 (\text{CH}_3)\text{3COH} + 2 \text{K} & \rightarrow 2 (\text{CH}_3)\text{3CO}^-\text{K}^+ + \text{H}_2
\end{align*}
\]

The reactivity of the alcohols used in this process decreases with increasing substitution, methanol being most reactive and tertiary alcohols least reactive.

**Relative Reactivity of ROH with Alkali Metals**

\[
\text{R} = \text{CH}_3 > \text{primary} > \text{secondary} > \text{tertiary}
\]

2-Methyl-2-propanol reacts so slowly that it can be used to safely destroy potassium residues in the laboratory.

What are alkoxides good for? We have already seen that they can be useful reagents in organic synthesis. For example, the reaction of hindered alkoxides with haloalkanes gives elimination.

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} + (\text{CH}_3)\text{CO}^-\text{K}^+ \rightarrow \text{CH}_3\text{CH}_2\text{CH}==\text{CH}_2 + (\text{CH}_3)\text{3CO}^- + \text{K}^+\text{Br}^-
\]

Less branched alkoxides attack primary haloalkanes by the S_N2 reaction to give ethers. This method is described in Section 9-6.

**In Summary** A strong base will convert an alcohol into an alkoxide by an acid-base reaction. The stronger the base, the more the equilibrium is displaced to the alkoxide side. Alkali metals react with alcohols by reduction to generate hydrogen gas and an alkoxide. This process is retarded by steric hindrance.

9-2 Reactions of Alcohols with Strong Acids: Alkoxonium Ions in Substitution and Elimination Reactions of Alcohols

We have seen that heterolytic cleavage of the O–H bond in alcohols is readily achieved with strong bases. Can we break the C–O linkage (bond b, Figure 9-1) as easily? Yes, but now we need acid. Recall (Section 2-2) that water has a high pK_a (15.7): It is a weak acid. Consequently, hydroxide, its conjugate base, is an exceedingly poor leaving group. *For alcohols to undergo substitution or elimination reactions, the OH must first be converted into a better leaving group.*
**Haloalkanes from primary alcohols and HX: Water can be a leaving group in S_N2 reactions**

The simplest way of turning the hydroxy substituent in alcohols into a good leaving group is to protonate the oxygen to form an alkyloxonium ion. Recall (Section 8-3) that this process ties up one of the oxygen lone pairs by forming a bond to a proton. The positive charge therefore resides on the oxygen atom. *Protonation changes OH from a bad leaving group into neutral water, a good leaving group.*

This reaction is reversible and, under normal conditions, the equilibrium lies on the side of unprotonated alcohol. However, this is immaterial if a nucleophile is present in the mixture that is capable of trapping the oxonium species. For example, alkyloxonium ions derived from primary alcohols are subject to such nucleophilic attack. Thus, the butyloxonium ion resulting from the treatment of 1-butanol with concentrated HBr undergoes displacement by bromide to form 1-bromobutane. The originally nucleophilic (red) oxygen is protonated by the electrophilic proton (blue) to give the alkyloxonium ion, containing an electrophilic (blue) carbon and H_2O as a leaving group (green). In the subsequent S_N2 reaction, bromide acts as a nucleophile.

**Primary Bromoalkane Synthesis from an Alcohol**

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH} + \text{HBr} \rightleftharpoons \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}^+ + \text{Br}^- \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} + \text{H}_2\text{O}
\]

The reaction of primary alcohols with concentrated HI proceeds in similar fashion to furnish primary iodoalkanes (margin). On the other hand, concentrated HCl is sluggish in turning primary alcohols into the corresponding chloroalkanes, because chloride ion is a relatively weak nucleophile. Therefore, this conversion, while possible, is usually carried out by other reagents (Section 9-4). In general, the acid-catalyzed S_N2 reaction of primary alcohols with HBr or HI is a good way of preparing simple primary haloalkanes. What about secondary and tertiary alcohols?

**Secondary and tertiary alcohols and HX: Water can be a leaving group to form carbocations in S_N1 and E1 reactions**

Alkyloxonium ions derived from secondary and tertiary alcohols, in contrast with their primary counterparts, lose water with increasing ease to give the corresponding carbocations. The reason for this difference in behavior is the difference in carbocation stability (Section 7-5). Primary carbocations are too high in energy to be accessible under ordinary laboratory conditions, whereas secondary and tertiary carbocations are generated with increasing ease. Thus, primary alkyloxonium ions undergo only S_N2 reactions, whereas their secondary and tertiary relatives enter into S_N1 and E1 processes. When good nucleophiles are present, we observe S_N1 products.

**Reactivity of Oxonium Ions**

<table>

<td></td>
</tr>
</tbody>
</table>

**Increasing ease of carbocation formation**

Synthetically, this fact is exploited in the preparation of tertiary haloalkanes from tertiary alcohols in the presence of excess concentrated aqueous hydrogen halide. The product forms in minutes at room temperature. The mechanism is precisely the reverse of that of solvolysis (Section 7-2).
Chapter 9

Conversion of 2-Methyl-2-propanol into 2-Bromo-2-methylpropane

\[(\text{CH}_3)_3\text{COH} + \text{HBr} \underset{\text{Excess}}{\rightleftharpoons} (\text{CH}_3)_3\text{CBr} + \text{H}_2\text{O}\]

Mechanism of the S_N1 Reaction of Tertiary Alcohols with Hydrogen Halides

\[(\text{CH}_3)_3\text{C} \overset{\text{OH}}{\rightleftharpoons} \text{H} \overset{\text{Br}}{\rightarrow} \underset{\text{H}_2\text{O}}{\rightleftharpoons} \text{(CH}_3)_3\text{C} \overset{\text{OH}_2}{\rightleftharpoons} \text{HBr} \overset{\text{H}_2\text{O}}{\rightarrow} \text{(CH}_3)_3\text{C} \overset{\text{Br}}{\rightarrow}\]

The reason for the success of this process is that relatively low temperatures are sufficient to generate the tertiary carbocation, thus largely preventing competing E1 reactions (Section 7-6). Indeed, at higher temperatures (or in the absence of good nucleophiles), elimination becomes dominant.* This explains why protonated secondary alcohols show the most complex behavior in the presence of HX, following S_N2, S_N1, and E1 pathways: They are relatively hindered, compared with their primary counterparts (i.e., retarded S_N2 reactivity), and relatively slow in forming carbocations, compared with their tertiary counterparts (e.g., retarded S_N1 reactivity); review Section 7-9.

The E1 reaction, here called dehydration because it results in the loss of a molecule of water (Figure 9-1, breaking bonds b and c; see also Sections 9-3 and 9-7), is one of the methods for the synthesis of alkenes (Section 11-7). Rather than the “nucleophilic” acids HBr and HI, so called because the conjugate base is a good nucleophile, “nonnucleophilic” acids, such as H_3PO_4 or H_2SO_4, are employed.

**Exercise 9-2**

Write the structure of the product that you expect from the reaction of 4-methyl-1-pentanol with concentrated aqueous HI. Give the mechanism of its formation.

---

*The preference for elimination at high temperatures has its origin in its relatively large positive entropy (Section 2-1), as two molecules (alkene + H_2O) result from one (alcohol), and the \(\Delta S^\circ\) term in the expression \(\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ\) increases with temperature (see also Exercise 7-17).
In Summary  Treatment of alcohols with strong acid leads to protonation to give alkyl-
oxonium ions, which, when primary, undergo S\text{N}2 reactions in the presence of good nucleo-
philes. Alkyloxonium ions from secondary or tertiary alcohols convert into carbocations,
which furnish products of substitution and elimination (dehydration).

9-3 Carbocation Rearrangements

When alcohols are transformed into carbocations, the carbocations themselves are subject
to rearrangements. The two rearrangements, known as hydride shifts and alkyl shifts, can
occur with most types of carbocations. The rearranged molecules can then undergo further
S\text{N}1 or E1 reactions. The result is likely to be a complex mixture, unless we can establish
a thermodynamic driving force toward one specific product.

Hydride shifts give new S\text{N}1 products

Treatment of 2-propanol with concentrated hydrogen bromide gives 2-bromopropane, as
expected. However, exposure of the more highly substituted secondary alcohol 3-methyl-
2-butanol to the same reaction conditions produces a surprising result. The expected
S\text{N}1 product, 2-bromo-3-methylbutane, is only a minor component of the reaction mixture;
the major product is 2-bromo-2-methylbutane.

What is the mechanism of this transformation? The answer is that carbocations can undergo
rearrangement by hydride shifts, in which the hydrogen (yellow) moves with both electrons
from its original position to the neighboring carbon atom. Initially, protonation of the alcohol
followed by loss of water gives the expected secondary carbocation. A shift of the tertiary
hydrogen to the electron-deficient neighbor then generates a tertiary cation, which is more
stable. This species is finally trapped by bromide ion to give the rearranged S\text{N}1 product.
Mechanism of Carbocation Rearrangement

**Step 1.** Protonation

\[
\text{CH}_3\text{C}^+\text{CCH}_3 + \text{H}^+ \rightleftharpoons \text{CH}_3\text{C}^+\text{CCH}_3
\]

**Step 2.** Loss of water

\[
\text{CH}_3\text{C}^+\text{CCH}_3 \rightleftharpoons \text{CH}_3\text{C}^+\text{CCH}_3 + \text{H}_2\text{O}
\]

**Step 3.** Hydride shift

\[
\text{CH}_3\text{C}^+\text{CCH}_3 \longrightarrow \text{CH}_3\text{C}^+\text{CCH}_3
\]

**Step 4.** Trapping by bromide

\[
\text{CH}_3\text{C}^+\text{CCH}_3 + \text{Br}^+ \rightleftharpoons \text{CH}_3\text{C}^+\text{CCH}_3 + \text{Br}^-
\]

The details of the transition state of the observed hydride shift are shown schematically in Figure 9-2. A simple rule to remember when executing hydride shifts in carbocations is that the hydrogen and the positive charge formally exchange places between the two neighboring carbon atoms participating in the reaction.

Hydride shifts of carbocations are generally very fast—faster than SN1 or E1 reactions. In part, this rapidity is due to hyperconjugation, which weakens the C–H bond (Section 7-5 and Figure 9-2B). They are particularly favored when the new carbocation is more stable than the original one, as in the example depicted in Figure 9-2.

Figure 9-2 The rearrangement of a carbocation by a hydride shift: (A) dotted-line notation; (B) orbital picture. Note that the migrating hydrogen and the positive charge exchange places. In addition, you can see how hyperconjugation weakens the C–H bond by effecting some electron transfer into the empty neighboring π orbital.

Color is used to indicate the electrophilic (blue), nucleophilic (red), and leaving-group (green) character of the reacting centers. Therefore, a color may “switch” from one group or atom to another as the reaction proceeds.
Exercise 9-4

Working with the Concepts: Formulating a Carbocation Rearrangement

2-Methylcyclohexanol, on treatment with HBr, gives 1-bromo-1-methylcyclohexane. Explain by a mechanism.

**Strategy**

Let us dissect the problem along the lines of taking an inventory.

- What topological/connectivity changes are taking place? *Answer:* The six-membered ring stays intact, but the functionality has migrated from a secondary to a tertiary carbon.
- What is the change in molecular formula? *Answer:* We start with C₇H₁₄O and wind up with C₇H₁₃Br. The net change is that OH is being replaced by Br; no carbons are added or subtracted from the starting material.
- What thoughts come to mind when considering the functional group and the reagent to which it is exposed? *Answer:* We have an alcohol that is treated with HBr, a strong acid. The hydroxy function will be protonated, turning it into a good leaving group, and hence we have to consider substitution and elimination as possible reaction pathways.

**Solution**

- The answer to point 1 (rearrangement) and consideration of point 3 (alcohol and acid) strongly implicate an acid-catalyzed rearrangement via a carbocation.
- To arrive at the required carbocation, we need to protonate the alcohol and dissociate the leaving group. The result is a secondary carbocation.

\[
\begin{align*}
\text{CH}_3 & \quad \text{OH} \\
\text{\textbullet} & \quad \text{DLE} \\
\text{H} & \quad \text{DLE} \\
\text{\textbullet} & \quad \text{H}_2\text{O}; \\
\text{CH}_3 & \quad \text{OH}_2
\end{align*}
\]

- We know that the product contains the functional substituent Br at the neighboring tertiary center. Thus, to transfer functionality, we have to invoke a hydride shift.
- The ensuing tertiary carbocation is then trapped by bromide to give the product.

\[
\begin{align*}
\text{H}_2\text{C} & \quad \text{H} \\
\text{\textbullet} & \quad \text{DLE} \\
\text{CH}_3 & \quad \text{H} \\
\text{\textbullet} & \quad \text{H} \\
\text{\textbullet} & \quad \text{H} \\
\text{\textbullet} & \quad \text{Br} \\
\end{align*}
\]

Exercise 9-5

Try It Yourself

Predict the major product from the following reactions.

(a) 2-Methyl-3-pentanol + H₂SO₄, CH₃OH solvent

(b) \[
\begin{align*}
\text{OH} \\
\text{H} \\
\text{\textbullet} & \quad \text{DLE} \\
\text{+ HCl}
\end{align*}
\]

Primary carbocations are too unstable to be formed by rearrangement. However, carbocations of comparable stability—for example, the pairs secondary–secondary or tertiary–tertiary—equilibrate readily. In this case, any added nucleophile will trap all carbocations present, furnishing mixtures of products.
Carbocation rearrangements take place regardless of the nature of the precursor to the carbocation: alcohols (this section), haloalkanes (Chapter 7), and alkyl sulfonates (Section 6-7). For example, solvolysis of 2-bromo-3-ethyl-2-methylpentane in ethanol (ethanolysis) gives the two possible tertiary ethers.

Rearrangement in Solvolysis of a Haloalkane

\[
\begin{align*}
\text{Br} & \quad \text{H} \\
\text{H} & \quad \text{C} \\
\text{H}_3 & \quad \text{CH}_2 & \text{CH}_2 & \text{CH}_3 \\
\text{CH}_3 & \quad \text{C} & \quad \text{C} & \quad \text{CH}_2 & \text{CH}_3 & \text{Br} \\
\text{H} & \quad \text{H} & \quad \text{CH}_3 & \quad \text{CH}_2 & \text{CH}_3 \\
\text{CH}_3 & \quad \text{C} & \quad \text{C} & \quad \text{CH}_2 & \text{CH}_3 & \text{OCH}_3 \\
\text{H} & \quad \text{H} & \quad \text{H} & \quad \text{CH}_3 & \quad \text{CH}_2 & \text{CH}_3 \\
\text{CH}_3 & \quad \text{C} & \quad \text{C} & \quad \text{CH}_2 & \text{CH}_3 & \text{H} \\
\end{align*}
\]

2-Bromo-3-ethyl-2-methylpentane

2-Ethoxy-3-ethyl-2-methylpentane (Normal product)

3-Ethoxy-3-ethyl-2-methylpentane (Rearranged product)

Exercise 9-6

Give a mechanism for the preceding reaction. Then predict the outcome of the reaction of 2-chloro-4-methylpentane with methanol. (Hint: Try two successive hydride shifts to the most stable carbocation.)

Carbocation rearrangements also give new E1 products

How does the rearrangement of intermediates affect the outcome of reactions under conditions that favor elimination? At elevated temperatures and in relatively nonnucleophilic media, rearranged carbocations yield alkenes by the E1 mechanism (Section 9-2). For example, treatment of 2-methyl-2-pentanol with aqueous sulfuric acid at 80°C gives the same major alkene product as that formed when the starting material is 4-methyl-2-pentanol. The conversion of the latter alcohol includes a hydride shift of the initial carbocation followed by deprotonation.

Rearrangement in E1 Elimination

\[
\begin{align*}
\text{OH} & \quad \text{H} \\
\text{H}_3 & \quad \text{C} & \quad \text{C} & \quad \text{CH}_2 & \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_2 & \text{CH}_2 & \text{CH}_3 & \text{CH}_3 \\
\text{H}_3 & \quad \text{C} & \quad \text{C} & \quad \text{CH}_2 & \text{CH}_3 & \text{H} \\
\text{CH}_3 & \quad \text{C} & \quad \text{C} & \quad \text{CH}_2 & \text{CH}_3 & \text{OH} \\
\end{align*}
\]

2-Methyl-2-pentanol

2-Methyl-2-pentene

4-Methyl-2-pentanol

Exercise 9-7

(a) Give mechanisms for the preceding E1 reactions. (b) Treatment of 4-methylcyclohexanol with hot acid gives 1-methylcyclohexene. Explain by a mechanism. (Hint: Consider several sequential H shifts.)

Other carbocation rearrangements are due to alkyl shifts

Carbocations, particularly when lacking suitable (secondary and tertiary) hydrogens next to the positively charged carbon, can undergo another mode of rearrangement, known as alkyl group migration or alkyl shift.
Rearrangement by Alkyl Shift in S_N1 Reaction

\[ \text{H}_3\text{C} \text{CH}_3 \text{CH}_3 \text{COH} \xrightarrow{\text{HBr}/\text{HOH}} \text{Br} \text{CH}_3 \text{CCH}_3 \text{CH}_3 \text{H} \]

3,3-Dimethyl-2-butanol \rightarrow 2-Bromo-3,3-dimethylbutane

As in the hydride shift, the migrating group takes its electron pair with it to form a bond to the neighboring positively charged carbon. The moving alkyl group and the positive charge formally exchange places.

Mechanism of Alkyl Shift

\[ \text{CH}_3\text{C} \text{CH}_3 \text{COH} + \text{H}^+ \xrightarrow{-\text{H}_2\text{O}} \text{CH}_3\text{C} \text{CCH}_3 \text{CH}_3 \text{H} \xrightarrow{\text{CH}_3 \text{shift} + \text{Br}^-} \text{CH}_3\text{C} \text{CCH}_3 \text{CH}_3 \text{H} \xrightarrow{-\text{Br}^- \text{H}_2\text{O}} \text{CH}_3\text{C} \text{CCH}_3 \text{CH}_3 \text{H} \]

The rates of alkyl and hydride shifts are comparable when leading to carbocations of similar stability. However, either type of migration is faster when furnishing tertiary carbocations relative to those ending in their secondary counterparts. This explains why, in the preceding discussion of hydride shifts, alkyl group rearrangement was not observed: The less substituted cation would have been the result. Exceptions to this observation are found only if there are other compelling reasons for the preference of alkyl migration, such as electronic stabilization or steric relief (see Chapter Integration Problem 9-26 and Problem 9-61).

Exercise 9-8

Working with the Concepts: Formulating a More Complex Carbocation Rearrangement

Molecules of the type A have been shown to dehydrate to B. Formulate a mechanism.

Strategy
First we need to look carefully at the function(s) in A and B, as well as the reagent: We recognize the presence of a tertiary alcohol that is being treated with acid. These conditions are suggestive of the formation of a carbocation. Moreover, the net reaction is dehydration, indicating an E1 process. Second, it is important to inspect the carbon skeleton in A and compare it with that in B: We can see that the methyl group has migrated to its neighboring carbon. Conclusion: We are dealing with a carbocation rearrangement featuring a methyl shift.

Solution
• The first steps are protonation followed by loss of water to generate the carbocation.
Primary alcohols may undergo rearrangement

Treatment of a primary alcohol with HBr or HI normally produces the corresponding haloalkane through SN2 reaction of the alkyloxonium ion (Section 9-2). However, it is possible in some cases to observe alkyl and hydride shifts to primary carbons bearing leaving groups, even though primary carbocations are not formed in solution. For example, treating 2,2-dimethyl-1-propanol (neopentyl alcohol) with strong acid causes rearrangement, despite the fact that a primary carbocation cannot be an intermediate.

In this case, after protonation to form the alkyloxonium ion, steric hindrance interferes with direct displacement by bromide (Section 6-9). Instead, water leaves at the same time as a methyl group migrates from the neighboring carbon, thus bypassing formation of a primary carbocation.

Rearrangements of primary substrates are relatively difficult processes, usually requiring elevated temperatures and long reaction times.
In Summary Another mode of reactivity of carbocations, in addition to regular S_N1 and E1 processes, is rearrangement by hydride or alkyl shifts. In such rearrangements, the migrating group delivers its bonding electron pair to a positively charged carbon neighbor, exchanging places with the charge. Rearrangement may lead to a more stable cation—as in the conversion of a secondary cation into a tertiary one. Primary alcohols also can undergo rearrangement, but they do so by concerted pathways and not through the intermediacy of primary cations.

9-4 Esters from Alcohols and Haloalkane Synthesis

Reaction of alcohols with carboxylic acids converts them to organic esters, also called carboxylates or alkanoates (Table 2-3). They are formally derived from the carboxylic acids by replacement of the hydroxy group with alkoxy. One can formulate a corresponding set of inorganic esters derived from inorganic acids, such as those based on phosphorus and sulfur in various oxidation states. In such inorganic esters, the attachment of the heteroatom turns the normally poor leaving group OH in alcohols into a good leaving group (highlighted in the green boxes), which can be used in the synthesis of haloalkanes (see also Section 9-2). We have already mentioned the good leaving-group ability of sulfate and sulfonate groups in S_N2 reactions (Section 6-7). Here, we shall see how specific phosphorus and sulfur reagents accomplish this task:

Alcohols react with carboxylic acids to give organic esters

Alcohols react with carboxylic acids in the presence of catalytic amounts of a strong inorganic acid, such as H_2SO_4 or HCl, to give organic esters and water, a process called esterification. Starting materials and products in this transformation form an equilibrium that can be shifted in either direction. The formation and reactions of organic esters will be presented in detail in Chapters 19 and 20.

**Esterification**

\[
\text{CH}_3\text{COH} + \text{CH}_3\text{CH}_2\text{OH} \xrightarrow{\text{H}^+} \text{CH}_3\text{COCH}_2\text{CH}_3 + \text{HOH}
\]
Haloalkanes can be made from alcohols through inorganic esters

Because of the difficulties and complications that can be encountered in the acid-catalyzed conversions of alcohols into haloalkanes (Section 9-2), several alternatives have been developed. These methods rely on a number of inorganic reagents that are capable of changing the hydroxy function into a good leaving group under milder conditions. Thus, primary and secondary alcohols react with phosphorus tribromide, a readily available commercial compound, to give bromoalkanes and phosphorous acid. This method constitutes a general way of making bromoalkanes from alcohols. All three bromine atoms are transferred from phosphorus to alkyl groups.

\[
\begin{align*}
3 \text{OH} & \quad + \quad \text{PBr}_3 & \quad \overset{(\text{CH}_3\text{CH}_2)_3\text{O}}{\longrightarrow} & \quad 3 \text{Br} & \quad + \quad \text{H}_3\text{PO}_3 \\
\text{3-Pentanol} & \quad \text{Phosphorus} & \quad \text{3-Bromopentane} & \quad \text{Phosphorous} & \quad \text{acid}
\end{align*}
\]

What is the mechanism of action of PBr\(_3\)? In the first step, the alcohol attacks the phosphorus reagent as a nucleophile to form a protonated inorganic ester, a derivative of phosphorous acid.

**Step 1**

\[
\begin{align*}
\text{RCH}_2\text{OH} & \quad + \quad \text{PBr}_3 \quad \rightarrow \quad \text{RCH}_2\text{O}^{\cdot}\text{PBr}_2 \quad + \quad \text{H}^{\cdot}\text{Br}^{-} \\
\text{Br} & \quad \text{Br}
\end{align*}
\]

Next, HOPBr\(_2\), a good leaving group, is displaced (S\(_N2\)) by the bromide generated in step 1, producing the haloalkane.

**Step 2**

\[
\begin{align*}
\text{Br}^{-} & \quad + \quad \text{RCH}_2\text{O}^{\cdot}\text{PBr}_2 \quad \rightarrow \quad \text{RCH}_2\text{Br}^{\cdot} \quad + \quad \text{H}^{\cdot}\text{OPBr}_2 \\
\text{H} & \quad \text{H}
\end{align*}
\]

This method of haloalkane synthesis is especially efficient because HOPBr\(_2\) continues to react successively with two more molecules of alcohol, converting them into haloalkane as well.

\[
\begin{align*}
2 \text{RCH}_2\text{OH} & \quad + \quad \text{HOPBr}_2 \quad \rightarrow \quad 2 \text{RCH}_2\text{Br}^{\cdot} \quad + \quad \text{H}_3\text{PO}_3 \\
\text{CH}_3\text{(CH}_2)_4\text{CH}_2\text{OH} & \quad \downarrow \text{P} \cdot \text{L} \cdot \Delta \\
\text{CH}_3\text{(CH}_2)_4\text{CH}_2\text{I} & \quad 85\% \quad + \quad \text{H}_3\text{PO}_3
\end{align*}
\]

What if, instead of a bromoalkane, we want the corresponding iodoalkane? The required phosphorus triiodide, PI\(_3\), is best generated in the reaction mixture in which it will be used, because it is a reactive species. We do this by adding red elemental phosphorus and elemental iodine to the alcohol (margin). The reagent is consumed as soon as it is formed.

A chlorinating agent commonly used to convert alcohols into chloroalkanes is thionyl chloride, SOCl\(_2\). Simply warming an alcohol in its presence results in the evolution of SO\(_2\) and HCl and the formation of the chloroalkane.

**Chloroalkane Synthesis with SOCl\(_2\)**

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_2\text{OH} & \quad + \quad \text{SOCl}_2 \quad \rightarrow \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} \quad + \quad \text{O} \equiv \text{S} \equiv \text{O} \quad + \quad \text{HCl} \\
\text{91}\% & \quad & \quad \uparrow \text{P} \cdot \text{L} \\
\text{CH}_3\text{(CH}_2)_4\text{CH}_2\text{OH} & \quad \downarrow \text{P} \cdot \text{L} \cdot \Delta \\
\text{CH}_3\text{(CH}_2)_4\text{CH}_2\text{I} & \quad 85\% \quad + \quad \text{H}_3\text{PO}_3
\end{align*}
\]

Mechanistically, the alcohol RCH\(_2\)OH again first forms an inorganic ester, RCH\(_2\)O\(_2\)SCl.
Step 1

\[
\text{RCH}_2\text{-OH} + \cdot \text{Cl}^- \rightarrow \text{RCH}_2\text{-SOCl}^- + \text{H}^+ + \cdot \text{Cl}^-
\]

The chloride ion created in this process then acts as a nucleophile and attacks the ester, an \( S_N2 \) reaction yielding one molecule each of \( \text{SO}_2 \) and \( \text{HCl} \).

Step 2

\[
\text{H}^+ + \cdot \text{Cl}^- + \text{CH}_2\text{-O}^- \rightarrow \cdot \text{Cl}^- + \text{CH}_2\text{R} + \cdot \text{O}=\text{S}=\cdot\text{O}^- + \text{HCl}^-
\]

The reaction works better in the presence of an amine, which neutralizes the hydrogen chloride generated. One such reagent is \( N,N \)-diethylthlenamine (triethylamine), which forms the corresponding ammonium chloride under these conditions.

**Alkyl sulfonates are versatile substrates for substitution reactions**

The inorganic esters in the reactions of \( \text{SOCl}_2 \) are special examples of leaving groups derived from sulfur-based acids. They are related to the sulfonates (Section 6-7). Alkyl sulfonates contain excellent leaving groups and can be readily prepared from the corresponding sulfonyl chlorides and an alcohol. A mild base such as pyridine or a tertiary amine is often added to remove the \( \text{HCl} \) formed.

**Synthesis of an Alkyl Sulfonate**

\[
\begin{align*}
\text{CH}_3 \text{CHCH}_2\text{OH} + \text{CH}_3\text{ScI} \rightarrow \text{CH}_3\text{CHCH}_2\text{OSCH}_3 + \text{Pyridinium hydrochloride}
\end{align*}
\]

Unlike the inorganic esters derived from phosphorus tribromide and thionyl chloride, alkyl sulfonates are often crystalline solids that can be isolated and purified before further reaction. They then can be used in reactions with a variety of nucleophiles to give the corresponding products of nucleophilic substitution.

**Sulfonate Intermediates in Nucleophilic Displacement of the Hydroxy Group in Alcohols**

\[
\begin{align*}
\text{R-OH} \rightarrow \text{R-OSR'} \rightarrow \text{R-Nu}
\end{align*}
\]

The displacement of sulfonate groups by halide ions (\( \text{Cl}^-, \text{Br}^-, \Gamma^- \)) readily yields the corresponding haloalkanes, particularly with primary and secondary systems, in which \( S_N2 \) reactivity is good. In addition, however, alkyl sulfonates allow replacement of the hydroxy
group by any good nucleophile: They are not limited to halides alone, as is the case with hydrogen, phosphorus, and thionyl halides.

**Substitution Reactions of Alkyl Sulfonates**

![Reaction diagram]

Exercise 9-10

What is the product of the reaction sequence shown in the margin?

Exercise 9-11

Supply reagents with which you would prepare the following haloalkanes from the corresponding alcohols.

(a) I(CH₂)₆I  
(b) (CH₃CH₂)₃CCl  
(c) 

![Reaction diagram]

**In Summary**

Alcohols react with carboxylic acids by loss of water to furnish organic esters. They also react with inorganic halides, such as PBr₃, SOCl₂, and RSO₂Cl, by loss of HX to produce inorganic esters. These inorganic esters contain good leaving groups in nucleophilic substitutions that are, for example, displaced by halide ions to give the corresponding haloalkanes.

**9-5 Names and Physical Properties of Ethers**

Ethers may be thought of as derivatives of alcohols in which the hydroxy proton has been replaced by an alkyl group. We now introduce this class of compounds systematically. This section gives the rules for naming ethers and describes some of their physical properties.

**In the IUPAC system, ethers are alkoxyalkanes**

The IUPAC system for naming ethers treats them as alkanes that bear an alkoxy substituent—that is, as alkoxyalkanes. The smaller substituent is considered part of the alkoxy group and the larger chain defines the stem.

In common names, the names of the two alkyl groups are followed by the word ether. Hence, CH₂OCH₂CH₃ is dimethyl ether, CH₃OCH₂CH₃ is ethyl methyl ether, and so forth.

Ethers are generally fairly unreactive (except for strained cyclic derivatives; see Section 9-9) and are therefore frequently used as solvents in organic reactions. Some of these ether solvents are cyclic; they may even contain several ether functions. All have common names.
Ether Solvents and Their Names

\[
\begin{align*}
\text{Ethoxyethane} & \quad \text{(Diethyl ether)} \\
\text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3 \\
1,4\text{-Dioxacyclohexane} & \quad \text{(1,4-Dioxane)} \\
\text{CH}_3\text{OCH}_2\text{CH}_2\text{OCH}_3 \\
1,2\text{-Dimethoxyethane} & \quad \text{(Glycol dimethyl ether, glyme)} \\
\text{Oxacyclopentane} & \quad \text{(Tetrahydrofuran, THF)}
\end{align*}
\]

Cyclic ethers are members of a class of cycloalkanes in which one or more carbons have been replaced by a heteroatom—in this case, oxygen. (A heteroatom is defined as any atom except carbon and hydrogen.) Cyclic compounds of this type, called heterocycles, are discussed more fully in Chapter 25.

The simplest system for naming cyclic ethers is based on the oxacycloalkane stem, in which the prefix oxad indicates the replacement of carbon by oxygen in the ring. Thus, three-membered cyclic ethers are oxacyclopropanes (other names used are oxiranes, epoxides, and ethylene oxides), four-membered systems are oxacyclobutanes, and the next two higher homologs are oxacyclopentanes (tetrahydrofurans) and oxacyclohexanes (tetrahydropyrans). The compounds are numbered by starting at the oxygen and proceeding around the ring.

Cyclic polyethers that contain multiple ether functional groups based on the 1,2-ethanediol unit are called crown ethers, so named because the molecules adopt a crownlike conformation in the crystalline state and, presumably, in solution. The polyether 18-crown-6 is shown in Figure 9-3. The number 18 refers to the total number of atoms in the ring, and 6 to the number of oxygens. The electrostatic potential map on the right of Figure 9-3 shows that the inside of the ring is quite electron rich due to the core electron pairs on the ether oxygens.

**Figure 9-3** The crownlike structural arrangement of 18-crown-6.

The absence of hydrogen bonding affects the physical properties of ethers

The molecular formula of simple alkoxyalkanes is \( \text{C}_n\text{H}_{2n+1}\text{O} \), identical with that of the alkanols. However, because of the absence of hydrogen bonding, the boiling points of ethers are much lower than those of the corresponding isomeric alcohols (Table 9-1). The two smallest members of the series are water miscible, but ethers become less water soluble as the hydrocarbon residues increase in size. For example, methoxymethane is completely water soluble, whereas ethoxyethane forms only an approximately 10% aqueous solution.
Polyethers solvate metal ions: crown ethers and ionophores

The oxygen in ethers, as in alcohols, is (Lewis) basic (Section 2-2); that is, its lone pairs of electrons can coordinate to electron-deficient metals, such as the magnesium in Grignard reagents (Section 8-7). This solvating power is particularly striking in polyethers, in which several such oxygen atoms may surround metal ions. The structure of crown ethers enables them to function as strong cation binders, including cations found in ordinary salts. In this way, crown ethers can render the salts soluble in organic solvents. For example, potassium permanganate (KMnO₄), a deep-violet solid, completely insoluble in benzene, is readily dissolved in that solvent if 18-crown-6 is added to it. This solution is useful because it allows oxidations with potassium permanganate to be carried out in organic solvents. Dissolution is possible by effective solvation of the metal ion by the six crown oxygens.

The size of the “cavity” in the crown ether can be tailored to allow for the selective binding of only certain cations—namely, those whose ionic radius is best accommodated by the polyether. This concept has been extended successfully into three dimensions by the synthesis of polycyclic ethers, also called cryptands (kryptos, Greek, hidden), which are highly selective in alkali and other metal binding (Figure 9-4). The significance of these

![Space-filling model of the cation [K⁺ 18-crown-6] MnO₄⁻](image)

Figure 9-4 The binding of a cation by a polycyclic ether (cryptand) to form a complex (cryptate). The system shown selectively binds the potassium ion, with a binding constant of $K = 10^{10}$. The order of selectivity is $K^+ > Rb^+ > Na^+ > Cs^+ > Li^+$. The binding constant for lithium is about 100. Thus, the total range within the series of alkali metals spans eight orders of magnitude.
compounds was recognized by the award of the Nobel Prize in chemistry in 1987, shared by Cram, Lehn, and Pedersen.*

Crown ethers and cryptands are often called ion transport agents and are part of the general class of ionophores (from the Greek, bearing, hence “ion bearing”), compounds that organize themselves around cations by coordination. In general, the result of this interaction is that the polar hydrophilic nature of the ion is masked by a hydrophobic shell, hence making the ion much more soluble in nonpolar solvents. In nature, ionophores can transport ions through hydrophobic cell membranes. The ion balance between the inside and outside of the cell is carefully regulated to ensure cell survival, and therefore any undue disruption causes cell destruction. This property is put to medicinal use in fighting invading organisms with polyether antibiotics. However, because ion transport affects nerve transmission, some naturally occurring ionophores are also deadly neurotoxins (see below and the cover of this book).

In Summary
Acyclic ethers can be named as alkoxyalkanes or as alkyl ethers. Their cyclic counterparts are called oxacycloalkanes. Ethers have lower boiling points than do alcohols of comparable size, because they cannot hydrogen bond to each other. The Lewis basicity of the oxygen lone pairs, particularly in polyethers, allows efficient metal ion complexation.

9-6 Williamson Ether Synthesis

Alkoxides are excellent nucleophiles. This section describes their use in the most common method for the preparation of ethers.

Ethers are prepared by $S_{N2}$ reactions

The simplest way to synthesize an ether is to have an alkoxide react with a primary haloalkane or a sulfonate ester under typical $S_{N2}$ conditions (Chapter 6). This approach is known as the Williamson† ether synthesis. The alcohol from which the alkoxide is derived can

---

**CHEMICAL HIGHLIGHT 9-1**

**Chemiluminescence of 1,2-Dioxacyclobutanes**

An intramolecular Williamson-type reaction of a special kind is that in which a 2-bromohydroperoxide is the reactant. The product is a 1,2-dioxacyclobutane (1,2-dioxetane). This compound is unusual because it decomposes to the corresponding carbonyl compounds with emission of light (chemiluminescence). Dioxacyclobutanes seem to be responsible for the bioluminescence of certain species in nature. Terrestrial organisms, such as the firefly, the glowworm, and certain click beetles, are well-known light emitters. However, most bioluminescent species live in the ocean; they range from microscopic bacteria and plankton to fish. The emitted light serves many purposes and seems to be important in courtship and communication, sex differentiation, finding prey, and hiding from or scaring off predators.

An example of a chemiluminescent molecule in nature is firefly luciferin. The base oxidation of this molecule furnishes a dioxacyclobutanone intermediate that decomposes in a manner analogous to that of 3,3,4,4-tetramethyl-1,2-dioxacyclobutane to give a complex heterocycle, carbon dioxide, and emitted light.

**Bioluminescence is extraordinarily efficient. For example, the firefly converts about 40% of the energy of the underlying chemical process into visible light. For your calibration, a normal light bulb is only 10% efficient, most of the (electric) energy being emitted as heat.**

Male and female fireflies glowing in concert.
Exercise 9-12

The following ethers can, in principle, be made by more than one Williamson ether synthesis. Consider the relative merits of your approaches. (a) 1-Ethoxybutane; (b) 2-methoxypentane; (c) propoxycyclohexane; (d) 1,4-diethoxybutane. [Cautions: Alkoxides are strong bases. What is wrong with 4-bromo-1-butanol as a starting material for (d)??]

Cyclic ethers can be prepared by intramolecular Williamson synthesis

The Williamson ether synthesis is also applicable to the preparation of cyclic ethers, starting from haloalcohols. Figure 9-5 depicts the reaction of hydroxide ion with a bromoalcohol. The black curved lines denote the chain of carbon atoms linking the functional groups. The mechanism consists of initial formation of a bromoalkoxide by fast proton transfer to the base, followed by ring closure to furnish the cyclic ether. The ring closure is an example of an intramolecular displacement. Cyclic ether formation is usually much faster than the side reaction shown in Figure 9-5, namely intermolecular displacement of bromide by hydroxide to give a diol. The reason is entropy (Section 2-1). In the intramolecular reaction, the two reacting centers are in the same molecule; in the transition state, one molecule of bromoalkoxide turns into two molecules of products, the ether and the leaving group. In the intermolecular reaction, the alkoxide and the nucleophile have to be brought together at an entropic cost to the transition state, and, overall, the number of molecules stays the same. In those cases in which the intermolecular SN2 reaction competes with its intramolecular counterpart, the intermolecular process can be effectively suppressed by using high dilution conditions, which drastically reduce the rate of bimolecular processes (Section 2-1).

Intramolecular Williamson synthesis allows the preparation of cyclic ethers of various sizes, including small rings.

Figure 9-5 The mechanism of cyclic ether synthesis from a bromoalcohol and hydroxide ion (upper reactions). A competing but slower side reaction, direct displacement of bromide by hydroxide, is also shown (lower reaction). The curved lines denote a chain of carbon atoms.

Exercise 9-13

The product of the reaction of 5-bromo-3,3-dimethyl-1-pentanol with hydroxide is a cyclic ether. Suggest a mechanism for its formation.

Ring size controls the speed of cyclic ether formation

A comparison of the relative rates of cyclic ether formation reveals a surprising fact: Three-membered rings form quickly, about as fast as five-membered rings. Six-membered ring systems, four-membered rings, and the larger oxacycloalkanes are generated more slowly.

Relative Rates of Cyclic Ether Formation

\[
k_3 \approx k_5 > k_6 > k_4 \approx k_7 > k_8
\]

\(k_n = \text{reaction rate, } n = \text{ring size}\)

What effects are at work here? Since we are concerned with rates, we need to compare the structures and hence energies of the transition states of the intramolecular Williamson ether synthesis. We shall find that the answer is composed of both enthalpic and entropic contributions (Section 2-1). Recall that enthalpy reflects changes not only in bond strengths during a reaction, but also in strain (Section 4-2). Entropy, on the other hand, is related to changes in the extent of order (or energy dispersal) in the system. What are the differences between the various transition states for ring formation with respect to these quantities?

As we proceed from larger ring to three-membered ring closures, the most obvious enthalpy effect is ring strain. If it were dominant, the most strained rings should be formed at the lowest rate, even though the full effect of strain may not be felt in the structure of the respective transition states. However, this is not observed, and we need to look for other factors that complicate this simple analysis. One such factor is entropy.

To understand how entropy comes into play, put yourself into the position of the nucleophilic, negatively charged oxygen in search of the backside of the electrophilic carbon bearing the leaving group. Clearly, the closer you are to the target, the easier it is to find it. If the target is remote, the intervening chain has to be arranged or “ordered” in such a way as to bring it closer to you. This is more difficult when the chain gets longer.

In molecular terms, to reach the transition state for ring formation, the opposite ends of the molecule must approach each other. In the ensuing conformation, rotation about the intervening bonds becomes restricted, and energy dispersal in the molecule is reduced: The entropy change is unfavorable (negative). This effect is most severe for long chains, making the formation of medium-sized and larger rings relatively most difficult. In addition, their rates of formation suffer from eclipsing, gauche, and transannular strain (Section 4-5). In contrast, cyclization of shorter chains requires less restriction of bond rotation and therefore a smaller unfavorable reduction in entropy: Three- to six-membered rings are generated relatively quickly. In fact, on entropy grounds alone, the relative rates for ring closure should be \(k_3 > k_4 > k_5 > k_6\). Superposition of ring strain effects then leads to the observed trends listed above (see also margin structures).
Recent studies have shown that entropy alone cannot explain why three-membered rings are generated fastest. A second enthalpic phenomenon, which has been called the *proximity effect*, operates, especially in 2-haloalkoxides. To understand it, you need to remember that all $S_N2$ reactions suffer to a varying degree from steric hindrance of the nucleophile (Section 6-9). In 2-haloalkoxides (and related three-membered ring precursors), the nucleophilic part of the molecule is so close to the electrophilic carbon that part of the strain of the transition state is already present in the ground state. In other words, the molecule is activated along the reaction coordinate of the “normal” (unstrained) substitution process. This rate-accelerating proximity effect is dramatically reduced in four-membered ring synthesis (and so is the entropy advantage), while the ring strain is still large; therefore, ring closure to oxacyclobutanes is comparatively slow. As we shall find, the general conclusions reached in this section apply also to other ring closing transformations that we shall encounter in later chapters.

**The intramolecular Williamson synthesis is stereospecific**

The Williamson ether synthesis proceeds with inversion of configuration at the carbon bearing the leaving group, in accord with expectations based on an $S_N2$ mechanism. The attacking nucleophile approaches the electrophilic carbon from the opposite side of the leaving group. Only one conformation of the haloalkoxide can undergo efficient substitution. For example, oxacyclop propane formation requires an *anti* arrangement of the nucleophile and the leaving group. The alternative two *gauche* conformations cannot give the product (Figure 9-6).

![Figure 9-6](image)

**Figure 9-6** Only the *anti* conformation of a 2-bromoalkoxide allows for oxacyclop propane formation. The two *gauche* conformers cannot undergo intramolecular backside attack at the bromine-bearing carbon.

**Exercise 9-14**

Working with the Concepts: Stereochemistry of the Intramolecular Williamson Ether Synthesis

$(1R,2R)$-2-Bromocyclopentanol reacts rapidly with sodium hydroxide to yield an optically inactive product. In contrast, the $(1S,2R)$ isomer is much less reactive. Explain.

**Strategy**

The first thing to do is to write down the two isomeric bromocyclopentanols (even better, build models!), so you can visualize their differences. How do these differences affect reactivity?

![Model Building](image)

**Solution**

- Conformational freedom around the bond connecting the two functional groups is restricted (unlike the situation shown in Figure 9-6). In the $(1R,2R)$ isomer the functional groups are arranged...
In Summary

Ethers are prepared by the Williamson synthesis, an $S_N2$ reaction of an alkoxide with a haloalkane. This reaction works best with primary halides or sulfonates that do not undergo ready elimination. Cyclic ethers are formed by the intramolecular version of this method. The relative rates of ring closure in this case are highest for three- and five-membered rings.

9-7 Synthesis of Ethers: Alcohols and Mineral Acids

An even simpler, albeit less selective, route to ethers is the reaction of a strong inorganic acid (e.g., $H_2SO_4$) with an alcohol. Protonation of the OH group in one alcohol generates water as a leaving group. Nucleophilic displacement of this leaving group by a second alcohol then results in the corresponding alkoxyalkane.

**Alcohols give ethers by both $S_N2$ and $S_N1$ mechanisms**

We have learned that treating primary alcohols with HBr or HI furnishes the corresponding haloalkanes through intermediate alkyloxonium ions (Section 9-2). However, when strong nonnucleophilic acids—such as sulfuric acid—are used at elevated temperatures, the main products are ethers.

Symmetrical Ether Synthesis from a Primary Alcohol with Strong Acid

$$2 \text{CH}_3\text{CH}_2\text{OH} \xrightleftharpoons{\text{H}_2\text{SO}_4, 130^\circ\text{C}} \text{Relatively high temperature} \text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3 + \text{HOH}$$
In this reaction, the strongest nucleophile present in solution is the unprotonated starting alcohol. As soon as one alcohol molecule has been protonated, nucleophilic attack begins, the ultimate products being an ether and water.

**Mechanism of Ether Synthesis from Primary Alcohols: Protonation and SN2**

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OH} & + \stackrel{+\text{H}^+}{\rightarrow} \text{CH}_3\text{CH}_2\text{O}^+ \text{H}^- \\
\text{CH}_3\text{CH}_2\text{OH} & \rightarrow \text{CH}_3\text{CH}_2\text{O}^- \text{H}^+ \\
\text{CH}_3\text{CH}_2\text{OH} & \rightarrow \text{CH}_3\text{CH}_2\text{O}^- \text{H}^+ \\
\end{align*}
\]

Only symmetric ethers can be prepared by this method.

At even higher temperatures (see footnote on p. 337), elimination of water to generate an alkene is observed. This reaction proceeds by an E2 mechanism (Sections 7-7 and 11-7), in which the neutral alcohol serves as the base that attacks the alkyloxonium ion (margin).

**Alkene Synthesis from a Primary Alcohol and Strong Acid at Elevated Temperature: E2**

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OH} & \stackrel{\text{H}_2\text{SO}_4, 180^\circ\text{C}}{\rightarrow} \text{CH}_3\text{C}==\text{CH}_2 + \text{HOH} \\
\end{align*}
\]

Secondary and tertiary ethers can also be made by acid treatment of secondary and tertiary alcohols. However, in these cases, a carbocation is formed initially and is then trapped by an alcohol (SN1), as described in Section 9-2.

**Symmetrical Ether Synthesis from a Secondary Alcohol**

\[
\begin{align*}
2 \text{CH}_3\text{CCH}_3 & \stackrel{\text{H}_2\text{SO}_4, 40^\circ\text{C}}{\rightarrow} \text{(CH}_3\text{)}_2\text{CHOCH(CH}_3\text{)}_2 + \text{HOH} + \text{H}^+ \\
\end{align*}
\]

The major side reaction follows the E1 pathway (Sections 9-2, 9-3, and 11-7), which, again, becomes dominant at higher temperatures.

It is harder to synthesize ethers containing two different alkyl groups, because mixing two alcohols in the presence of an acid usually results in mixtures of all three possible products. However, mixed ethers containing one tertiary and one primary or secondary alkyl substituent can be prepared in good yield in the presence of dilute acid. Under these conditions, the much more rapidly formed tertiary carbocation is trapped by the other alcohol.

**Synthesis of a Mixed Ether from a Tertiary Alcohol**

\[
\begin{align*}
\text{CH}_3\text{COH} + \text{CH}_3\text{CH}_2\text{OH} \text{ (excess)} & \stackrel{15\% \text{aqueous } \text{H}_2\text{SO}_4, 40^\circ\text{C}}{\rightarrow} \text{CH}_3\text{COCH}_2\text{CH}_3 \\
\end{align*}
\]
Ethers also form by alcoholysis

As we know, tertiary and secondary ethers may also form by the alcoholysis of the corresponding haloalkanes or alkyl sulfonates (Section 7-1). The starting material is simply dissolved in an alcohol until the \( \text{SN}_1 \) process is complete (see margin).

\[
\begin{align*}
\text{H}_3C & \quad \text{Cl} \\
\text{CH}_3\text{CH}_2\text{OH} & \quad \text{CH}_3\text{CH}_2\text{Br} \\
\text{H}_3C & \quad \text{OCH}_2\text{CH}_3 \\
\text{H}_3C & \quad \text{OCH}_2\text{CH}_3 \\
\text{Cl} & \quad \text{H}^+ & \quad \text{Cl}^-
\end{align*}
\]

\[
\begin{align*}
\text{H}_3C & \quad \text{Cl} \\
\text{CH}_3\text{CH}_2\text{OH} & \quad \text{CH}_3\text{CH}_2\text{Br} \\
\text{H}_3C & \quad \text{OCH}_2\text{CH}_3 \\
\text{H}_3C & \quad \text{OCH}_2\text{CH}_3 \\
\text{Cl} & \quad \text{H}^+ & \quad \text{Cl}^-
\end{align*}
\]

\[
\begin{align*}
\text{H}_3C & \quad \text{Cl} \\

\end{align*}
\]

\[
\begin{align*}
\text{H}_3C & \quad \text{Cl} \\
\text{CH}_3\text{CH}_2\text{OH} & \quad \text{CH}_3\text{CH}_2\text{Br} \\
\text{H}_3C & \quad \text{OCH}_2\text{CH}_3 \\
\text{H}_3C & \quad \text{OCH}_2\text{CH}_3 \\
\text{Cl} & \quad \text{H}^+ & \quad \text{Cl}^-
\end{align*}
\]

Exercise 9-16

Write mechanisms for the following two reactions. (a) 1,4-Butanediol + \( \text{H}^+ \rightarrow \) oxacyclopentane (tetrahydrofuran); (b) 5-methyl-1,5-hexanediol + \( \text{H}^+ \rightarrow \) 2,2-dimethyloxacyclohexane (2,2-dimethyltetrahydropyran).

Exercise 9-17

You now know several ways of constructing an ether from an alcohol and a haloalkane. Which approach would you choose for the preparation of (a) 2-methyl-2-(1-methylethoxy)butane; (b) 1-methoxy-2,2-dimethylpropane? [Hint: The product for (a) is a tertiary ether, that for (b) is a neopentyl ether.]

In Summary

Ethers can be prepared by treatment of alcohols with acid through \( \text{SN}_2 \) and \( \text{SN}_1 \) pathways, with alkylxonium ions or carbocations as intermediates, and by alcoholysis of secondary or tertiary haloalkanes or alkyl sulfonates.

9-8 Reactions of Ethers

As mentioned earlier, ethers are normally rather inert. They do, however, react slowly with oxygen by radical mechanisms to form hydroperoxides and peroxides. Because peroxides can decompose explosively, extreme care should be taken with samples of ethers that have been exposed to air for several days.

\[
\begin{align*}
2 \text{ROCH} & + \text{O}_2 \rightarrow 2 \text{RO} & \text{O} & \text{O} & \text{COR} \\
\text{An ether hydroperoxide} & \quad & \text{An ether peroxide}
\end{align*}
\]

A more useful reaction is cleavage by strong acid. The oxygen in ethers, like that in alcohols, may be protonated to generate alkylxonium ions. The subsequent reactivity of these ions depends on the alkyl substituents. With primary groups and strong nucleophilic acids such as \( \text{HBr} \), \( \text{SN}_2 \) displacement takes place.

Primary Ether Cleavage with \( \text{HBr} \)

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3 & \quad \text{HBr} \rightarrow \text{CH}_3\text{CH}_2\text{Br} & \text{Bromoethane} & \text{CH}_3\text{CH}_2\text{OH} & \text{Ethanol}
\end{align*}
\]

Mechanism of Primary Ether Cleavage: \( \text{SN}_2 \)

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3 & \quad \text{H}^+ \rightarrow \text{CH}_3\text{CH}_2\text{O} & \text{H} \quad \text{CH}_3\text{CH}_2\text{O} & \text{CH}_3\text{CH}_2\text{Br} & \text{HOC}_2\text{CH}_3
\end{align*}
\]

Alkylxonium ion

The alcohol formed as the second product may in turn be attacked by additional \( \text{HBr} \) to give more of the bromoalkane.
Oxonium ions derived from secondary ethers can transform by either \( S_N2 \) or \( S_N1 \) (E1) reactions, depending on the system and conditions (Section 7-9 and Tables 7-2 and 7-4). For example, 2-ethoxypropane is protonated by aqueous HI and then converted into 2-propanol and iodoethane by selective attack by iodide at the less hindered primary center.

**Primary-Secondary Ether Cleavage with HI: \( S_N2 \) at Primary Center**

\[
\text{2-Ethoxypropane} \xrightarrow{\text{HI, H}_2\text{O}} \text{2-Propanol} + \text{Iodoethane}
\]

**Tertiary butyl ethers function to protect alcohols**

Ethers containing tertiary alkyl groups transform even in dilute acid to give intermediate tertiary carbocations, which are either trapped by \( S_N1 \) processes, when good nucleophiles are present, or deprotonated in their absence:

**Primary-Tertiary Ether Cleavage with Dilute Acid: \( S_N1 \) and E1 at Tertiary Center**

\[
\text{Primary-Tertiary Ether Cleavage with Dilute Acid: } \text{H}_2\text{SO}_4, \text{H}_2\text{O}, 50^\circ\text{C}
\]

Because tertiary ethers are made under similarly mild conditions from alcohols (Section 9-7), they act as protecting groups for the hydroxy function. A protecting group renders a specific functionality in a molecule unreactive with respect to reagents and conditions that would normally transform it. Such protection allows chemistry to be carried out elsewhere in a molecule without interference. Subsequently, the original function is restored (deprotection). A protecting group has to be reversibly installed, readily and in high yield. Such is the case with tertiary ethers, in which the original alcohol is protected from base, organometallic reagents, oxidants, and reductants. Another method of alcohol protection is esterification (Section 9-4; Chemical Highlight 9-2).

**Protection of Alcohols as Tertiary Butyl Ethers**

\[
\text{ROH} \xrightarrow{\text{(CH}_3)_3\text{COH, H}^+, \text{H}_2\text{O}} \text{ROC(CH}_3)_3 \xrightarrow{\text{Carry out reactions on R by using Grignard reagents, oxidizing agents, etc.}} \text{R’OC(CH}_3)_3 \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{R’OH}
\]

Using protecting groups is a common procedure in organic synthesis, which enables chemists to carry out many transformations that would otherwise be impossible. We shall see other protecting strategies in conjunction with other functional groups later in the course.

---

**Exercise 9-18**

Treatment of methoxymethane with hot concentrated HI gives two equivalents of iodomethane. Suggest a mechanism.

**Exercise 9-19**

Reaction of oxacyclohexane (tetrahydropyran; shown in the margin) with hot concentrated HI gives 1,5-diiodopentane. Give a mechanism for this reaction.
In Summary Ethers are cleaved by (strong) acids. Protonation of an ether containing methyl or primary alkyl groups gives an alklyloxonium ion that is subject to $S_N_2$ attack by...
nucleophiles. Carbocation formation follows protonation when secondary and tertiary groups are present, leading to $S_N1$ and $E1$ products. The hydroxy group of alcohols can be protected in the form of a tert-butyl ether.

**9-9 Reactions of Oxacyclopropanes**

Although ordinary ethers are relatively inert, the strained structure of the oxacyclopropanes makes possible nucleophilic ring-opening reactions. This section presents details of these processes.

**Nucleophilic ring opening of oxacyclopropanes by $S_N2$ is regioselective and stereospecific**

Oxacyclopropane is subject to bimolecular ring opening by anionic nucleophiles. Because of the symmetry of the substrate, substitution occurs to the same extent at either carbon. The reaction proceeds by nucleophilic attack, with the ether oxygen functioning as an intramolecular leaving group.

\[
\begin{align*}
\text{Oxacyclopropane} & \quad + \quad \text{CH}_3\text{S}^- \quad \rightarrow \quad \text{OHCH}_2\text{CH}_2\text{SCH}_3 \\
& \quad \text{2-Methylthioethanol}
\end{align*}
\]

This $S_N2$ transformation is unusual for two reasons. First, alkoxides are usually very poor leaving groups. Second, the leaving group does not actually “leave”; it stays bound to the molecule. The driving force is the release of strain as the ring opens.

What is the situation with unsymmetric systems? Consider, for example, the reaction of 2,2-dimethyloxacyclopropane with methoxide. There are two possible reaction sites: at the primary carbon ($a$), to give 1-methoxy-2-methyl-2-propanol, and at the tertiary carbon ($b$), to yield 2-methoxy-2-methyl-1-propanol. Evidently, this system transforms solely through path $a$.

**Nucleophilic Ring Opening of an Unsymmetrically Substituted Oxacyclopropane**

Is this result surprising? No, because, as we know, if there is more than one possibility, $S_N2$ attack will be at the less substituted carbon center (Section 6-9). This selectivity in the nucleophilic opening of substituted oxacyclopropanes is referred to as **regioselectivity**, because, of two possible and similar “regions,” the nucleophile attacks only one.

In addition, when the ring opens at a stereocenter, inversion is observed. Thus, we find that the rules of nucleophilic substitution developed for simple alkyl derivatives also apply to strained cyclic ethers.

**Hydride and organometallic reagents convert strained ethers into alcohols**

The highly reactive lithium aluminum hydride is able to open the rings of oxacyclopropanes, a reaction leading to alcohols. Ordinary ethers, lacking the ring strain of oxacyclopropanes, do not react with LiAlH₄. The reaction also proceeds by the $S_N2$ mechanism. Thus, in unsymmetric systems, the hydride attacks the less substituted side; when the reacting carbon constitutes a stereocenter, inversion is observed.
Ring Opening of an Oxacyclopropane by Lithium Aluminum Hydride

\end{align*}
\]

Inversion on Oxacyclopropane Opening

Exercise 9-21

Working with the Concepts: A Retrosynthetic Analysis of an Oxacyclopropane

Applying the principles of retrosynthetic analysis, as described in Section 8-9, which oxacyclopropane would be the best precursor to racemic 3-hexanol after treatment with LiAlH₄, followed by acidic aqueous work-up?

**Strategy**

The first thing to do is write the structure of 3-hexanol. Then look to see how many pathways lead to this structure from oxacyclopropanes and examine each path for feasibility.

**Solution**

• We recognize two possible retrosynthetic paths to 3-hexanol from oxacyclopropanes: removal of an anti H with simultaneous ring closure either to the “left” side or the “right” side. In our drawing, these two pathways are indicated by a and b, respectively.

```
anti  anti
\[ a \quad b \]
```

```
3-Hexanol
```

• Now that we have drawn the two possible precursors to 3-hexanol, let us see which one is better at making the desired product when it is reacted with LiAlH₄. (**Caution:** Remember that both carbons of an oxacyclopropane are electrophilic, so attack by hydride can occur in two possible ways.)

• Inspection of the precursor derived from retrosynthetic path a shows that it is unsymmetrical. Because both ring carbons are equally hindered, ring opening by hydride will give the two isomers, 2- and 3-hexanol.

• On the other hand, retrosynthetic path b furnishes a symmetric oxacyclopropane in which the regiochemistry of hydride opening is immaterial. Hence this precursor is best.
In contrast with haloalkanes (Section 8-8), oxacyclopropanes are sufficiently reactive electrophiles to be attacked by organometallic compounds. Thus, Grignard reagents and alkyllithium compounds undergo 2-hydroxyethylation by ether ring opening, following the $S_N2$ mechanism. This reaction constitutes a two-carbon homologation of an alkyl chain, as opposed to the one-carbon homologation of alkyl organometallic reagents by formaldehyde (Sections 8-8 and 8-9).

**Oxacyclopropane Ring Opening by a Grignard Reagent: 2-Hydroxyethylation**

\[

\end{align*}
\]

Oxacyclopropane Butylmagnesium bromide 1-Hexanol: “2-hydroxyethylated butyl”

**Exercise 9-22**

**Try It Yourself**

$(2R)$-Butanol can be made by LiAlH₄ reduction of an oxacyclopropane. Which one?

In our example, the most obvious feature is that members of the respective groups are shaped completely differently and could be separated by an achiral device, such as a sieve. From the resulting two piles, the right hands would be recovered and recycled, leaving the right shoes separated from the left ones.

A much better machine would be a fishing device, in which the hook would be shaped like a right (or left) foot. This machine would pull out only right shoes from the pile, allowing their selective tagging, for example by attaching a weight. Left and right shoes could then be separated by an achiral device on the basis of their differing weights. Such a process at the molecular level is called catalytic kinetic resolution. An example is the hydrolysis of methyloxacyclopropane with basic water. Normally, starting with a racemate, the result is racemic 1,2-propanediol. This is to be expected, as the two respective transition states for the reactions of $R$ and $S$ starting ether are enantiomeric (Section 5-7).

However, in the presence of an enantiomer of a chiral cobalt catalyst (the “right foot” in our device above), water attacks the $R$ form of starting material much more rapidly than the $S$ counterpart, converting it selectively to $(2R)$-1,2-propanediol (our “selective tagging”), leaving behind pure $(S)$-oxacyclopropane. The reason is the chiral nature of the catalyst, rendering the two respective transition states of the reaction diastereomeric. Thus, they are of unequal energy,
Acids catalyze oxacyclopropane ring opening

Ring opening of oxacyclopropanes is also catalyzed by acids. The reaction in this case proceeds through initial cyclic alkyloxonium ion formation followed by ring opening as a result of nucleophilic attack.

Acid-Catalyzed Ring Opening of Oxacyclopropane

\[
\begin{align*}
H_2C-\text{CH}_2 + \text{CH}_3\text{OH} & \xrightarrow{H^+} \text{HOCH}_2\text{CH}_2\text{OCH}_3 \\
\text{2-Methoxethanol} & 
\end{align*}
\]

Mechanism of Acid-Catalyzed Ring Opening

The anionic nucleophilic opening of oxacyclopropanes just discussed is regioselective and stereospecific. What about acid-catalyzed ring opening—is that also regioselective and stereospecific? Yes, but the details are different. Thus, acid-catalyzed methanolysis of 2,2-dimethyloxacyclopropane proceeds by exclusive ring opening at the more hindered carbon, allowing one enantiomer of oxacyclopropane to hydrolyze faster than the other.

The structure of the catalyst enantiomer is shown below. You can see the chiral environment around the metal, provided by the substituted cyclohexane scaffold. The cobalt attacks selectively the lone pairs on the (R)-oxacyclopropane substrate as a Lewis acid (Section 2-2), thus facilitating ring opening by water.

Using the mirror image of the catalyst shown gives the complementary results to our example: Only (S)-methyloxacyclopropane is attacked to furnish (S)-diol, leaving behind unreacted R starting material. Such highly functionalized small chiral building blocks are of great value in the synthesis of medicines and other fine chemicals and therefore in great demand by synthetic chemists. As a result, the above kinetic resolution has been refined to require less than 1 kg of catalyst to make 1 ton of product and is being used by Daiso Co. in Japan on a 50-ton/year scale.
Acid-Catalyzed Ring Opening of 2,2-Dimethyloxacyclopropane

Why is the more hindered position attacked? Protonation at the oxygen of the ether generates a reactive intermediate alkylloxonium ion with substantially polarized oxygen–carbon bonds. This polarization places partial positive charges on the ring carbons. Because alkyl groups act as electron donors (Section 7-5), more positive charge is located on the tertiary than on the primary carbon. You can see this difference in the electrostatic potential map in the margin, in which the molecule is viewed from the perspective of the attacking nucleophile. The tertiary carbon at the bottom is more positive (blue) than the primary neighbor above (green). The proton in the back is strongly blue. The color-energy scale of this map was changed to make this subtle gradation in shading visible.

Mechanism of Acid-Catalyzed Ring Opening of 2,2-Dimethyloxacyclopropane by Methanol

This uneven charge distribution counteracts steric hindrance: Methanol is attracted by coulombic forces more to the tertiary than to the primary center. Although the result is clear-cut in this example, it is less so in cases in which the two carbons are not quite as different. For example, mixtures of isomeric products are formed by acid-catalyzed ring opening of 2-methyloxacyclopropane.

Why do we not simply write free carbocations as intermediates in the acid-catalyzed ring openings? The reason is that inversion is observed when the reaction takes place at a stereocenter. Like the reaction of oxacyclopropanes with anionic nucleophiles, the acid-catalyzed process includes backside displacement—in this case, on a highly polarized cyclic alkyloxonium ion.

Exercise 9-24

Predict the major product of ring opening of 2,2-dimethyloxacyclopropane on treatment with each of the following reagents. (a) LiAlH₄, then H⁺, H₂O; (b) CH₃CH₂CH₂MgBr, then H⁺, H₂O; (c) CH₃SNa in CH₃OH; (d) dilute HCl in CH₃CH₂OH; (e) concentrated aqueous HBr.

In Summary Although ordinary ethers are relatively inert, the ring in oxacyclopropanes can be opened both regioselectively and stereospecifically. For anionic nucleophiles, the usual rules of bimolecular nucleophilic substitution hold: Attack is at the less hindered carbon center, which undergoes inversion. Acid catalysis, however, changes the regioselectivity (but not the stereospecificity): Attack is at the more hindered center. Hydride and organometallic reagents behave like other anionic nucleophiles, furnishing alcohols by an S_N2 pathway.
9-10 Sulfur Analogs of Alcohols and Ethers

Sulfur is located directly below oxygen in the periodic table, and therefore one might expect the sulfur analogs of alcohols and ethers to behave in a rather similar manner. In this section, we shall see whether this assumption is true.

The sulfur analogs of alcohols and ethers are thiols and sulfides

The sulfur analogs of alcohols, R–SH, are called thiols in the IUPAC system (theion, Greek, brimstone—an older name for sulfur). The ending thiol is added to the alkane stem to yield the alkanethiol name. The SH group is referred to as mercapto, from the Latin mercurium, mercury, and captare, to capture, because of its ability to precipitate mercury (and other heavy metal) ions. Its location is indicated by numbering the longest chain, as in alkanol nomenclature. The mercapto functional group has lower precedence than hydroxy.

The sulfur analogs of ethers (common name, thioethers) are called sulfides, as in alkyl ether nomenclature. The RS group is named alkylthio, the RS– group alkanethiolate.

Thiols are less hydrogen bonded and more acidic than alcohols

Sulfur, because of its large size, its diffuse orbitals, and the relatively nonpolarized S–H bond (Table 1-2), does not enter into hydrogen bonding very efficiently. Thus, the boiling points of thiols are not as abnormally high as those of alcohols; rather, their volatilities lie close to those of the analogous haloalkanes (Table 9-2).

Partly because of the relatively weak S–H bond, thiols are also more acidic than water, with \( pK_a \) values ranging from 9 to 12. They can therefore be more readily deprotonated by hydroxide and alkoxide ions.

Thiols and sulfides react much like alcohols and ethers

Many reactions of thiols and sulfides resemble those of their oxygen analogs. The sulfur in these compounds is even more nucleophilic and much less basic than the oxygen in alcohols and ethers. Therefore, thiols and sulfides are readily made through nucleophilic attack by \( \text{RS}^- \) or \( \text{HS}^- \) on haloalkanes, with little competing elimination. A large excess of the \( \text{HS}^- \) is used in the preparation of thiols to ensure that the product does not react with the starting halide to give the dialkyl sulfide.

Sulfides are prepared in an analogous way by alkylation of thiols in the presence of base, such as hydroxide. The base generates the alkanethiolate, which reacts with the haloalkane by an $S_N2$ process. Because of the strong nucleophilicity of thiolates, there is no competition from hydroxide in this displacement.

![Sulfides by Alkylation of Thiols](image)

The nucleophilicity of sulfur also explains the ability of sulfides to attack haloalkanes to furnish sulfonium ions.

![Valence-shell expansion of sulfur accounts for the special reactivity of thiols and sulfides](image)

Valence-shell expansion of sulfur accounts for the special reactivity of thiols and sulfides

As a third-row element with $d$ orbitals, sulfur’s valence shell can expand to accommodate more electrons than are allowed by the octet rule (Section 1-4). We have already seen that, in some of its compounds, sulfur is surrounded by 10 or even 12 valence electrons, and this capacity enables sulfur compounds to undergo reactions inaccessible to the corresponding oxygen analogs. For example, oxidation of thiols with strong oxidizing agents, such as hydrogen peroxide or potassium permanganate, gives the corresponding sulfonic acids. In this way, methanethiol is converted into methanesulfonic acid. Sulfonic acids react with $PCl_5$ to give sulfonyl chlorides, which are used in sulfonate synthesis, as discussed in Section 9-4.

More careful oxidation of thiols, by the use of iodine, results in the formation of disulfides, the sulfur analogs of peroxides (Section 9-8). Disulfides are readily reduced back to thiols by mild reducing agents, such as aqueous sodium borohydride.
The Thiol–Disulfide Redox Reaction

Oxidation:

\[
2 \text{CH}_3\text{CH}_2\text{CH}_2\text{SH} + \text{I}_2 \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{S} = \text{SCH}_2\text{CH}_3 + 2 \text{HI}
\]

1-Propanethiol

Dipropyl disulfide

Reduction:

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{S} = \text{SCH}_2\text{CH}_3 + \text{NaBH}_4 \xrightarrow{\text{H}_2\text{O}} 2 \text{CH}_3\text{CH}_2\text{CH}_2\text{SH}
\]

Disulfide formation by oxidation of thiols and its reverse are important biological processes, although nature uses much milder reagents and conditions than those depicted above. Many proteins and peptides contain free SH groups that form bridging disulfide linkages. Nature exploits this mechanism to link amino acid chains. By thus helping to control the shape of enzymes in three dimensions, the mechanism makes biocatalysis far more efficient and selective.

Sulfides are readily oxidized to sulfones, a transformation proceeding through a sulfoxide intermediate. For example, oxidation of dimethyl sulfide first gives dimethyl sulfoxide (DMSO), which subsequently furnishes dimethyl sulfate. Dimethyl sulfoxide has already been mentioned as a highly polar nonprotic solvent of great use in organic chemistry, particularly in nucleophilic substitutions (see Section 6-8 and Table 6-5).

**In Summary** The naming of thiols and sulfides is related to the system used for alcohols and ethers. Thiols are more volatile, more acidic, and more nucleophilic than alcohols. Thiols and sulfides can be oxidized, thiols to disulfides or sulfonic acids and sulfides to sulfoxides and sulfones.

**9-11 Physiological Properties and Uses of Alcohols and Ethers**

Since we live in an oxidizing atmosphere, it is not surprising that oxygen is found in abundance in the chemicals of nature. Many of them are alcohols and ethers with varied biological functions, exploited by medicinal chemists in drug synthesis. Industrial chemists produce alcohols and ethers on a large scale, to be used as solvents and synthetic intermediates. This section gives a glimpse of the versatile uses of these compound classes.

*Methanol*, made in large amounts by the catalytic hydrogenation of carbon monoxide (Section 8-4), is sold as a solvent for paint and other materials, as a fuel for camp stoves and soldering torches, and as a synthetic intermediate. It is highly poisonous—ingestion or chronic exposure may lead to blindness. Death from ingestion of as little as 30 mL has been reported. It is sometimes added to commercial ethanol to render it unfit for consumption (denatured alcohol). The toxicity of methanol is thought to be due to metabolic oxidation to formaldehyde, \(\text{CH}_2\equiv\text{O}\), which interferes with the physiochemical processes of vision. Further oxidation to formic acid, \(\text{HCOOH}\), causes acidosis, an unusual lowering of the blood pH. This condition disrupts oxygen transport in the blood and leads eventually to coma.

Methanol has been studied as a possible precursor of gasoline. For example, certain zeolite catalysts (Section 3-3) allow the conversion of methanol into a mixture of hydrocarbons,
ranging in length from four-carbon chains to ten-carbon ones, with a composition that, on distillation, yields largely gasoline (see Table 3-3).

\[ n \text{CH}_3\text{OH} \xrightarrow{\text{Zeolite, 340°-375°C}} C_n\text{H}_{2n+2} + C_n\text{H}_{2n} + \text{aromatics} \]

\[ 67\% + 6\% + 27\% \]

Ethanol—diluted by various amounts of flavored water—is an alcoholic beverage. It is classified pharmacologically as a general depressant, because it induces a nonselective, reversible depression of the central nervous system. Approximately 95% of the alcohol ingested is metabolized in the body (usually in the liver) to products that are transformed eventually into carbon dioxide and water. Although it is high in calories, ethanol has little nutritional value.

The rate of metabolism of most drugs increases with their concentration in the liver, but this is not true for alcohol, which degrades linearly with time. An adult metabolizes about 10 mL of pure ethanol per hour, roughly the ethanol content of a cocktail, a shot of spirits, or a can of beer. As few as two or three drinks—depending on a person’s weight, the ethanol content of the drink, and the speed with which it is consumed—can produce a level of alcohol in the blood that is more than 0.08%, a concentration at or above the legal limit beyond which the operation of a motorized vehicle is prohibited in much of the United States.

Ethanol is poisonous. Its lethal concentration in the bloodstream has been estimated at 0.4%. Its effects include progressive euphoria, disinhibition, disorientation, and decreased judgment (drunkenness), followed by general anesthesia, coma, and death. It dilates the blood vessels, producing a “warm flush,” but it actually decreases body temperature. Although long-term ingestion of moderate amounts (the equivalent of about two beers a day) does not appear to be harmful, larger amounts can be the cause of a variety of physical and psychological symptoms, usually described by the general term alcoholism. These symptoms include hallucinations, psychomotor agitation, liver diseases, dementia, gastritis, and addiction.

Interestingly, a near-toxic dose of ethanol is given in cases of acute methanol or 1,2-ethanediol (ethylene glycol) poisoning. This treatment prevents the metabolism of the more toxic alcohols and allows their excretion before damaging concentrations of secondary products can accumulate.

Ethanol destined for human consumption is prepared by fermentation of sugars and starch (rice, potatoes, corn, wheat, flowers, fruit, etc.; Chapter 24). Fermentation is catalyzed by enzymes in a multistep sequence that converts carbohydrates into ethanol and carbon dioxide.

\[ (C_6H_{10}O_5)_n \xrightarrow{\text{Enzymes}} C_6H_{12}O_6 \xrightarrow{\text{Enzymes}} 2\text{CH}_3\text{CH}_2\text{OH} + 2\text{CO}_2 \]

Interest in ethanol production from such “green” sources (“bioethanol”) has surged because of its potential as a gasoline additive (“gasohol”) or even substitute (see Chapter 8 Opening). For example, in Brazil, which has the world’s largest biofuels program, ethanol provides about 30% of the country’s automotive fuel needs. While not quite as calorific as the hydrocarbon mixture in gasoline (see Table 3-7), ethanol burns more efficiently and cleanly:

\[ \text{CH}_3\text{CH}_2\text{OH} + 3\text{O}_2 \xrightarrow{\text{Combustion}} 2\text{CO}_2 + 3\text{H}_2\text{O} -326.7 \text{ kcal mol}^{-1} \]

Therefore, a biofuels economy, in essence, converts glucose to carbon dioxide and water:

\[ C_6H_{12}O_6 + 6\text{O}_2 \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O} + \text{heat (car mileage)} \]

This process is sustainable because green plants use sunlight for the reverse process, called photosynthesis (Chemical Highlight 24-3):

\[ 6\text{CO}_2 + 6\text{H}_2\text{O} \xrightarrow{\text{Sunlight, Photosynthesis}} C_6H_{12}O_6 + 6\text{O}_2 \]

Thus, simply put, the idea is to power our cars with sunlight in a roundabout way. In practice, however, switching to biofuels is not without problems, primarily because of the sheer size
of our fuel needs. For example, in 2006, the United States committed 20% of its corn crop for the preparation of 4.8 billion gallons of ethanol. Compare this to our daily consumption of almost 400 million gallons of gasoline, and you realize the scope of this undertaking! The potential negative impact of committing large agricultural areas of our planet to biofuel production on the environment, the economy, and the supply (hence price) of food is a matter of concern. On a more fundamental level, some critics argue that, at least for certain crops, the complete process of growing, harvesting, fermenting, and then distributing biofuels consumes more energy than it returns, dealing a fatal blow to the viability of such efforts.

Commercial alcohol that is not intended as a beverage is made industrially by hydration of ethene (Section 8-4). It is used, for example, as a solvent in perfumes, varnishes, and shellacs and as a synthetic intermediate, as demonstrated in earlier equations.

1,2-Ethanediol (ethylene glycol) is prepared by oxidation of ethene to oxacyclopropane, followed by hydrolysis, in quantities exceeding 7 billion pounds (3.5 million tons) in the United States per year. Its low melting point (−11.5°C), its high boiling point (198°C), and its complete miscibility with water make it a useful antifreeze. Its toxicity is similar to that of other simple alcohols.

\[
\begin{align*}
\text{CH}_2\equiv\text{CH}_2 & \quad \overset{\text{Oxidation}}{\longrightarrow} \quad \text{O} \\
\text{Oxacyclopropane} & \quad \overset{\text{H}_2\text{O}}{\longrightarrow} \quad \text{HOCH}_2\text{CH}_2\text{OH} \\
\end{align*}
\]

1,2,3-Propanetriol (glycerol, glycerine), HOCH\(_2\)CHOHCH\(_2\)OH, is a viscous greasy substance, soluble in water, and nontoxic. It is obtained by alkaline hydrolysis of triglycerides, the major component of fatty tissue. The sodium and potassium salts of the long-alkyl-chain acids produced from fats (“fatty acids,” Chapter 19) are sold as soaps.

\[
\begin{align*}
\text{CH}_2\text{OCR} & \quad \overset{\text{H}_2\text{O, NaOH}}{\longrightarrow} \quad \text{CH}_2\text{OH} \\
\text{HCOCHR} & \quad \overset{\text{H}_2\text{O, NaOH}}{\longrightarrow} \quad \text{HCOH} + \text{RCO}^{-}\text{Na}^+ \\
\text{Triglyceride ("Fat")} & \quad \overset{\text{Soap}}{\longrightarrow} \quad \text{1,2,3-Propanetriol (Glycerol, glycerine)} \\
\end{align*}
\]

Phosphoric esters of 1,2,3-propanetriols (phosphoglycerides; Section 20-4) are primary components of cell membranes.

1,2,3-Propanetriol is present in lotions and other cosmetics, as well as in medicinal preparations. Treatment with nitric acid gives a trinitrate ester known as nitroglycerin, used medicinally in the treatment of the symptoms of angina, especially the chest pain caused by insufficient flow of blood to the heart. The drug relaxes the blood vessels, thus increasing blood flow. A totally different application of nitroglycerin is as an extremely powerful explosive. The explosive potential of this substance results from its shock-induced, highly exothermic decomposition to gaseous products (\(\text{N}_2, \text{CO}_2, \text{H}_2\text{O}\) gas, \(\text{O}_2\)), raising temperatures to more than 3000°C and creating pressures higher than 2000 atmospheres in a fraction of a second (see also Chemical Highlight 16-1).

Ethoxyethane (diethyl ether) was at one time employed as a general anesthetic (see Chapter Opening). It produces unconsciousness by depressing central nervous system activity. Because of adverse effects such as irritation of the respiratory tract and extreme nausea, its use has been discontinued, and 1-methoxypropane (methyl propyl ether, “neothyl”) and other compounds have replaced it in such applications. Ethoxyethane and other ethers are explosive when they are mixed with air.

Oxacyclopropane (oxirane, ethylene oxide) is a large-volume industrial chemical intermediate and a fumigating agent for seeds and grains. In nature, oxacyclopropane derivatives control insect metamorphosis (see Chemical Highlight 12-1) and are formed in the course
of enzyme-catalyzed oxidation of aromatic hydrocarbons, often leading to highly carcinogenic (cancer-causing) products (see Section 16-7).

Many natural products, some of which are quite active physiologically, contain alcohol and ether groups. For example, morphine is a powerful analgesic. Its synthetic acetate derivative, heroin, is a widely abused street drug. Tetrahydrocannabinol is the main active ingredient in marijuana (cannabis), whose mood-altering effects have been known for thousands of years. Efforts are ongoing in the United States and worldwide to legalize marijuana for medical purposes, on the basis of the finding that it provides relief to patients afflicted with cancer, AIDS, multiple sclerosis, and other diseases from the effects of nausea, pain, and loss of appetite.

The lower-molecular-weight thiols and sulfides are most notorious for their foul smell. Ethanethiol is detectable by its odor even when it is diluted in 50 million parts of air. The major volatile components of the skunk’s defensive spray are 3-methyl-1-butanethiol, trans-2-butenyl methyl disulfide. The all-too-familiar human “BO” (body odor) emanating from sweaty armpits was analyzed by chemists in the perfume industry in 2004. The major chemical culprit is 3-methyl-3-methylthio-1-hexanol, specifically the obnoxious \( S \)-enantiomer. It is excreted admixed with 25\% of its mirror image, which, curiously, has a fruity odor.

Strangely enough, when they are highly diluted, sulfur compounds can have a rather pleasant odor. For example, the smell of freshly chopped onions or garlic is due to the presence of low-molecular-weight thiols and sulfides (Chemical Highlight 9-4). Dimethyl sulfide is a component of the aroma of black tea. The compound 2-(4-methyl-3-cyclohexenyl)-2-propanethiol (margin) is responsible for the unique taste of grapefruit, in which it is present in concentrations below the parts-per-billion (ppb; i.e., 1-in-\(10^9\)) range. It can be tasted at even lower concentrations, at a dilution of \( 10^{-4} \) ppb. In other words, you can notice the presence of 1 mg of this compound when it is dissolved in 10 million liters of water!

Many beneficial drugs contain sulfur in their molecular framework. Particularly well known are the sulfonamides, or sulfa drugs, powerful antibacterial agents (Section 15-10):

\[
\text{Sulfadiazine} (\text{An antibacterial drug}) \\
\text{Diaminodiphenylsulfone} (\text{An antileprotic drug})
\]
In Summary

Alcohols and ethers have various uses, both as chemical raw materials and as medicinal agents. Many of their derivatives can be found in nature; others are readily synthesized.

THE BIG PICTURE

We have now completed our coverage of alcohols, the second major class of functional-group compounds in this text. This does not mean that we are done with them, however. On the contrary, alcohols show up again in every one of the following chapters, often in conjunction with new functional-group substituents.

In this chapter, we also examined the last complication that may be encountered in the reactions of RX with nucleophiles/bases—carbocation rearrangements. We shall see later that skeletal rearrangements are also possible by other mechanisms, but acid catalysis is by far the most important.

Before we go on to present other classes of organic compounds, with other functional groups, we shall examine some of the key analytical techniques used by organic chemists to determine molecular structure. You should now have enough experience with the fundamentals of structure and function to appreciate that subtle differences in structures can lead...
to distinct changes in the electronic environment of molecules. By analyzing the interaction of molecules with various forms of electromagnetic radiation, chemists can infer a wealth of information about molecular structure. This forms the basis for the fundamental analytical tool available to us: spectroscopy.

CHAPTER INTEGRATION PROBLEMS

![Chemical Structure](image)

**SOLUTION**

This is an example of a mechanistic, rather than a synthetic, problem. In other words, to solve it, we cannot add any reagents as in a multistep synthetic sequence; what we see is what we have to work with. Let us take an inventory of what we have:

1. The (tertiary) alcohol function disappears and the (secondary) thioether unit (from CH₃SH) is introduced.
2. The four-membered ring turns into cyclopentyl.
3. The molecular formula of compound A, C₇H₁₄O, turns into that of compound B, C₈H₁₆S.

Focusing on the alkyl part attached to the respective functional group, we can rewrite these changes as C₇H₁₃–OH → C₇H₁₃–SCH₃.

4. The reaction medium contains catalytic acid in the presence of a tertiary alcohol.

What can we conclude from this information? We have a carbocation rearrangement (Section 9-3) in which the strained cyclobutane ring undergoes expansion to a substituted cyclopentane. The initial carbocation must derive from a protonation–water loss sequence (Section 9-2), as applied to A, and product B must be formed through S_N1 capture of the rearranged cation by CH₃SH.

We can now begin to formulate a step-by-step description of these thoughts.

**Step 1.** The hydroxy group is protonated and leaves as H₂O.

![Step 1](image)

**Step 2.** The tertiary carbocation undergoes ring expansion by alkyl shift (the migrating carbon is represented by a dot).

![Step 2](image)

**Step 3.** The new carbocation is trapped by the relatively (compared with water) nucleophilic sulfur of CH₃SH, followed by proton loss to give product B (Section 9-10).

![Step 3](image)

Visually, the most difficult step to follow in this sequence is step 2, because it consists of a fairly extreme topological change: The migrating carbon “drags” with it the appended chain, which is part of the ring. A good way of eliminating confusion is to label the “action pieces” in your molecule, as was done in the scheme for step 2, and to keep in mind the “bare bones” of an alkyl (or H) shift. Thus, only
three key atoms take part: the cationic center, which will receive the migrating group; the neighboring carbon, which will become charged; and the migrating atom. A simple aid in remembering the basic feature of a carbocation rearrangement is the slogan: “The charge and the migrating center trade places.”

Finally, note that rearrangement step 2 converts a tertiary into a secondary carbocation. The driving force is the release of ring strain in going from a four- (26.3 kcal mol$^{-1}$ strain) to a five-membered ring (6.5 kcal mol$^{-1}$ strain; Section 4-2). In our particular case, the secondary carbocation is trapped by the highly nucleophilic sulfur of the thiol before it rearranges further by methyl migration to the tertiary counterpart, a potential source of other products, which are not observed. Problems 36 and 61 provide further practice with related mechanisms.

9-27. Write a synthetic scheme that will convert enantiomer A to enantiomer B efficiently.

SOLUTION
This is an example of a synthetic, rather than mechanistic, problem. In other words, to solve it, we need to use reagents, specify conditions, and use as many steps as we see fit to get us from starting material to product. Let us take an inventory:

1. The strained oxacyclopropane ring has been opened in the product, which is another ether.

2. The molecular formula of A, C$_4$H$_8$O, is altered to that in B, C$_{11}$H$_{22}$O. The added increment is therefore C$_7$H$_{14}$. An obvious component of this increment is the cyclopentyl group, C$_5$H$_9$. Subtraction leaves C$_2$H$_5$. This looks like ethyl; however, comparison of the substituents in A (two methyls) with the substituents in B suggests that the extra two carbons are due to the introduction of two methyls (in addition to the added cyclopentyl group).

3. We have two stereocenters (both S) in starting material and only one (S) in the product. Remember that $R,S$-nomenclature does not correlate necessarily with changes in absolute configuration, only with changes in the priority sequence of substituents at a stereocenter (Section 5-3). How does the remaining stereocenter in B then relate to those in A? We get the answer by rewriting B in a conformation B’ that is visually clearer with respect to the stereochemical arrangement around the stereocenter, with the CH$_3$ and H connected to the chain by a wedged and hashed line, respectively, as in A. This reveals that the ether oxygen in A has been replaced by a cyclopentyl group with inversion.

What hints do we derive from this analysis? It is clear that the stereocenter in B can be derived from A by nucleophilic ring opening with a cyclopentyl organometallic:

However, that would provide an alcohol C, not an ether, and the oxygen-bearing carbon misses the extra methyl group.

Let us work retrosynthetically. Ether disconnection by retro-Williamson synthesis (Section 9-6) gives the tertiary alcohol D. How do we unravel D to C? Answer: We go back to Section 8-9, recognizing that complex alcohols can be made from simpler ones by organometallic additions to carbonyl compounds:
The solution therefore looks as follows:

Problem 55 contains similar synthesis exercises.

**New Reactions**

1. **Alkoxides from Alcohols (Sections 8-3, 9-1)**
   Using strong bases
   \[ \text{ROH} \xrightleftharpoons{\text{Strong base}} \text{RO}^- \]
   Examples of strong bases: \( \text{Li}^{+} [\text{N(CH(CH_3)_2)}]_2; \text{CH}_3\text{CH}_2\text{CH}_2\text{Li}; \text{K}^+ \text{H}^- \)

   Using alkali metals
   \[ \text{ROH} + \text{M} \rightarrow \text{RO}^- \text{M}^+ + \frac{1}{2}\text{H}_2 \]
   \( \text{M} = \text{Li}, \text{Na}, \text{K} \)

2. **Haloalkanes from Alcohols**
   2. Using Hydrogen Halides (Sections 8-3, 9-2, 9-3)
   \[ \text{ROH} \xrightarrow{\text{Conc. HX}} \text{RX} \]
   \( \text{X} = \text{Br} \) or \( \text{I} \) (S\(_2\)2 mechanism)
   \[ \text{ROH} \xrightarrow{\text{Conc. HX}} \text{RX} \]
   \( \text{X} = \text{Cl}, \text{Br}, \text{or} \text{I} \) (S\(_1\) mechanism)

3. **Using Phosphorus Reagents (Section 9-4)**
   \[ 3 \text{ROH} + \text{PBr}_3 \rightarrow 3 \text{RBr} + \text{H}_3\text{PO}_3 \]
   \[ 6 \text{ROH} + 2 \text{P} + 3 \text{I}_2 \rightarrow 6 \text{RI} + 2 \text{H}_3\text{PO}_3 \]
   S\(_2\)2 mechanism with primary and secondary ROH
   Less likelihood of carbocation rearrangements than with HX

4. **Using Sulfur Reagents (Section 9-4)**
   \[ \text{ROH} + \text{SOCl}_2 \xrightarrow{\text{N(CH_2CH_3)_3}} \text{Cl}^- \quad \text{ROH} + \text{R'SO_2Cl} \xrightarrow{\text{Na}^+, \text{DMSO}} \text{R'OSO_2R} \]
   \[ \text{ROH} + \text{SOCl}_2 \xrightarrow{\text{N(CH_2CH_3)_3}} \text{Cl}^- \quad \text{ROH} + \text{R'SO_2Cl} \xrightarrow{\text{Na}^+, \text{DMSO}} \text{R'OSO_2R} \]
   \( \text{Alkyl sulfonate} \)

**Carbocation Rearrangements in Alcohols**

5. **Carbocation Rearrangements by Alkyl and Hydride Shifts (Section 9-3)**

6. **Concerted Alkyl Shifts from Primary Alcohols (Section 9-3)**
Elimination Reactions of Alcohols

7. Dehydration with Strong Nonnucleophilic Acid (Sections 9-2, 9-3, 9-7, 11-5)

\[
\begin{align*}
\text{H}_2\text{SO}_4, \text{heat} & \quad \xrightarrow{} \quad \text{C} = \text{C} + \text{H}_2\text{O} \\
\text{Temperature required} & \\
\text{Primary ROH:} & 170^\circ\text{C}–180^\circ\text{C} \text{ (E2 mechanism)} \\
\text{Secondary ROH:} & 100^\circ\text{C}–140^\circ\text{C} \text{ (usually E1)} \\
\text{Tertiary ROH:} & 25^\circ\text{C}–80^\circ\text{C} \text{ (E1 mechanism)}
\end{align*}
\]

Carbocation rearrangements may occur

Preparation of Ethers

8. Williamson Synthesis (Section 9-6)

\[
\begin{align*}
\text{ROH} + \text{NaH, DMSO} & \xrightarrow{} \text{RO}^- + \text{Na}^+ \\
\text{R’} \text{ must be methyl or primary} \\
\text{ROH can be primary or secondary (tertiary alkoxides usually give E2 products, unless R’ = methyl)} \\
\text{Ease of intramolecular version forming cyclic ethers:} & k_3 \geq k_5 > k_4 \geq k_7 > k_8 \\
& (k_n = \text{reaction rate}, n = \text{ring size})
\end{align*}
\]

9. Mineral Acid Method (Section 9-7)

**Primary alcohols:**

\[
\begin{align*}
\text{RCH}_2\text{OH} & \xrightarrow{\text{H}^+, \text{low temperature}} \text{RCH}_2\text{OH}^+ \\
\text{RCH}_2\text{OH}_2 & \xrightarrow{\text{RCH}_2\text{OH, 130}^\circ\text{C–140}^\circ\text{C}} \xrightarrow{\text{H}_2\text{O}} \text{RCH}_2\text{OCH}_2\text{R}
\end{align*}
\]

**Secondary alcohols:**

\[
\begin{align*}
\text{OH} & \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{R} \xrightarrow{\text{H}_2\text{O}} \text{CH}--\text{O}--\text{CH} + \text{E1 products}
\end{align*}
\]

**Tertiary alcohols:**

\[
\begin{align*}
\text{R}_2\text{COH} + \text{R’OH} & \xrightarrow{\text{NaHSO}_3, \text{H}_2\text{O}} \xrightarrow{\text{Sn1}, \text{H}_2\text{O}} \text{R}_2\text{C}--\text{OR’} + \text{E1 products}
\end{align*}
\]

Reactions of Ethers

10. Cleavage by Hydrogen Halides (Section 9-8)

\[
\begin{align*}
\text{ROR} & \xrightarrow{\text{Conc. HX}} \text{RX} + \text{ROH} \xrightarrow{\text{Conc. HX}} 2 \text{RX}
\end{align*}
\]

\(X = \text{Br or I}\)

Primary R: SN2 mechanism

Secondary R: \(\text{Sn1 or Sn2 mechanism}\)

Tertiary R: \(\text{Sn1 mechanism}\)

11. Nucleophilic Opening of Oxacyclopropanes (Sections 9-9, 25-2)

**Anionic nucleophiles:**

\[
\begin{align*}
\text{Nu} & \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{NuCH}_2\text{CR}_2 \\
\text{Examples of Nu}: \text{HO}^-, \text{RO}^-, \text{RS}^-
\end{align*}
\]

**Acid-catalyzed opening:**

\[
\begin{align*}
\text{Nu} & \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{HOCH}_2\text{CR}_2 \\
\text{Examples of Nu}: \text{H}_2\text{O, ROH, halide}
\end{align*}
\]
12. Nucleophilic Opening of Oxacyclopropane by Lithium Aluminum Hydride (Section 9-9)

\[
\text{H}_2\text{C} = \text{CH}_2 \xrightarrow{1. \text{LiAlH}_4 (\text{CH}_3\text{CH}_2\text{O})} \text{CH}_3\text{CH}_2\text{OH}
\]

13. Nucleophilic Opening of Oxacyclopropane by Organometallic Compounds (Section 9-9)

\[
\text{RLi} \text{ or } \text{RMgX} + \text{H}_2\text{C} = \text{CH}_2 \xrightarrow{\text{THF} \text{, } \text{H}_2\text{O}} \text{RCH}_2\text{CH}_2\text{OH}
\]

### Sulfur Compounds

14. Preparation of Thiols and Sulfi des (Section 9-10)

\[
\text{RX} + \text{HS}^- \xrightarrow{\text{Excess}} \text{RSH} \quad \text{Thiol}
\]

\[
\text{RSH} + \text{R}'\text{X} \xrightarrow{\text{Base}} \text{R'SR}' \quad \text{Alkyl sulfide}
\]

15. Acidity of Thiols (Section 9-10)

\[
\text{RSH} + \text{HO}^- \xrightarrow{\text{Acidity of RSH} \gg \text{H}_2\text{O} \approx \text{ROH}} \text{RS}^- + \text{H}_2\text{O} \quad \text{pK}_a(\text{RSH}) = 9–12
\]

16. Nucleophilicity of Sulfi des (Section 9-10)

\[
\text{R}_2\text{S}^- \xrightarrow{\text{R}'\text{X}} \text{R}_2\text{SR}^- \quad \text{Sulfonium salt}
\]

17. Oxidation of Thiols (Section 9-10)

\[
\text{RSH} \xrightarrow{\text{KMnO}_4 \text{ or } \text{H}_2\text{O}_2} \text{RSO}_2\text{H} \quad \text{Alkanesulfonic acid}
\]

\[
\text{RSH} \xrightarrow{\text{I}_2 \text{ or } \text{NaBH}_4} \text{RS}^-\text{SR} \quad \text{Dialkyl disulfide}
\]

18. Oxidation of Sulfi des (Section 9-10)

\[
\text{R}_2\text{SR}' \xrightarrow{\text{H}_2\text{O}_2} \text{R}_2\text{SO} \quad \text{Dialkyl sulfoxide}
\]

\[
\text{R}_2\text{SR}' \xrightarrow{\text{H}_2\text{O}_2} \text{R}_2\text{SO}_2\text{H} \quad \text{Dialkyl sulfone}
\]

### Important Concepts

1. The reactivity of ROH with alkali metals to give alkoxides and hydrogen follows the order

   \[
   \text{R} = \text{CH}_3 > \text{primary} > \text{secondary} > \text{tertiary}.
   \]

2. In the presence of acid and a nucleophilic counterion, primary alcohols undergo S_N2 reactions. Secondary and tertiary alcohols tend to form carbocations in the presence of acid, capable of E1 and S_N1 product formation, before and after rearrangement.

3. Carbocation rearrangements take place by hydride and alkyl group shifts. They usually result in interconversion of secondary carbocations or conversion of a secondary into a tertiary carbocation. Primary alkylxonium ions can rearrange by a concerted process consisting of loss of water and simultaneous hydride or alkyl shift to give secondary or tertiary carbocations.

4. Synthesis of primary and secondary haloalkanes can be achieved with less risk of rearrangement by methods using inorganic esters.

5. Ethers are prepared by either the Williamson ether synthesis or by reaction of alcohols with strong nonnucleophilic acids. The first method is best when S_N2 reactivity is high. In the latter case, elimination (dehydration) is a competing process at higher temperatures.
6. **Crown ethers** and **cryptands** are examples of **ionophores**, polyethers that coordinate around metal ions, thus rendering them soluble in hydrophobic media.

7. Whereas nucleophilic **ring opening of oxacyclopropanes** by anions is at the less substituted ring carbon according to the rules of the **S_N2** reaction, acid-catalyzed opening favors the more substituted carbon, because of charge control of nucleophilic attack.

8. Sulfur has more diffuse orbitals than does oxygen. In **thiols**, the S–H bond is less polarized than the O–H bond in alcohols, thus leading to **diminished hydrogen bonding**. Because the S–H bond is also weaker than the O–H bond, the **acidity** of thiols is **greater** than that of alcohols.

9. **Note on color use**: Throughout the main parts of the text, beginning in Chapter 6, reacting species in mechanisms and most examples of new transformations are color coded **red** for **nucleophiles**, **blue** for **electrophiles**, and **green** for **leaving groups**. Color coding is **not** used in exercises, summaries of new reactions, or chapter-end problems.

**Problems**

28. On which side of the equation do you expect each of the following equilibria to lie (left or right)?

(a) \((\text{CH}_3)_3\text{COH} + K^+\cdot\text{OH} \rightleftharpoons (\text{CH}_3)_2\text{CO}^+\cdot\text{K}^+ + \text{H}_2\text{O}\)
(b) \(\text{CH}_3\text{OH} + \text{NH}_3 \rightleftharpoons \text{CH}_3\text{O}^- + \text{NH}_4^+ (pK_a = 9.2)\)
(c) \(\text{CH}_3\text{CH}_2\text{OH} + \text{N}^-\text{Li}^+ \rightleftharpoons \text{CH}_3\text{CH}_2\text{O}^-\text{Li}^+ + \text{NH}_3 (pK_a = 40)\)
(d) \(\text{NH}_3(pK_a = 35) + \text{Na}^+\text{H}^- \rightleftharpoons \text{Na}^+\cdot\text{NH}_2^- + \text{H}_2(pK_a \sim 38)\)

29. Give the expected major product of each of the following reactions.

(a) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{OH} \xrightarrow{\text{Conc. HI}} \text{CH}_3\text{CH}_2\text{CH}_2\text{OH}^+\)
(b) \((\text{CH}_3)_2\text{CHCH}_2\text{CH}_2\text{OH} \xrightarrow{\text{Conc. HBr}} \)
(c) \(\text{CH}_3\text{CH}_2\text{OH} \xrightarrow{\text{Conc. HI}} \)
(d) \((\text{CH}_3\text{CH}_2)_3\text{COH} \xrightarrow{\text{Conc. HCl}} \)

30. For each reaction in Problem 29, write out a detailed step-by-step mechanism.

31. For each of the following alcohols, write the structure of the alkyloxonium ion produced after protonation by strong acid; if the alkyloxonium ion is capable of losing water readily, write the structure of the resulting carbocation; if the carbocation obtained is likely to be susceptible to rearrangement, write the structures of all new carbocations that might be reasonably expected to form.

(a) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}\)
(b) \(\text{CH}_3\text{CHCH}_3\)
(c) \(\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}\)
(d) \((\text{CH}_3)_2\text{CHCH}_2\text{OH}\)
(e) \((\text{CH}_3)_3\text{CCH}_2\text{CH}_2\text{OH}\)
(f) \(\text{CH}_3\text{C}^+\text{OOH}\)
(g) \(\text{CH}_3\text{C}^+\text{C}^+\text{OH}\)
(h) \(\text{CH}_3\text{C}^+\text{C}^+\text{CH}_3\)

32. Write all products of the reaction of each of the alcohols in Problem 31 with concentrated \(\text{H}_2\text{SO}_4\) under elimination conditions.

33. Write all sensible products of the reaction of each of the alcohols in Problem 31 with concentrated aqueous \(\text{HBr}\).
34. Give detailed mechanisms and final products for the reaction of 3-methyl-2-pentanol with each of the reagents that follow.
   (a) NaH   (b) Concentrated HBr
   (c) PBr₅   (d) SOCl₂
   (e) Concentrated H₂SO₄ at 130°C   (f) Dilute H₂SO₄ in (CH₃)₂COH

35. Primary alcohols are often converted into bromides by reaction with NaBr in H₂SO₄. Explain how this transformation works and why it might be considered a superior method to that using concentrated aqueous HBr.

\[
\text{CH₃CH₂CH₂CH₂OH} \xrightarrow{\text{NaBr, H₂SO₄}} \text{CH₃CH₂CH₂CH₂Br}
\]

36. What are the most likely product(s) of each of the following reactions?

(a) \[
\begin{array}{c}
\text{CH₃} \\
\text{CH₂OH}
\end{array}
\xrightarrow{\text{CH₃CH₂OH, H₂SO₄}}
\begin{array}{c}
\text{CH₃} \\
\text{CH₂OH}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{CH₃} \\
\text{CH₂OH}
\end{array}
\xrightarrow{\text{Optical旋转}}
\begin{array}{c}
\text{CH₃} \\
\text{CH₂OH}
\end{array}
\]

(c) \[
\begin{array}{c}
\text{CH₃} \\
\text{CH₂OH}
\end{array}
\xrightarrow{\text{Conc. H₂SO₄, 180°C}}
\begin{array}{c}
\text{CH₃} \\
\text{CH₂OH}
\end{array}
\]

37. Give the expected main product of the reaction of each of the alcohols in Problem 31 with PBr₅. Compare the results with those of Problem 33.

38. Give the expected product(s) of the reaction of 1-pentanol with each of the following reagents.

(a) K⁺ ½OC(CH₃)₃   (b) Sodium metal   (c) CH₃Li
   (d) Concentrated HI   (e) Concentrated HCl   (f) FSO₃H
   (g) Concentrated H₂SO₄ at 130°C   (h) Concentrated H₂SO₄ at 180°C   (i) CH₃SO₂Cl, (CH₃CH₂)₃N
   (j) PBr₅   (k) SOCl₂   (l) K₂Cr₂O₇ + H₂SO₄ + H₂O
   (m) PCC, CH₂Cl₂   (n) (CH₃)₂C(OH) + H₂SO₄ (as catalyst)

39. Give the expected product(s) of the reaction of trans-3-methylcyclopentanol with each of the reagents in Problem 38.

40. Suggest a good synthetic method for preparing each of the following haloalkanes from the corresponding alcohols.

(a) CH₃CH₂CH₂Cl   (b) CH₃CH₂CHCH₂Br   (c) \[
\begin{array}{c}
\text{H₃C} \\
\text{Cl}
\end{array}
\]   (d) CH₃CHCH(CH₃)₂

41. Name each of the following molecules according to IUPAC.

(a) (CH₃)₂CHOCH₂CH₃   (b) CH₃OCH₂CH₂OH   (c) \[
\begin{array}{c}
\text{H₂C} \\
\text{OCH₃}
\end{array}
\]
   (d) (ClCH₂CH₂)₂O   (e) \[
\begin{array}{c}
\text{H₂C} \\
\text{OCH₃}
\end{array}
\]
   (f) CH₃OCH₂OCH₃   (g) CH₃OCH₂Cl

42. Explain why the boiling points of ethers are lower than those of the isomeric alcohols. Would you expect the relative water solubilities to differ in a similar way?

43. Suggest the best syntheses for each of the following ethers. Use alcohols or haloalkanes or both as your starting materials.

(a) \[
\begin{array}{c}
\text{O}
\end{array}
\]
   (b) \[
\begin{array}{c}
\text{O}
\end{array}
\]
   (c) \[
\begin{array}{c}
\text{O}
\end{array}
\]
   (d) \[
\begin{array}{c}
\text{O}
\end{array}
\]
   (e) \[
\begin{array}{c}
\text{O}
\end{array}
\]
   (f) \[
\begin{array}{c}
\text{O}
\end{array}
\]
44. Write the expected major product(s) of each of the following attempted ether syntheses.

(a) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} + \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_3 \xrightarrow{\text{DMSO}} \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_3\text{O}^- \)

(b) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{O}^- + \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_3 \xrightarrow{\text{HMPA}} \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CH}_3\text{Cl} \)

(c) \( \text{H}_3\text{C} + \text{CH}_3\text{I} \xrightarrow{\text{DMSO}} \text{H}_3\text{C} \text{O}^- + \text{CH}_3\text{CH}_2\text{I} \)

(d) \( (\text{CH}_3)_2\text{CHO}^- + (\text{CH}_3)_2\text{CHCH}_2\text{CH}_3\text{Br} \xrightarrow{(\text{CH}_3)_2\text{CHOH}} \)

(e) \( \text{H}_2\text{C} \text{O}^- + \text{CH}_3\text{I} \xrightarrow{\text{DMSO}} \text{H}_3\text{C} \text{H}_2\text{I} \)

(f) \( \text{CH}_3\text{CH}_2\text{I} \xrightarrow{\text{CH}_3\text{CO}^-/\text{H}_2\text{O}/\text{H}_1\text{O}_2} \text{CH}_3\text{CH}_2\text{H}_2\text{OH} \)

45. For each reaction in Problem 44, write out a detailed step-by-step mechanism.

46. For each synthesis proposed in Problem 44 that is not likely to give a good yield of ether product, suggest an alternative synthesis beginning with suitable alcohols or haloalkanes that will give a superior result. (Hint: See Problem 25 in Chapter 7.)

47. (a) What would be the product of reaction of \textit{trans}-2-bromocyclooctanol (margin) with NaOH? 
(b) Compare the effect of entropy on the transition state of this reaction with its effect in the reactions presented in Figure 9-6 and in Exercise 9-14.

48. Propose efficient syntheses for each of the following ethers, using haloalkanes or alcohols as starting materials.

(a) \( \text{CH}_3\text{CH}_2\text{CHOCH}_2\text{CH}_3 \) 
(b) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{CH}_3 \) 
(c) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{OCH}_3 \) 
(d) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{Br} \)

49. Give the major product(s) of each of the following reactions.

(a) \( \text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3 \xrightarrow{\text{Excess conc. HBr}} \text{H}_3\text{C} \text{H}_2\text{O}^- \)

(b) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{Br} \xrightarrow{\text{Excess conc. HBr}} \text{H}_3\text{C} \text{H}_2\text{O}^- \)

(c) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{OCH}_3 \xrightarrow{\text{Excess conc. HBr}} \text{H}_3\text{C} \text{H}_2\text{O}^- \)

(d) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{Br} \xrightarrow{\text{Concentrated HBr}} \text{H}_3\text{C} \text{H}_2\text{O}^- \)

(e) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{OCH}_3 \xrightarrow{\text{Concentrated HBr}} \text{H}_3\text{C} \text{H}_2\text{O}^- \)

50. Give the expected major product of reaction of 2,2-dimethyloxacyclopropane with each of the following reagents.

(a) Dilute \( \text{H}_2\text{SO}_4 \) in \( \text{CH}_3\text{OH} \) 
(b) \( \text{Na}^+\text{OCH}_3 \) in \( \text{CH}_3\text{OH} \) 
(c) Dilute, aqueous HBr 
(d) Concentrated HBr 
(e) \( \text{CH}_3\text{MgI}, \text{ then H}^+, \text{H}_2\text{O} \) 
(f) \( \text{C}_6\text{H}_5\text{Li}, \text{ then H}^+, \text{H}_2\text{O} \)

51. Propose a synthesis of \( \text{CH}_3\text{CH}_2\text{CH}_2\text{OH} \) beginning with cyclohexanone, \( \text{CH}_3\text{OH} \), and 3-bromopropanol. (Hint: Beware of a possible pitfall in planning this synthesis (recall Section 8-9).)

52. Cleavage of tertiary butyl ethers requires the use of an aqueous acid (Chapter 7, Problem 57, and Section 9-8). Why do strong bases not cleave ethers (other than oxacyclopropanes)?
53. Provide an IUPAC name for each of the structures pictured below.

(a) 
(b) 
(c) 
(d) 
(e) 
(f) 

54. Give the major product(s) of each of the following reactions. (Hint: The strained oxacyclobutanes react like oxacyclopropanes.)

(a) 
(b) 
(c) 
(d) 
(e) 
(f) 

55. For each alcohol in Problem 51 of Chapter 8, suggest a synthetic route that starts with an oxacyclopropane (if possible).

56. Give the major product(s) expected from each of the reactions shown below. Watch stereochemistry.

(a) 
(b) 

57. Name each of the following compounds according to IUPAC.

(a) 
(b) 
(c) 
(d) 

58. In each of the following pairs of compounds, indicate which is the stronger acid and which is the stronger base. (a) CH₃SH, CH₃OH; (b) HS⁻, HO⁻; (c) Hₛ⁺, H₂S.

59. Give reasonable products for each of the following reactions.

(a) 
(b) 
(c) 
(d) 
(e) 
(f) 

(h) 

(i) 

(j) 

(k)
60. Give the structures of compounds A, B, and C (with stereochemistry) from the information in the following scheme. (Hint: A is acyclic.) To what compound class does the product belong?

\[
\begin{align*}
A & \xrightarrow{2 \text{CH}_3\text{SO}_4\text{Cl}, (\text{CH}_3\text{CH}_2)_3\text{N}, \text{CH}_2\text{Cl}_2} B & \xrightarrow{\text{Na}_2\text{S}, \text{H}_2\text{O}, \text{DMF}} C & \xrightarrow{\text{Excess H}_2\text{O}_2} \\
\text{C}_8\text{H}_{16}\text{O}_2 & & \text{C}_8\text{H}_{18}\text{S}_2\text{O}_6 & \text{C}_8\text{H}_2\text{S} \\
\end{align*}
\]

61. In an attempt to make 1-chloro-1-cyclobutylpentane, the following reaction sequence was employed. The actual product isolated, however, was not the desired molecule but an isomer of it. Suggest a structure for the product and give a mechanistic explanation for its formation. (Hint: See Chapter Integration Problem 9-26.)

63. In an early study of the stereochemistry of nucleophilic displacements, optically pure (R)-1-deuterio-1-pentanol was treated with 4-methylphenylsulfonyl (tosyl) chloride to make the corresponding tosylate. The tosylate was then treated with excess ammonia to convert it to 1-deuterio-1-pentanamine:

\[
\begin{align*}
\text{(R)}\text{-CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CHDOH} & \xrightarrow{\text{CH}_3\text{SO}_2\text{Cl}} \text{(R)}\text{-1-Deuterio-1-pentanol} & \xrightarrow{\text{Excess NH}_3} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CHDNH}_2 \\
& & \text{1-Deuterio-1-pentanamine} \\
\end{align*}
\]

(a) Describe the stereochemistry that you expect to observe at C1 of both the intermediate tosylate and the final amine. 

(b) When the reaction sequence is actually carried out, the expected results are not obtained. Instead, the final amine is isolated as a 70:30 mixture of (S)- and (R)-1-deuterio-1-pentanamine. Suggest a mechanistic explanation. (Hint: Recall that reaction of an alcohol with a sulfonyl chloride displaces chloride ion, which is a nucleophile.)

64. What is the product of the reaction shown in the margin? (Pay attention to stereochemistry at the reacting centers.) What is the kinetic order of this reaction?

65. Propose syntheses of the following molecules, choosing reasonable starting materials on the basis of the principles of synthetic strategy introduced in preceding chapters, particularly in Section 8-9. Suggested positions for carbon–carbon bond formation are indicated by wavy lines.

\[
\begin{align*}
& \xrightarrow{\text{DMSO}} \\
\end{align*}
\]

66. Give efficient syntheses of each of the following compounds, beginning with the indicated starting material.

(a) trans-1-Bromo-2-methylcyclopentane, from cis-2-methylcyclopentanol

(b) from 3-pentanol
(c) 3-Chloro-3-methylhexane, from 3-methyl-2-hexanol

(d) \[ \text{S} \]

from 2-bromoethanol (two equivalents)

67. Compare the following methods of alkene synthesis from a general primary alcohol. State the advantages and disadvantages of each one.

\[
\begin{align*}
\text{RCH}_2\text{CH}_2\text{OH} & \xrightarrow{\text{H}_2\text{SO}_4, 385^\circ\text{C}} \text{RCH}═\text{CH}_2 \\
\text{RCH}_2\text{CH}_2\text{OH} & \xrightarrow{\text{PBr}_3} \text{RCH}_2\text{CH}_2\text{Br} \xrightarrow{\text{K}^+\text{OCl(CH}_3}_3 \rightarrow \text{RCH}═\text{CH}_2 \\
\end{align*}
\]

68. Sugars, being polyhydroxylic compounds (Chapter 24), undergo reactions characteristic of alcohols. In one of the later steps in glycolysis (the metabolism of glucose), one of the glucose metabolites with a remaining hydroxy group, 2-phosphoglyceric acid, is converted into 2-phosphoenolpyruvic acid. This reaction is catalyzed by the enzyme enolase in the presence of a Lewis acid such as Mg\(^{2+}\). (a) How would you classify this reaction? (b) What is the possible role of the Lewis acidic metal ion?

\[
\begin{align*}
\text{HOCH}_2\text{—CH—COOH} & \xrightarrow{\text{Enolase, Mg}^{2+}} \text{CH}_2═\text{C}—\text{OPo}_3^{2—} \\
\end{align*}
\]

69. The formidable-looking molecule 5-methyltetrahydrofolic acid (abbreviated 5-methyl-FH\(_4\)) is the product of sequences of biological reactions that convert carbon atoms from a variety of simple molecules, such as formic acid and the amino acid histidine, into methyl groups.

\[
\begin{align*}
\text{H}_2\text{N}—\text{CH}═\text{CH}—\text{NH}_2 & \xrightarrow{\text{Four steps}} \text{H}_2\text{N}—\text{CH}═\text{CH}—\text{NH}_2 \\
\text{Formic acid} & \text{Histidine} \quad \begin{array}{c}
\text{H}_2\text{N}—\text{CH}═\text{CH}—\text{NH}_2 \\
\text{Seven steps}
\end{array} \quad \text{O═C—OH} \\
\text{5-Methyltetrahydrofolic acid} & \quad \text{(5-Methyl-FH}\(_4\)) \\
\end{align*}
\]

The simplest synthesis of 5-methyltetrahydrofolic acid is from tetrahydrofolic acid (FH\(_4\)) and trimethylsulfonium ion, a reaction carried out by microorganisms in the soil.

\[
\begin{align*}
\text{FH}_4 & + \text{S}—\text{CH}—\text{CH}_3 \rightarrow \text{FH}_4 + \text{CH}_3—\text{S}—\text{CH}—\text{CH}_3 + \text{H}^+ \\
\end{align*}
\]
(a) Can this reaction be reasonably assumed to proceed through a nucleophilic substitution mechanism? Write the mechanism, using the “electron-pushing” arrow notation. (b) Identify the nucleophile, the nucleophilic and electrophilic atoms participating in the reaction, and the leaving group. (c) On the basis of the concepts presented in Sections 6-7, 6-8, 9-2, and 9-9, are all the groups that you identified in (b) behaving in a reasonable way in this reaction? Does it help to know that species such as $\text{H}_2\text{S}^+$ are very strong acids (e.g., $pK_a$ of $\text{CH}_3\text{SH}_2^+$ is $-7$)?

70. **[Challenge]** The role of 5-methyl-$\text{FH}_4$ (Problem 69) in biology is to serve as a donor of methyl groups to small molecules. The synthesis of the amino acid methionine from homocysteine is perhaps the best-known example.

![Chemical Structures]

For this problem, answer the same questions that were posed in Problem 69. The $pK_a$ of the circled hydrogen in $\text{FH}_4$ is 5. Does this cause a problem with any feature of your mechanism? In fact, methyl transfer reactions of 5-methyl-$\text{FH}_4$ require a proton source. Review the material in Section 9-2, especially the subsection titled “Haloalkanes from primary alcohols and $\text{HX}$.” Then suggest a useful role for a proton in the reaction illustrated here.

71. Epinephrine (adrenalin; see also Chapter 6 Opening) is produced in your body in a two-step process that accomplishes the transfer of a methyl group from methionine (Problem 70) to norepinephrine (see reactions 1 and 2 below). (a) Explain in detail what is going on mechanistically in these two reactions, and analyze the role played by the molecule of ATP. (b) Would you expect methionine to react directly with norepinephrine? Explain. (c) Propose a laboratory synthesis of epinephrine from norepinephrine.

**Reaction 1**

**Reaction 2**
72. (a) Only the trans isomer of 2-bromocyclohexanol can react with sodium hydroxide to form an oxacyclopropane-containing product. Explain the lack of reactivity of the cis isomer. [Hint: Draw the available conformations of both the cis and trans isomers around the C1–C2 bonds (compare Figure 4-12). Use models if necessary.] (b) The synthesis of some oxacyclopropane-containing steroids has been achieved by use of a two-step procedure starting with steroidal bromoketones. Suggest suitable reagents for accomplishing a conversion such as the following one.

\[
\begin{align*}
\text{CH}_3\text{CHCH}_2\text{CH}_2\text{CH}\text{=CH}_2 & \quad \text{Allicin} \\
\text{CH}_2\text{=CHCH}_2\text{CHCH}_2\text{CH}\text{=CH}_2 & \quad \text{Enol}
\end{align*}
\]

(c) Do any of the steps in your proposed sequence have specific stereochemical requirements for the success of the oxacyclopropane-forming step?

73. Freshly cut garlic contains allicin, a compound responsible for the true garlic odor (see Chemical Highlight 9-4). Propose a short synthesis of allicin, starting with 3-chloropropene.

74. There are four diastereomers (A–D, margin) of (4S)-2-bromo-4-phenylcyclohexanol. As a team, formulate their structures and draw each diastereomer in the most stable chair conformation (see Table 4-3; the \(\Delta G^\circ\) value for axial versus equatorial \(\text{C}_6\text{H}_5\) is 2.9 kcal mol\(^{-1}\)). Divide your team into equal groups to consider the outcome of the reaction of each isomer with base (\(\text{OH}\)).

(a) Using the curved-arrow formalism (Section 6-3), show the flow of electrons in the attack of the base on the various cyclohexane conformers. Reconvene and present your mechanisms to your teammates, justifying the structural assignments of A–D. Find an explanation for the qualitative rate differences and the divergent course of the reactions of A and B versus C and D.

(b) When compounds A–D are exposed to conditions favoring bromide dissociation in the presence of \(\text{Ag}^+\) salts (to accelerate heterolysis with formation of insoluble \(\text{AgBr}\)), A, C, and D give the same products as those obtained on treatment with base. Discuss the mechanism as a group.

(c) Curiously, compound B traverses another pathway under the conditions described in (b); that is, rearrangement to the aldehyde \(E\). Discuss a possible mechanism for this ring contraction. [Hint: Keep in mind the principles outlined in Section 9-3. The mechanism proceeds through a hydroxylation. What is the driving force for its formation?]
Preprofessional Problems

75. The compound whose structure is

![Chemical structure image]

is best named (IUPAC)

(a) 3,5-dimethylcyclopentyl ether  
(b) 3,5-dimethylcyclopentane-oxo  
(c) cis-3,5-dimethyloxacyclohexane  
(d) trans-3,5-dimethyloxacyclohexane

76. The first step in the detailed mechanism for the dehydration of 1-propanol with concentrated H₂SO₄ would be

(a) loss of OH⁻  
(b) formation of a sulfate ester  
(c) protonation of the alcohol  
(d) loss of H⁺ by the alcohol  
(e) elimination of H₂O by the alcohol

77. Identify the nucleophile in the following reaction:

\[ RX + H₂O \rightarrow ROH + H⁺X⁻ \]

(a) X⁻  
(b) H⁺  
(c) H₂O  
(d) ROH  
(e) RX

78. Which is the method of choice for preparing the ether (CH₃CH₂)₃COCH₃?

(a) CH₃Br + (CH₃CH₂)₂CO⁻K⁺  
(b) (CH₃CH₂)₂COH + CH₃MgBr  
(c) (CH₃CH₂)₂CMgBr + CH₃OH  
(d) (CH₃CH₂)₂CBr + CH₃O⁻K⁺
We have seen that one of the main goals of studying organic chemistry is to appreciate how details of molecular structure affect the ways in which molecules function in reactions—whether those reactions take place in industrial settings, in laboratory syntheses, or within the body. But how do we know the detailed structures of molecules? How can we identify new products or be sure that we have isolated the product we want from a reaction mixture? Wouldn’t it be nice if we had some technique that could allow us to recognize the presence of certain nuclei in a molecule, count their relative numbers, describe the nature of their electronic environment, and tell us how they are connected to other atoms?

We do have such a technique, known as nuclear magnetic resonance (NMR) spectroscopy. Not only does this method enable us to identify the structure of an organic molecule, it can be applied to the imaging of whole body organs, a variation known as magnetic resonance imaging (MRI). Just as NMR spectroscopy has become one of the most powerful tools for the organic chemist, MRI has become one of the most powerful applications in medical diagnosis.

We begin with a brief consideration of how classical physical measurements and chemical tests can help in determining a compound’s structure. Then we shall discuss how...
s NMR spectroscopy works, how we can interpret its results, and what information we can obtain from the latest advances in spectroscopic instruments and techniques.

**10-1 Physical and Chemical Tests**

Let us imagine that you have run a reaction yielding an unidentified compound. To study our sample, we must first purify it—by chromatography, distillation, or recrystallization. We can then compare its melting point, boiling point, and other physical properties with data for known compounds. Even when our measurements match values in the literature (or appropriate handbooks), we cannot be reasonably certain of the identity and structure of our molecule. Moreover, many substances made in the laboratory are new: No published data are available. We need ways to determine their structures for the first time.

Elemental analysis will reveal the sample’s gross chemical composition. Chemical tests of the compound can then help us to identify its functional groups. For example, we saw in Section 1-9 that we can distinguish between methoxymethane and ethanol on the basis of their physical properties. Section 9-1 indicated how we could do so also on the basis of differing reactivity, for example, in the presence of sodium (ethanol will form sodium ethoxide and hydrogen; methoxymethane is inert).

The problem becomes considerably more difficult for larger molecules, which vary far more in structure. What if a reaction gave us an alcohol of molecular formula C7H16O? A test with sodium metal would reveal a hydroxy functional group—but not an unambiguous structure. In fact, there are many possibilities, only three of which are shown here.

Three Structural Possibilities for an Alcohol C7H16O

\[
\begin{align*}
\text{CH}_3(\text{CH}_2)_3\text{CH}_2\text{OH} & \quad \text{CH}_3\text{CCH}_2\text{CH}_2\text{OH} \quad \text{CH}_2\text{CH}_3\text{CCH}_2\text{CH}_2\text{OH} \\
\text{CH}_3 & \quad \text{CH}_3 & \quad \text{CH}_3
\end{align*}
\]

**Exercise 10-1**

Write the structures of several secondary and tertiary alcohols having the molecular formula C7H16O.

To differentiate among these alternatives, a modern organic chemist makes use of another tool: spectroscopy.

**10-2 Defining Spectroscopy**

Spectroscopy is a technique for analyzing the structure of molecules, usually based on differences in how they absorb electromagnetic radiation. Although there are many types of spectroscopy, four are used most often in organic chemistry: (1) nuclear magnetic resonance (NMR) spectroscopy; (2) infrared (IR) spectroscopy; (3) ultraviolet (UV) spectroscopy; and (based on a different principle) (4) mass spectrometry (MS). The first, NMR spectroscopy, probes the structure in the vicinity of individual nuclei, particularly hydrogens and carbons, and provides the most detailed information regarding the atomic connectivity of a molecule.

We begin with a simple overview of spectroscopy as it relates to NMR, IR, and UV. Then we describe how a spectrometer works. Finally, we consider the principles and applications of NMR spectroscopy in more detail. We shall return to the other major forms of spectroscopy in Chapters 11 and 14.

**Molecules undergo distinctive excitations**

Electromagnetic radiation can be described in the form of waves (or particles; Section 1-6). A wave is defined by its wavelength \( \lambda \) (see margin) or by its frequency \( \nu \). The two are related by the expressions

\[
\nu = \frac{c}{\lambda} \quad \text{or} \quad \lambda \nu = c
\]
Exercise 10-2

What type of radiation (in wavelengths, $\lambda$) would be minimally required to initiate the radical chlorination of methane? [Hint: The initiation step requires the breaking of the Cl–Cl bond (see Section 3-4).]

A spectrometer records the absorption of radiation

As illustrated in Figure 10-1, the absorption of quanta of radiation by a molecule brings about transitions from its (normal) ground state to (a variety of) excited states. Spectroscopy is a procedure by which these absorptions can be mapped by instruments called **spectrometers**.

Figure 10-3 shows the principle of a spectrometer. It contains a source of electromagnetic radiation with a frequency in the region of interest, such as the visible, infrared, or radio. The apparatus is designed so that radiation of a specific wavelength range (NMR, IR, UV, etc.) passes through the sample. In the traditional continuous-wave (CW) spectrometer, the frequency of this radiation is changed continuously, and its intensity is measured at a detector and recorded on calibrated paper. In the absence of absorption, the sweep of radiation appears as a straight line, the baseline. Whenever the sample absorbs electromagnetic radiation, however, the resulting change in intensity at the detector registers as a peak, or deviation from the baseline. The resulting pattern is the spectrum (Latin, appearance, apparition) of the sample.

New-generation spectrometers use a different and much faster recording technique, in which a pulse of electromagnetic radiation that covers the entire frequency range under scrutiny (NMR, IR, UV) is used to obtain the whole spectrum instantly. Moreover, rather than simple absorption, as in traditional CW instruments, the decay of the absorption event with time is recorded, a procedure that requires a more elaborate computer analysis, called **Fourier transform (FT)**, after the French mathematician Joseph Fourier (1768–1830). Apart from the speed of this technique, multiple pulse accumulation of the same spectrum allows for much higher sensitivity, which is of great value when only small amounts of sample are available.
In Summary

Molecules absorb electromagnetic radiation in discrete quanta of incident energy measurable by spectroscopy. Spectrometers scan samples with radiation of varying wavelength as it passes through a sample of the compound under investigation, resulting in a plot of the absorptions occurring at certain energies: the spectrum.

10-3 Hydrogen Nuclear Magnetic Resonance

Nuclear magnetic resonance spectroscopy requires low-energy radiation in the radio-frequency (RF) range. This section presents the principles behind this technique.

Nuclear spins can be excited by the absorption of radio waves

Many atomic nuclei can be thought of as spinning around an axis and are therefore said to have a nuclear spin. One of those nuclei is hydrogen, written as \(^1\text{H}\) (the hydrogen isotope of mass 1) to differentiate it from other isotopes [deuterium (\(^2\text{H}\)), tritium (\(^3\text{H}\))]. Let us consider the simplest form of hydrogen, the proton. Because the proton is positively charged, its spinning motion creates a magnetic field (as does any moving charged particle). The net result is that a proton may be viewed as a tiny cylindrical (bar) magnet floating freely in solution or in space (see margin). When the proton is exposed to an external magnetic field of strength \(H_0\), it may have one of two orientations: It may be aligned either with \(H_0\), an energetically favorable choice, or (unlike a normal bar magnet) against \(H_0\), an orientation that is higher in energy. The two possibilities are designated the \(\alpha\) and \(\beta\) spin states, respectively (Figure 10-4).

These two energetically different states afford the necessary condition for spectroscopy. Irradiation of the sample at just the right frequency to bridge the difference in energy...
between the \( \alpha \) and \( \beta \) states produces resonance, an absorption of energy, \( \Delta E \), as an \( \alpha \) proton “flips” to the \( \beta \) spin state. This phenomenon is illustrated for a pair of protons in Figure 10-5. After excitation, the nuclei relax and return to their original states by a variety of pathways (which will not be discussed here). At resonance, therefore, there is continuous excitation and relaxation.

As you might expect, increasing the magnetic field strength \( H_0 \) makes the \( \alpha \to \beta \) spin flip more difficult. Indeed, the difference in energy \( \Delta E \) between the two spin states is directly proportional to \( H_0 \). Consequently, since \( \Delta E = h\nu \), the resonance frequency is also proportional to the magnetic field strength. You can see this relationship in commercial spectrometers, for which the size of the magnet field is given in units of tesla (T)* and the corresponding hydrogen resonance frequency in megahertz (MHz).

* Nikola Tesla (1856–1943), American inventor (of Serbian origin), physicist, and mechanical and electrical engineer.
Chapter 10
Using NMR Spectroscopy to Deduce Structure

To give you a feeling for the size of these magnets, the maximum intensity of Earth’s magnetic field anywhere on its surface is about 0.00007 T.

How much energy must be expended for the spin of a proton to flip from $\alpha$ to $\beta$? Because $\Delta E_{\beta \rightarrow \alpha} = \hbar \nu$, we can calculate how much. The amount is very small, that is, $\Delta E_{\beta \rightarrow \alpha}$ at 300 MHz is of the order of $3 \times 10^{-5}$ kcal mol$^{-1}$ ($1.5 \times 10^{-4}$ kJ mol$^{-1}$). Equilibration between the two states is fast, and typically only slightly more than half of all proton nuclei in a magnetic field will adopt the $\alpha$ state, the remainder having a $\beta$ spin. At resonance, this difference is diminished, as $\alpha$ spins flip to $\beta$ spins, but the nearly equal proportionality is not perturbed much.

Many nuclei undergo magnetic resonance

Hydrogen is not the only nucleus capable of magnetic resonance. Table 10-1 lists a number of nuclei that are responsive to NMR and are of importance in organic chemistry, as well as several that lack NMR activity. In general, nuclei composed of an odd number of protons, such as $^1$H (and its isotopes), $^{14}$N, $^{19}$F, and $^{31}$P, or an odd number of neutrons, such as $^{13}$C, exhibit magnetic behavior. On the other hand, when both the proton and the neutron counts are even, as in $^{12}$C or $^{16}$O, the nuclei are nonmagnetic.

Upon exposure to equal magnetic fields, different NMR-active nuclei will resonate at different values of $\nu$. For example, if we were to scan a hypothetical spectrum of a sample of chlorofluoromethane, CH$_2$ClF, in a 7.05-T magnet, we would observe six absorptions corresponding to the six NMR-active nuclei in the sample: the highly abundant $^1$H, $^{19}$F, $^{35}$Cl, and $^{37}$Cl, and the much less plentiful $^{13}$C (1.11%) and $^2$H (0.015%), as shown in Figure 10-6.

High-resolution NMR spectroscopy can differentiate nuclei of the same element

Consider now the NMR spectrum of chloro(methoxy)methane (chloromethyl methyl ether), CICH$_2$OCH$_3$. A sweep at 7.05 T from 0 to 300 MHz would give one peak for each element present (Figure 10-7A). Just as a microscope allows you to magnify a detail of the macroscopic world, we can “peek” into any of these signals and expand them to reveal much

Abbreviations: D, deuterium; T, tritium.
Figure 10-6 A hypothetical NMR spectrum of CH₂ClF at 7.05 T. Because each NMR-active nucleus resonates at a characteristic frequency, six lines are observed. We show them here with similar heights for simplicity, even though the natural abundance of the isotopes ²H and ¹³C is much less than that of the others. The spectrum, as shown, could not be scanned in a single experiment, because most NMR instruments are tuned to only one nucleus, such as ¹H, for each run.

Chemical Highlight 10-1

Recording an NMR Spectrum

To take an NMR spectrum, the sample to be studied (a few milligrams) is usually dissolved in a solvent (0.3–0.5 mL), preferably one that does not contain any atoms that themselves absorb in the NMR range under investigation. Typical solvents are deuterated, such as trichlorodeuteriomethane (deuteriochloroform), CDCl₃; hexadeuterioacetone, CD₆COCD₆; hexadeuteriobenzene, C₆D₆; and octadeuteriooxacyclopentane (octadeuteriotetrahydrofuran), C₄D₈O. The effect of replacing hydrogen by deuterium is to remove any solvent peaks from the proton spectrum. Note that the resonance frequency of deuterium lies in a completely different spectral region than that of hydrogen (¹H) (Figure 10-6). The solution is transferred into an NMR sample container (a cylindrical glass tube), which is inserted into a superconducting magnet (left photograph). To make sure that all molecules in the sample are rapidly averaged with respect to their position in the magnetic field, the NMR tube is rapidly spun by an air jet inside a radio-frequency coil (see diagram). The sample is irradiated with a pulse of RF across the entire spectral region, the ensuing response is registered by the detector unit, and the decay of the spectral signals with time is Fourier transformed by the computer to give the final spectrum. The right photograph depicts a student at a workstation, analyzing her NMR data.
Figure 10-7 High resolution can reveal additional peaks in an NMR spectrum. (A) At low resolution, the spectrum of ClCH$_2$OCH$_3$ at 7.05 T shows six peaks for the six NMR active isotopes present in the molecule. (B) At high resolution, the hydrogen spectrum shows two peaks for the two sets of hydrogens (one shown in blue in the structure, the other in red). Note that the high-resolution sweep covers only 0.001% of that at low resolution. (C) The high-resolution $^{13}$C spectrum (see Section 10-9) shows peaks for the two different carbon atoms in the molecule.

Figure 10-8 300-MHz
$^1$H NMR spectrum of chloro(methoxy)methane. Because the frequency range of interest starts at 300 MHz, we set this frequency to be 0 Hz at the right-hand side of the recording paper, for simplicity.
**In Summary** Certain nuclei, such as $^1\text{H}$ and $^{13}\text{C}$, can be viewed as tiny atomic magnets that, when exposed to a magnetic field, can align with ($\alpha$) or against the field ($\beta$). These two states are of unequal energy, a condition exploited in nuclear magnetic resonance spectroscopy. At resonance, radio-frequency radiation is absorbed by the nucleus to effect $\alpha$-to-$\beta$ transitions (excitation). Nuclei in the $\beta$ state relax to the $\alpha$ state by giving off energy (in the form of a miniscule amount of heat). The resonance frequency, which is characteristic of the nucleus and its environment, is proportional to the strength of the external magnetic field.

**10-4 Using NMR Spectra to Analyze Molecular Structure: The Proton Chemical Shift**

Why do the two different groups of hydrogens in chloro(methoxy)methane give rise to distinct NMR peaks? How does the molecular structure affect the position of an NMR signal? This section will answer these questions.

The position of an NMR absorption, also called the chemical shift, depends on the electron density around the hydrogen. This density, in turn, is controlled by the structural environment of the observed nucleus. Therefore, the NMR chemical shifts of the hydrogens in a molecule are important clues for determining its molecular structure. At the same time, the structure of a molecule determines how it “functions” in an NMR experiment.

**The position of an NMR signal depends on the electronic environment of the nucleus**

The high-resolution $^1\text{H}$ NMR spectrum of chloro(methoxy)methane depicted in Figure 10-8 reveals that the two kinds of hydrogens give rise to two separate resonance absorptions. What is the origin of this effect? It is the differing electronic environments of the respective hydrogen nuclei. A free proton is essentially unperturbed by electrons. Organic molecules, however, contain covalently bonded hydrogen nuclei, not free protons, and the electrons in these bonds affect nuclear magnetic resonance absorptions.*

Bound hydrogens are surrounded by orbitals whose electron density varies depending on the polarity of the bond, the hybridization of the attached atom, and the presence of electron-donating or -withdrawing groups. When a nucleus surrounded by electrons is exposed to a magnetic field of strength $H_0$, these electrons move in such a way as to generate a small local magnetic field, $h_{local}$, opposing $H_0$. As a consequence, the total field strength near the hydrogen nucleus is reduced, and the nucleus is thus said to be shielded from $H_0$ by its electron cloud (Figure 10-9). The degree of shielding depends on the amount

---

*In discussions of NMR, the terms proton and hydrogen are frequently (albeit incorrectly) interchanged. “Proton NMR” and “protons in molecules” are used even in reference to covalently bound hydrogen.

---

Figure 10-9 The external field, $H_0$, causes movement of the bonding electrons around a hydrogen nucleus. This current, in turn, generates a local magnetic field opposing $H_0$. [You may recognize this as Lenz’s law, named for Russian physicist Heinrich Friedrich Emil Lenz (1804–1865). Note that the direction of electron movement is opposite that of the corresponding electric current, which is defined as flowing from anode (+) to cathode (−)].
of electron density surrounding the nucleus. Adding electrons increases shielding; their removal causes deshielding.

What is the effect of shielding on the relative position of an NMR absorption? As a result of the way in which NMR spectra are displayed, shielding causes a displacement of the absorption peak to the right in the spectrum. Deshielding shifts such a peak to the left (Figure 10-10). Rather than using the terms right and left, chemists are accustomed to terminology that is derived from the old way (pre-FT) in which NMR spectra were recorded. Here, to compensate for shielding, the external field strength $H_0$ is increased to achieve resonance (remember that $H_0$ is proportional to $\nu$), and therefore the peak is said to be at high field, or shifted upfield (to the right). Conversely, deshielding causes signals to appear at low field (to the left).

Because each chemically distinct hydrogen has a unique electronic environment, it gives rise to a characteristic resonance. Moreover, chemically equivalent hydrogens show peaks at the same position. Chemically equivalent hydrogens are those related by symmetry, such as the hydrogens of methyl groups, the methylene hydrogens in butane, or all the hydrogens in cycloalkanes (see, however, Section 10-5).

**$^1$H NMR: Different Types of Hydrogens Give Rise to Different Signals**

We describe in more detail some tests for chemical equivalency in the next section, but for simple molecules such equivalence is obvious. An example is the NMR spectrum of 2,2-dimethyl-1-propanol in Figure 10-11: There are three absorptions—one (most shielded) for the nine equivalent methyl hydrogens of the tertiary butyl group, another for the OH, and a third (most deshielded) for the CH$_2$ hydrogens.

**The chemical shift describes the position of an NMR peak**

How are spectral data reported? As noted earlier, most hydrogen absorptions in 300-MHz $^1$H NMR fall within a range of 3000 Hz. Rather than record the exact frequency of each resonance, we measure it relative to an internal standard, the compound tetramethylsilane, (CH$_3$)$_4$Si. Its 12 equivalent hydrogens are shielded relative to those in most organic molecules, resulting in a resonance line conveniently removed from the usual spectral range. The position of the NMR absorptions of a compound under investigation can then be measured (in hertz) relative to the internal standard. In this way, the signals of, for example,
2,2-dimethyl-1-propanol (Figure 10-11) are reported as being located 266, 541, and 978 Hz downfield from (CH₃)₄Si.

A problem with these numbers, however, is that they vary with the strength of the applied magnetic field. Because field strength and resonance frequency are directly proportional, doubling or tripling the field strength will double or triple the distance (in hertz) of the observed peaks relative to (CH₃)₄Si. To make it easier to compare reported literature spectra, we standardize the measured frequency by dividing the distance to (CH₃)₄Si (in hertz) by the frequency of the spectrometer. This procedure yields a field-independent number, the chemical shift $\delta$.

The Chemical Shift

$\delta = \frac{\text{distance of peak from } (\text{CH}_3)_4\text{Si in hertz}}{\text{spectrometer frequency in megahertz}}$ [ppm]

The chemical shift is reported in units of parts per million (ppm). For (CH₃)₄Si, $\delta$ is defined as 0.00. The NMR spectrum of 2,2-dimethyl-1-propanol in Figure 10-11 would then be reported in the following format: $^1$H NMR (300 MHz, CDCl₃) $\delta = 0.89, 1.80, 3.26$ ppm.

Exercise 10-3

With a 90-MHz NMR instrument, the three signals for 2,2-dimethyl-1-propanol are recorded at 80, 162, and 293 Hz, respectively, downfield from (CH₃)₄Si. Calculate the $\delta$ values and compare them with those obtained at 300 MHz.

Functional groups cause characteristic chemical shifts

The reason that NMR is such a valuable analytical tool is that it can identify certain types of hydrogens in a molecule. Each type has a characteristic chemical shift depending on its...
Structural environment. The hydrogen chemical shifts typical of standard organic structural units are listed in Table 10-2. It is important to be familiar with the chemical shift ranges for the structural types described so far: alkanes, haloalkanes, ethers, alcohols, aldehydes, and ketones. Others will be discussed in more detail in subsequent chapters.

‘R, R’, alkyl groups; Ar, aromatic group (not argon).
Note that the absorptions of the alkane hydrogens occur at relatively high field ($\delta = 0.8 \text{–} 1.7 \text{ ppm}$). A hydrogen close to an electron-withdrawing group or atom (such as a halogen or oxygen) is shifted to relatively lower field: Such substituents deshield their neighbors. Table 10-3 shows how adjacent heteroatoms affect the chemical shifts of a methyl group. The more electronegative the atom, the more deshielded are the methyl hydrogens relative to methane. Several such substituents exert a cumulative effect, as seen in the series of the three chlorinated methanes shown in the margin. The deshielding influence of electron-withdrawing groups diminishes rapidly with distance. This “tapering off” is seen in the electrostatic potential map of 1-bromopropane in the margin. The area around the bromine-bearing carbon is relatively electron deficient (blue). Progressing farther along the propyl chain reveals shading that tends first toward green, then orange-yellow, signifying increasing electron density.

Exercise 10-4

Explain the assignment of the $^1$H NMR signals of chloro(methoxy)methane (see color scheme, Figure 10-8). (Hint: Consider the number of electronegative neighbors to each type of hydrogen.)

Exercise 10-5

Provide the expected $\delta$ values in the $^1$H NMR spectra of the following compounds by consulting Table 10-2.

(a) CH$_3$CH$_2$OCO$_2$CH$_3$  
(b) H$_3$C

(c) H$_3$C

(d) H

As noted in Table 10-2, hydroxy, mercapto, and amino hydrogens absorb over a range of frequencies. In spectra of such samples, the absorption peak of the proton attached to the heteroatom may be relatively broad. This variability of chemical shift is due to hydrogen bonding and proton exchange, and depends on temperature, concentration, and the presence of water (i.e., moisture). In simple terms, these effects alter the electronic environment of the hydrogen nuclei. When such a broad line is observed, it usually indicates the presence of OH, SH, or NH$_2$(NHR) groups (see Figure 10-11).
**In Summary** The various hydrogen atoms present in an organic molecule can be recognized by their characteristic NMR peaks at certain chemical shifts, $\delta$. An electron-poor environment is deshielded and leads to low-field (high-$\delta$) absorptions, whereas an electron-rich environment results in shielded or high-field peaks. The chemical shift $\delta$ is measured in parts per million by dividing the difference in hertz between the measured resonance and that of the internal standard, tetramethylsilane, $(\text{CH}_3)_4\text{Si}$, by the spectrometer frequency in megahertz. The NMR spectra for the OH groups of alcohols, the SH groups of thiols, and the NH$_2$ (NHR) groups of amines exhibit characteristically broad peaks with concentration- and moisture-dependent $\delta$ values.

**10-5 Tests for Chemical Equivalence**

In the NMR spectra presented so far, two or more hydrogens occupying positions that are chemically equivalent give rise to only one NMR absorption. It can be said, in general, that chemically equivalent protons have the same chemical shift. However, we shall see that it is not always easy to identify chemically equivalent nuclei. We shall resort to the symmetry operations presented in Chapter 5 to help us decide on the expected NMR spectrum of a specific compound.

**Molecular symmetry helps establish chemical equivalence**

To establish chemical equivalence, we have to recognize the symmetry of molecules and their substituent groups. As we know, one form of symmetry is the presence of a mirror plane (Section 5-1, Figure 5-4). Another is rotational equivalence. For example, Figure 10-12 demonstrates how two successive $120^\circ$ rotations of a methyl group allow each hydrogen to occupy the position of either of the other two without effecting any structural change. Thus, in a rapidly rotating methyl group, all hydrogens are equivalent and should have the same chemical shift. We shall see shortly that this is indeed the case.

Application of the principles of rotational or mirror symmetry or both allows the assignment of equivalent nuclei in other compounds (Figure 10-13).

![Figure 10-12](image1.png) Rotation of a methyl group as a test of symmetry.

![Figure 10-13](image2.png) The recognition of rotational and mirror symmetry in organic molecules allows the identification of chemical-shift–equivalent hydrogens. The different colors distinguish among nuclei giving rise to separate absorptions with distinct chemical shifts.
Exercise 10-6

Working with the Concepts: How to Establish the Presence of Equivalent Hydrogens

How many $^1$H NMR absorptions would you expect for $\text{CH}_3\text{OCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_3$?

**Strategy**

The best way to approach this kind of problem is to make a model or draw the structure in detail, showing all hydrogens in place.

Then you need to identify any mirror planes or rotational axes that render groups of hydrogens equivalent.

**Solution**

- We can recognize the vertical mirror plane 1, which coincides with the molecular plane and makes all wedged hydrogens equivalent to their hashed neighbors.
- Next, we can see a second mirror plane 2, through the central oxygen lying perpendicular to the molecular plane, which makes the left half of the molecule the same as the right half.
- Finally, the methyl hydrogens are equivalent by rotation.
- There are no symmetry operations that would turn one methylene group into its neighbor, and the methyl groups are obviously distinct.

We would therefore anticipate three proton resonance signals.

Exercise 10-7

Try It Yourself

How many $^1$H NMR absorptions would you expect for (a) 2,2,3,3-tetramethylbutane; (b) oxacyclopropane?

Conformational interconversion may result in equivalence on the NMR time scale

Let us look more closely at two more examples, chloroethane and cyclohexane. Chloroethane should have two NMR peaks because it has the two sets of equivalent hydrogens; cyclohexane has 12 chemically equivalent hydrogen nuclei and is expected to show only one absorption. However, are these expectations really justified? Consider the possible conformations of these two molecules (Figure 10-14).
**Chapter 10**

Using NMR Spectroscopy to Deduce Structure

A Rotation of the methyl group, located in the back

Figure 10-14 (A) Newman projections of chloroethane. In the initial conformation, H\(_{b1}\) and H\(_{b2}\) are located gauche and H\(_{b3}\) anti to the chlorine, and therefore are not in the same environments. However, fast rotation moves each type of H through all positions, thus averaging all the methyl hydrogens on the NMR time scale. (B) In any given conformation of cyclohexane, the axial hydrogens are different from the equatorial ones. However, conformational flip is rapid on the NMR time scale, equilibrating axial and equatorial hydrogens, so only one average signal is observed. Colors are used here to distinguish among environments and thus to indicate distinct chemical shifts.

Begin with chloroethane. The most stable conformation is the staggered arrangement, in which one of the methyl hydrogens (H\(_{b3}\) in the first Newman projection in Figure 10-14) is located anti with respect to the chlorine atom. We expect this particular nucleus to have a chemical shift different from the two gauche hydrogens (H\(_{b1}\) and H\(_{b2}\)). In fact, however, the NMR spectrometer cannot resolve that difference, because the fast rotation of the methyl group averages the signals for H\(_{b}\). This rotation is said to be “fast on the NMR time scale.” The resulting absorption appears at an average \(\delta\) of the two signals expected for H\(_{b}\).

In theory, it should be possible to slow the rotation in chloroethane by cooling the sample. In practice, “freezing” the rotation is very difficult to do, because the activation barrier to rotation is only a few kilocalories per mole. We would have to cool the sample to about \(-180^\circ\text{C}\), at which point most solvents would solidify—and ordinary NMR spectroscopy would not be possible.

A similar situation is encountered for cyclohexane. Here, fast conformational isomerism causes the axial hydrogens to be in equilibrium with the equatorial ones on the NMR time scale (Figure 10-14B); so, at room temperature, the NMR spectrum shows only one sharp line at \(\delta = 1.36\) ppm. However, in contrast with that for chloroethane, the process is slow enough at \(-90^\circ\text{C}\) that, instead of a single absorption, two are observed: one for the six axial hydrogens at \(\delta = 1.12\) ppm, the other for the six equatorial hydrogens at \(\delta = 1.60\) ppm. The conformational isomerization in cyclohexane is frozen on the NMR time scale at this temperature because the activation barrier to ring flip is much higher \([E_a = 10.8\ \text{kcal mol}^{-1} (45.2\ \text{kJ mol}^{-1})]\); Section 4-3).

In general, the lifetime of a molecule in an equilibrium must be of the order of about a second to allow its resolution by NMR. If the molecule is substantially shorter lived, an average spectrum is obtained. Organic chemists use such temperature-dependent NMR spectra to measure the rates of chemical processes and thus their activation parameters (Section 2-1). As a simple analogy, you can relate the phenomenon of NMR time scale to that of vision. If you consider your eyes a “spectrometer,” you can “resolve” events only if they occur below a certain speed. Try moving one hand back and forth in front of you. At a rate of once per second, your view is sharp. Now try it at five times per second: Your hand will appear as an averaged blur.

**Exercise 10-8**

How many signals would you expect in the \(^1\text{H} \) NMR spectrum of bromocyclohexane? (Caution: Even considering fast ring flip, do the hydrogens located cis to the bromine ever become equivalent to those located trans? Build a model!)
**Exercise 10-9**

**Working with the Concepts: \(^1\)H NMR Spectra of Two Stereoisomers**

How many signals would you expect in the \(^1\)H NMR spectra of cis- and trans-1,2-dichlorocyclobutane?

**Strategy**
As always with stereochemical problems, it is useful to build models. Draw both molecules and their stereochemistry using the hashed-wedged line notation. Then search for symmetry elements: mirror planes and rotational axes.

**Solution**
- Looking at the cis isomer, you will recognize that the molecule contains a mirror plane, bisecting the bonds C1–C2 and C3–C4, the left half (as we look at it in the first structure below) being mirrored by the right half, making it a meso stereoisomer (Section 5-6). This renders the corresponding pairs of hydrogens equivalent (as indicated in color). Note that the green hydrogens, located cis to the chlorine substituents, cannot be equivalent to the blue ones, which are located trans (see also Exercise 10-8). Therefore, we would expect three signals in the \(^1\)H NMR spectrum of this isomer.

- Turning to the trans isomer, there is no mirror plane, making the molecule chiral (Section 5-6), but there is an axis of rotation. This symmetry property divides the molecule again into three pairs of equivalent hydrogens (indicated in color), but now apportioned differently at C3 and C4: Unlike the cis isomer, the like-colored hydrogens have a trans relationship. The green hydrogens are unique, because they are positioned cis to the nearest-neighbor chlorine atom, trans to the remote one. In contrast, the blue hydrogens are located trans to the nearest chlorine and cis to the other. Thus, this compound, too, will give rise to three signals, but, because it is stereoisomeric to the cis isomer, with differing chemical shifts. On the other hand, its mirror image will be identical in its NMR spectral properties (Section 5-2).

**Exercise 10-10**

**Try It Yourself**
Revisit Section 5-5: How many signals would you expect in the \(^1\)H NMR spectra of the two diastereomers of 2-bromo-3-chlorobutane? (**Caution:** Is there any symmetry in these molecules?)
After NMR spectroscopy was introduced to organic chemistry in the late 1960s, it did not take long for physicists and chemists to ask whether the technique could be used in medical diagnosis. In particular, if a spectrum is viewed as a sort of image of a molecule, why not image sections of the human (or animal) body? The answer emerged between the early 1970s and mid-1980s and relied not on the usual information embedded in chemical shifts, integration, and spin–spin splitting, but on a different phenomenon: proton relaxation times. Thus, the rate at which a hydrogen that has been induced to undergo the $\alpha \rightarrow \beta$ spin flip “relaxes” back to the $\alpha$ state is not constant but depends on the environment. Relaxation times can range from milliseconds to seconds and affect the line shapes of the corresponding signal. In the body, the hydrogens of water attached to the surface of biological molecules have been found to relax faster than those in the free fluid. In addition, there are slight differences depending on the nature of the tissue or structure to which the water is bound. For example, water in some cancerous tumors has a shorter relaxation time than that in healthy cells. These differences can be used to image the inside of the human body by magnetic resonance imaging, or MRI. In this application, a patient’s entire body is placed within the poles of a large electromagnet, and proton NMR spectra are collected and computer processed to give a series of cross-sectional plots of signal intensity. These cross-sectional plots are combined to produce a three-dimensional image of tissue proton density, as shown in the photo on the left.

Because most of the signal is due to water, variations from normal water-density patterns may be detected and used in diagnosis. Improvements during the last decade have shortened the time needed for analysis from minutes to seconds or less, permitting direct viewing of essentially every part of the body and monitoring changes in their environment instantaneously. Blood flow, kidney secretion, chemical imbalance, vascular condition, pancreatic abnormalities, cardiac function, and many other conditions of medical importance are now readily made visible. The Nobel prize in medicine was awarded in 2003 for the discovery of the use of MRI.* MRI is particularly helpful in detecting abnormalities that are not readily found by CAT (computerized axial tomography†) scans and conventional X-rays. Unlike other imaging methods, the technique is noninvasive, requiring neither ionizing radiation nor the injection of radioactive substances for visualization.

*Professor Paul C. Lauterbur (b. 1929), University of Illinois at Urbana-Champaign, Illinois; Professor Sir Peter Mansfield (b. 1933), University of Nottingham, UK.

†Tomography is a method for taking pictures of a specific plane of an object.
In Summary  The properties of symmetry, particularly mirror images and rotations, help to establish the chemical-shift equivalence or nonequivalence of the hydrogens in organic molecules. Those structures that undergo rapid conformational changes on the NMR time scale show only averaged spectra at room temperature. In some cases, these processes may be “frozen” at low temperatures to allow distinct absorptions to be observed.

10-6 Integration

So far we have looked only at the position of NMR peaks. We shall see in this section that another useful feature of NMR spectroscopy is its ability to measure the relative integrated intensity of a signal, which is proportional to the relative number of nuclei giving rise to that absorption.

Integration reveals the relative number of hydrogens responsible for an NMR peak

The more hydrogens of one kind there are in a molecule, the more intense is the corresponding NMR absorption relative to the other signals. By measuring the area under a peak (the “integrated area”) and comparing it with the corresponding peak areas of other signals, we can estimate the nuclear ratios quantitatively. For example, in the spectrum of 2,2-dimethyl-1-propanol (Figure 10-15A), three signals are observed, with relative areas of 9:2:1.

These numbers are obtained by computer and can be plotted on top of the regular spectrum by choosing the integration mode. In this mode, at the onset of an absorption peak, the recorder pen moves vertically upward a distance proportional to the area under the peak. It then again moves horizontally until the next peak is reached, and so forth. A ruler can be used to measure the distance by which the horizontal line is displaced at every peak. The relative sizes of these displacements furnish the ratio of hydrogens giving rise to the various signals. Figure 10-15 depicts the $^1$H NMR spectra of 2,2-dimethyl-1-propanol and 1,2-dimethoxyethane, including plots of the integration.

Such integrated plots are useful when the spectrum is unusually complex, either because the molecule has many types of hydrogens or because the sample is impure or a mixture, and visual inspection becomes advantageous. Normally, the computer provides digital readouts of integrated peak intensity automatically. Therefore, in subsequent spectra, these values will be given above the corresponding signals in numerical form.

Chemical shifts and peak integration can be used to determine structure

Consider the three products obtained in the monochlorination of 1-chloropropane, CH$_3$CH$_2$CH$_2$Cl. All have the same molecular formula C$_3$H$_6$Cl$_2$ and very similar physical properties (such as boiling points).

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} \xrightarrow{\text{Cl}_2, \text{hv}, 100^\circ\text{C}} \text{CH}_3\text{CH}_2\text{CHCl}_2 + \text{CH}_3\text{CHClCH}_2\text{Cl} + \text{Cl}\text{CH}_2\text{CH}_2\text{Cl} \\
10\% \quad \text{1,1-Dichloropropane (b.p. 87^\circ\text{C})} \quad 27\% \quad \text{1,2-Dichloropropane (b.p. 96^\circ\text{C})} \quad 14\% \quad \text{1,3-Dichloropropane (b.p. 120^\circ\text{C})}
\]

Ratio: 3 : 2 : 1

CH$_3$CH$_2$CHCl$_2$

Three signals

Strongly deshielded

CH$_3$CHClCH$_2$Cl

Three signals

Moderately deshielded

ClCH$_2$CH$_2$Cl

Two signals

Moderately deshielded
NMR spectroscopy clearly distinguishes all three isomers. 1,1-Dichloropropane contains three types of nonequivalent hydrogens, a situation giving rise to three NMR signals in the ratio of 3:2:1. The single hydrogen absorbs at relatively low field ($\delta = 5.93$ ppm) because of the cumulative deshielding effect of the two halogen atoms; the others absorb at relatively high field ($\delta = 1.01$ and 2.34 ppm).

1,2-Dichloropropane also shows three sets of signals associated with CH$_3$, CH$_2$, and CH groups (see also Chemical Highlight 10-3). In contrast, however, their chemical shifts are quite different: Each of the last two groups now bears a halogen atom and gives rise to a low-field signal as a result ($\delta = 3.68$ ppm for the CH$_2$, and $\delta = 4.17$ ppm for the CH).
Only one signal, shown by integration to represent three hydrogens and therefore the CH$_3$ group, is at relatively high field ($\delta = 1.70$ ppm).

Finally, 1,3-dichloropropane shows only two peaks ($\delta = 3.71$ and 2.25 ppm) in a relative ratio of 2:1, a pattern clearly distinct from those of the other two isomers. By this means, the structures of the three products are readily assigned by a simple measurement.

**Exercise 10-11**

Chlorination of chlorocyclopropane gives three compounds of molecular formula C$_3$H$_4$Cl$_2$. Draw their structures and describe how you would differentiate them by $^1$H NMR. (Hint: Look for symmetry. Use the deshielding effect of chlorine and integration.)

**In Summary**

The NMR spectrometer in the integration mode records the relative areas under the various peaks, values that represent the relative numbers of hydrogens giving rise to these absorptions. This information, in conjunction with chemical shift data, can be used for structure elucidation—for example, in the identification of isomeric compounds.

**10-7 Spin–Spin Splitting: The Effect of Nonequivalent Neighboring Hydrogens**

The high-resolution NMR spectra presented so far have rather simple line patterns—single sharp peaks, also called singlets. The compounds giving rise to these spectra have one feature in common: In each compound, nonequivalent hydrogens are separated by at least one carbon or oxygen atom. These examples were chosen for good reason, because neighboring hydrogen nuclei can complicate the spectrum as the result of a phenomenon called spin–spin splitting or spin–spin coupling.

Figure 10-16 shows that the NMR spectrum of 1,1-dichloro-2,2-diethoxyethane has four absorptions, characteristic of four sets of hydrogens (H$_a$–H$_d$). Instead of single peaks, they adopt more complex patterns called multiplets: two two-peak absorptions, or doublets.
(blue and green); one of four peaks, a **quartet** (black); and one of three peaks, a **triplet** (red). The detailed appearance of these multiplets depends on the number and kind of hydrogen atoms directly adjacent to the nuclei giving rise to the absorption.

In conjunction with chemical shifts and integration, spin–spin splitting frequently helps us arrive at a complete structure for an unknown compound. How can we interpret this information?

**One neighbor splits the signal of a resonating nucleus into a doublet**

Let us first consider the two doublets of relative integration 1, assigned to the two single hydrogens H_a and H_b. The splitting of these peaks is explained by the behavior of nuclei in an external magnetic field: They are like tiny magnets aligned with (\(\alpha\)) or against (\(\beta\)) the field. The energy difference between the two states is minuscule (see Section 10-3), and at room temperature their populations are nearly equal. In the case under consideration, this means that there are two magnetic types of H_a—approximately half next to an H_b in the \(\alpha\) state, the other half with a neighboring H_b in its \(\beta\) state. Conversely, H_b has two types of neighboring H_a—half of them in the \(\alpha\), half in the \(\beta\) state. H_a and H_b recognize that they are magnetic neighbors by communicating through the three bonds between them. What are the consequences of this phenomenon in the NMR spectrum?

A proton of type H_a that has as its neighbor an H_b aligned *with* the field is exposed to a total magnetic field that is strengthened by the addition of that due to the \(\alpha\) spin of H_b. To achieve resonance for this type of H_a, a smaller external field strength is required than that necessary for H_a in the absence of a perturbing neighbor. A peak at lower field than that expected is observed (Figure 10-17A). However, this absorption is due to only half the H_a protons. The other half have H_b in its \(\beta\) state as a neighbor. Because H_b in its \(\beta\) state is aligned *against* the external field, the strength of the local field around H_a in this case is **diminished**. To achieve resonance, the external field \(H_0\) has to be

![Diagram of NMR splitting](image-url)

**Figure 10-17** The effect of a hydrogen nucleus on the chemical shift of its neighbor is an example of spin–spin splitting. Two peaks are generated, because the hydrogen under observation has two types of neighbors. (A) When the neighboring nucleus H_b is in its \(\alpha\) state, it adds a local field, \(h_{local}\), to \(H_0\), thereby resulting in a downfield shift of the H_a peak. (B) When the neighboring nucleus is in its \(\beta\) state, its local field opposes the external one, and as a result the H_a peak is shifted to higher field. (C) The observed peak pattern is a doublet.
increased; an upfield shift is observed (Figure 10-17B). The resulting spectrum is a doublet (Figure 10-17C).

Because the local contribution of \( H_b \) to \( H_a \), whether positive or negative, is of the same magnitude, the downfield shift of the hypothetical signal equals the upfield shift. The single absorption expected for a neighbor-free \( H_a \) is said to be split by \( H_b \) into a doublet. Integration of each peak of this doublet shows a 50% contribution of each hydrogen. The chemical shift of \( H_a \) is reported as the center of the doublet (Figure 10-18).

The signal for \( H_b \) is subject to similar considerations. This hydrogen also has two types of hydrogens as neighbors — \( H_a \) (a) and \( H_a \) (b). Consequently its absorption lines appear in the form of a doublet. So, in NMR jargon, \( H_b \) is split by \( H_a \). The amount of this mutual splitting is equal; that is, the distance (in hertz) between the individual peaks making up each doublet is identical. This distance is termed the coupling constant, \( J \). In our example, \( J_{ab} = 7 \text{ Hz} \) (Figure 10-18). Because the coupling constant is related only to magnetic field contributions by neighboring nuclei communicating through intervening bonds, it is independent of the external field strength. Coupling constants remain unchanged regardless of the field strength of the NMR instrument being used.

Spin–spin splitting is generally observed only between hydrogens that are immediate neighbors, bound either to the same carbon atom [geminal coupling (geminus, Latin, twin)] or to two adjacent carbons [vicinal coupling (vicinus, Latin, neighboring)]. Hydrogen nuclei separated by more than two carbon atoms are usually too far apart to exhibit appreciable coupling. Moreover, equivalent nuclei do not exhibit mutual spin–spin splitting. For example, the NMR spectrum of ethane, \( \text{CH}_3\text{–CH}_3 \), consists of a single line at \( \delta = 0.85 \text{ ppm} \), similar to that of cyclohexane, \( \text{C}_6\text{H}_{12} \), which exhibits a singlet at \( \delta = 1.36 \text{ ppm} \) (at room temperature; see Section 10-5). Another example is 1,2-dimethoxyethane (Figure 10-15B), which gives rise to two singlets in NMR—one for the methyl groups and one for the chemical-shift–equivalent central methylene hydrogens. Splitting is observed only between nuclei with different chemical shifts.

**Local-field contributions from more than one hydrogen are additive**

How do we handle nuclei with two or more neighboring hydrogens? It turns out that we must consider the effect of each neighbor separately. Let us return to the spectrum of 1,1-dichloro-2,2-diethoxyethane shown in Figure 10-16. In addition to the two doublets assignable to \( H_a \) and \( H_b \), this spectrum exhibits a triplet due to the methyl protons \( H_d \) and a quartet assignable to the methylene hydrogens \( H_c \). Because these two nonequivalent sets of nuclei are next to each other, vicinal coupling is observed as expected. However, compared with the peak patterns for \( H_a \) and \( H_b \), those for \( H_c \) and \( H_d \) are considerably more complicated. They can be understood by expanding on the explanation used for the mutual coupling of \( H_a \) and \( H_b \).
Consider first the triplet whose chemical shift and integrated value allow it to be assigned to the hydrogens $H_d$ of the two methyl groups. Instead of one peak, we observe three, in the approximate ratio $1:2:1$. The splittings must be due to coupling to the adjacent methylene groups—but how?

The three equivalent methyl hydrogens in each ethoxy group have two equivalent methylene hydrogens as their neighbors, and each of these methylene hydrogens may adopt the $\alpha$ or $\beta$ spin orientation. Thus, each $H_d$ may “see” its two $H_c$ neighbors as an $\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, or $\beta\beta$ combination (Figure 10-19). Those methyl hydrogens that are adjacent to the first possibility, $H_{c(\alpha\alpha)}$, are exposed to a twice-strengthened local field and give rise to a lower-field absorption. In the $\alpha\beta$ or $\beta\alpha$ combination, one of the $H_c$ nuclei is aligned with the external field and the other is opposed to it. The net result is no net local-field contribution at $H_d$. In these cases, a spectral peak should appear at a chemical shift identical with the one expected if there were no coupling between $H_c$ and $H_d$. Moreover, because two equivalent combinations of neighboring $H_c$s ($H_{c(\alpha\alpha)}$ and $H_{c(\beta\alpha)}$) contribute to this signal (instead of only one, as did $H_{c(\alpha\beta)}$ to the first peak), its approximate height should be double that of the first peak, as observed. Finally, $H_d$ may have the $H_{c(\beta\beta)}$ combination as its neighbor. In this case, the local field subtracts from the external field and an upfield peak of relative intensity 1 is produced. The resulting pattern for $H_d$ is a $1:2:1$ triplet with a total integration corresponding to six hydrogens (because there are two methyl groups). The coupling constant $J_{cd}$, measured as the distance between each pair of adjacent peaks, is 8 Hz.

The quartet observed in Figure 10-16 for $H_c$ can be analyzed in the same manner (Figure 10-20). This nucleus is exposed to four different types of $H_d$ proton combinations as neighbors: one in which all protons are aligned with the field ($H_{d(\alpha\alpha\alpha\alpha)}$); three equivalent arrangements in which one $H_d$ is opposed to the external field and the other two are aligned with it ($H_{d(\beta\alpha\alpha\alpha)}$, $H_{d(\alpha\beta\alpha\alpha)}$, and $H_{d(\beta\beta\alpha\alpha)}$); another set of three equivalent arrangements in which only one proton remains aligned with the field ($H_{d(\beta\beta\beta\alpha)}$); and a final possibility in which all $H_d$s oppose the external magnetic field ($H_{d(\beta\beta\beta\beta)}$). The resulting spectrum is predicted—and observed—to consist of a $1:3:3:1$ quartet (integrated intensity 4). The coupling constant $J_{cd}$ is identical with that measured in the triplet for $H_d$ (8 Hz).

**In many cases, spin–spin splitting is given by the N + 1 rule**

We can summarize our analysis so far by a set of simple rules:

1. Equivalent nuclei located adjacent to one neighboring hydrogen resonate as a *doublet*.
2. Equivalent nuclei located adjacent to two hydrogens of a second set of equivalent nuclei resonate as a *triplet*.
3. Equivalent nuclei located adjacent to a set of three equivalent hydrogens resonate as a *quartet*.

Table 10-4 shows the expected splitting patterns for nuclei adjacent to N equivalent neighbors. The NMR signals of these nuclei *split into N + 1 peaks*, a result known as the *N + 1 rule*. Their relative ratio is given by a mathematical mnemonic device called Pascal’s* triangle. Each number in this triangle is the sum of the two numbers closest to it in the line above. The splitting patterns of two common alkyl groups, ethyl and 1-methylethyl (isopropyl), are shown in Figures 10-21 and 10-22, respectively. In both spectra, the relative

*Blaise Pascal (1623–1662), French mathematician, physicist, and religious philosopher.
intensities of the individual peaks of the respective multiplets conform (roughly) to those predicted by Pascal’s triangle. As a result, the outermost lines of the septet for the central hydrogen in 2-iodopropane (Figure 10-22) are barely visible and readily missed. This problem is general for hydrogen signals split by couplings to multiple neighbors, and you need to be careful in their interpretation. The task is aided by integration of the multiplets, which reveals the relative number of associated hydrogens.

It is important to remember that nonequivalent nuclei mutually split one another. In other words, the observation of one split absorption necessitates the presence of another split signal in the spectrum. Moreover, the coupling constants for these patterns must be the same. Some frequently encountered multiplets and the corresponding structural units are shown in Table 10-5.

**Exercise 10-12**

Predict the NMR spectra of (a) ethoxyethane (diethyl ether); (b) 1,3-dibromopropane; (c) 2-methyl-2-butanol; (d) 1,1,2-trichloroethane. Specify approximate chemical shifts, relative abundance (integration), and multiplicities.

**Exercise 10-13**

**Working with the Concepts: Using Chemical Shift, Integration, and Spin–Spin Splitting in Structure Elucidation**

There are several isomeric alcohols and ethers of molecular formula C₅H₁₂O (see, for example, 2,2-dimethyl-1-propanol; Figures 10-11 and 10-15; and Problem 47). Two of these, A and B, exhibit the following ¹H NMR spectra.

A: $\delta = 1.19$ (s, 9 H), 3.21 (s, 3 H) ppm
B: $\delta = 1.20$ (t, 3 H), 1.60 (sextet, 2 H), 3.37 (t, 2 H), 3.47 (q, 2 H) ppm

Deduce the structures of both isomers.

### Strategy
You may be tempted to solve this problem by drawing all isomers of C₅H₁₂O and then trying to match each structure with the given data. This approach is safe but very time consuming. Instead, it is better to extract as much information as possible from the spectra before formulating trial structures. In particular, often we can immediately associate certain patterns with certain pieces (substructures) of the molecule. Once these substructures are identified, we can subtract them from the molecular formula, leaving smaller fragments for consideration.

### Solution
Let us start with A.

- The presence of two singlets is an indication of extensive symmetry (Section 10-5).
- The absence of a peak integrating for 1 H excludes the presence of an OH function; hence, the molecule is an ether.
- A singlet integrating for 3 H is a strong indication of the presence of a CH₃ substituent. The singlet’s chemical shift suggests that it is attached to the ether oxygen (Table 10-2).
- Subtracting CH₃O from C₅H₁₂O leaves C₄H₉, which must be the source of the other singlet at higher field, in the alkane region (Table 10-2).
In Summary

Spin–spin splitting occurs between vicinal and geminal nonequivalent hydrogens. Usually, $N$ equivalent neighbors will split the absorption of the observed hydrogen into $N + 1$ peaks, their relative intensities being in accord with Pascal’s triangle. The common alkyl groups give rise to characteristic NMR patterns.

10-8 Spin–Spin Splitting: Some Complications

The rules governing the appearance of split peaks outlined in Section 10-7 are somewhat idealized. Thus, when there is a relatively small difference in $\delta$ between two absorptions, more complicated patterns (complex multiplets) are observed that are not interpretable.
without the use of computers. Moreover, the $N + 1$ rule may not be applicable in a direct way if two or more types of neighboring hydrogens are coupled to the resonating nucleus with fairly different coupling constants. Finally, the hydroxy proton may appear as a singlet (see Figure 10-11) even if vicinal hydrogens are present. Let us look in turn at each of these complications.

**Close-lying peak patterns may give rise to non-first-order spectra**

A careful look at the spectra shown in Figures 10-16, 10-21, and 10-22 reveals that the relative intensities of the splitting patterns do not conform to the idealized peak ratios expected from consideration of Pascal's triangle: The patterns are not completely symmetric, but skewed. Specifically, the two multiplets of two mutually coupled hydrogens are skewed toward each other such that the intensity of the lines facing each other is slightly larger than expected. The exact intensity ratios dictated by Pascal's triangle and the $N + 1$ rule are observed only when the difference between the resonance frequencies of coupled protons is much larger than their coupling constant: $\Delta \nu \gg J$. Under these circumstances, the spectrum is said to be **first order**. However, when these differences become smaller, the expected peak pattern is subject to increasing distortion.

In extreme cases, the simple rules devised in Section 10-7 do not apply any more, the resonance absorptions assume more complex shapes, and the spectra are said to be **non-first order**. Although such spectra can be simulated with the help of computers, this treatment is beyond the scope of the present discussion.

Particularly striking examples of non-first-order spectra are those of compounds that contain alkyl chains. Figure 10-23 shows an NMR spectrum of octane, which is not first order because all nonequivalent hydrogens (there are four types) have very similar chemical shifts. All the methylenes absorb as one broad multiplet. In addition, there is a highly distorted triplet for the terminal methyl groups.

Non-first-order spectra arise when $\Delta \nu = J$, so it should be possible to "improve" the appearance of a multiplet by measuring a spectrum at higher field, because the resonance frequency is proportional to the external field strength, whereas the coupling constant $J$ is

---

*This expression derives from the term **first-order theory**, that is, one that takes into account only the most important variables and terms of a system.*
independent of field (Section 10-7). Thus, at increasingly higher field, the individual multiplets become more and more separated (resolved), and the non-first-order effect of a close-lying absorption gradually disappears. The effect is similar to that of a magnifying glass in the observation of ordinary objects. The eye has a relatively low resolving power and cannot discern the fine structure of a sample that becomes evident only on appropriate magnification.

Greater field strength has a dramatic effect on the spectrum of 2-chloro-1-(2-chloroethoxy)ethane (Figure 10-24). In this compound, the deshielding effect of the oxygen is about equal to that of the chlorine substituent. As a consequence, the two sets of methylene hydrogens give rise to very close-lying peak patterns. At 90 MHz, the resulting absorption has a symmetric shape but is very complicated, exhibiting more than 32 peaks of various intensities. However, recording the NMR spectrum with a 500-MHz spectrometer (Figure 10-24B) produces a first-order pattern.
Chapter 10

10-8 Spin–Spin Splitting: Some Complications

Coupling to nonequivalent neighbors may modify the simple $N + 1$ rule

When hydrogens are coupled to two sets of nonequivalent neighbors, complicated splitting patterns may result. The spectrum of 1,1,2-trichloropropane illustrates this point (Figure 10-25). In this compound, the hydrogen at C2 is located between a methyl and a CHCl₂ group, and it is coupled to the hydrogens of each group independently and with different coupling constants.

Let us analyze the spectrum in detail. We first notice two doublets, one at low field ($\delta = 5.86$ ppm, $J = 3.6$ Hz, 1 H) and one at high field ($\delta = 1.69$ ppm, $J = 6.8$ Hz, 3 H). The low-field absorption is assignable to the hydrogen at C1 ($H_a$), adjacent to two deshielding halogens; and the methyl hydrogens ($H_c$) resonate as expected at highest field. In accord with the $N + 1$ rule, each signal is split into a doublet because of coupling with the hydrogen at C2 ($H_b$). The resonance of $H_b$ at $\delta = 4.35$ ppm consists of eight lines, with relative intensities that do not conform to those expected for ordinary splitting patterns (see Tables 10-4 and 10-5). What is the cause of this complexity?

The $N + 1$ rule strictly applies only to splitting by equivalent neighbors. In this molecule, we have two sets of different adjacent nuclei that couple to $H_b$ with different coupling constants. The effect of these couplings can be understood, however, if we apply the $N + 1$ rule sequentially. The methyl group causes a splitting of the $H_b$ resonance into a quartet, with the relatively larger $J_{bc} = 6.8$ Hz. Then, coupling with $H_a$ further splits each peak in this quartet into a doublet, with the smaller $J_{ab} = 3.6$ Hz, both splits resulting in the observed eight-line pattern (Figure 10-26). The hydrogen at C2 is said to be split into a quartet of doublets.

The hydrogens on C2 of 1-bromopropane also couple to two nonequivalent sets of neighbors. In this case, however, the resulting splitting pattern appears to conform with the $N + 1$ rule, and a (slightly distorted) sextet is observed (Figure 10-27). The reason is that the coupling constants to the two different groups are very similar, about 6–7 Hz. Although
### CHEMICAL HIGHLIGHT 10-3

#### The Nonequivalence of Diastereotopic Hydrogens

You have probably assumed that all methylene (CH₂) groups contain equivalent hydrogens, which give rise to only one signal in the NMR spectrum. Such is indeed the case when there is a symmetry element present that renders them equivalent, such as a mirror plane or axis of rotation. For example, the methylene hydrogens in butane or cyclohexane have this property. However, this symmetry is readily removed by substitution (Chapters 3 and 5), a change that has profound effects not only with respect to stereoisomerism (Chapter 5), but also to NMR spectroscopy.

Consider, for example, turning cyclohexane into bromocyclohexane, such as by radical bromination. Not only does this alteration make C1, C2, C3, and C4 different, but also all of the hydrogens cis to the bromine substituent have become different from those trans. In other words, the CH₂ groups exhibit nonequivalent geminal hydrogens. These hydrogens have separate chemical shifts and show mutual geminal (as well as vicinal) coupling. The resulting 300-MHz spectrum is quite complex, as shown on the right. Only the C1 hydrogen at $\delta = 4.17$ ppm, deshielded by the neighboring bromine, is readily assigned.

Methylene hydrogens that are not equivalent are called **diastereotopic**. This word is based on the stereochemical outcome of replacing either of these hydrogens by a substituent: diastereomers. For example, in the case of bromocyclohexane, substituting the wedged (red) hydrogen at C2 results in a cis product. The same alteration involving the hashed (blue) hydrogen generates the trans isomer. You can verify the same outcome of this procedure when applied to C3 and C4, respectively.

**Figure 10-27** 300-MHz $^1$H NMR spectrum of 1-bromopropane.
You might think that it is the rigidity of the cyclic frame that imparts this property to diastereotopic hydrogens. However, this is not true, as you can realize by reviewing Section 5-5. The chlorination of 2-bromobutane at C3 resulted in two diastereomers; therefore, the methylene group in 2-bromobutane also contains diastereotopic protons. We can recognize and generalize the origin of this effect: The presence of the stereocenter precludes a mirror plane through the CH$_2$ carbon, and rotation is ineffective in making the two hydrogens equivalent. To illustrate the presence of diastereotopic hydrogens in such chiral, acyclic molecules, we return to one of the three monochlorination products of 1-chloropropane, discussed in Section 10-6, namely, 1,2-dichloropropane. The 300-MHz $^1$H NMR spectrum shown reveals four signals (instead of the normally expected three), two of which are due to the diastereotopic hydrogens at C1. Specifically, these hydrogens appear as doublets of doublets at $\delta =$ 3.58 and 3.76 ppm, because they coupled to each other with $J_{\text{geminal}} =$ 10.8 Hz, and then with individual coupling constants to the hydrogen at C2 ($J_{\text{vicinal}} = 4.7$ and 9.1 Hz, respectively).

Frequently, diastereotopic hydrogens have such close chemical shifts that their nonequivalence is not visible in an NMR spectrum. For example, in the chiral 2-bromohexane, all three methylene groups contain diastereotopic hydrogens. In this compound, only the two methylenes closest to the stereocenter reveal their presence. The third one is too far removed for the asymmetry of the stereocenter to have a measurable effect.

an analysis similar to that given earlier for 1,1,2-trichloropropane would lead us to predict as many as 12 lines in this signal (a quartet of triplets), the nearly equal coupling constants cause many of the lines to overlap, thus simplifying the pattern (Figure 10-28). The hydrogens in many simple alkyl derivatives display similar coupling constants and, therefore, spectra that are in accord with the $N + 1$ rule.

![Figure 10-28 Splitting pattern expected for H$_b$ in a propyl derivative when $J_{ab} \approx J_{bc}$. Several of the peaks coincide, giving rise to a deceptively simple spectrum: a sextet.](image-url)
Exercise 10-15

Working with the Concepts: Applying the N + 1 Rule

Predict the coupling patterns for the boldface hydrogen in the structure shown, first according to the simple \( N + 1 \) rule and then according to the sequential \( N + 1 \) rule.

\[
\begin{align*}
\text{CH}_3 \\
\text{H}_3\text{C} &\quad \text{C} &\quad \text{CH}_2 &\quad \text{OH} \\
\text{H} &
\end{align*}
\]

Strategy

In general, to predict splitting patterns of specific hydrogens, you need to be clear about the identity of their “neighborhood.” It is therefore often useful to build a model and to draw the structure out fully, showing all hydrogens. In this way, you can recognize symmetry and establish the different types of hydrogen neighbors and their relative abundance.

Solution

• Applying the simple \( N + 1 \) rule is easy: All we have to do is count the number of neighbors to the bold hydrogen to determine \( N \). In this case, we have two \( \text{CH}_3 \) units and one \( \text{CH}_2 \) unit, adding up to 8 H. Therefore, the bold hydrogen should appear as a nonet or nine lines, their relative intensities following Pascal’s triangle (Table 10-4): 1:8:28:56:70:56:28:8:1. In practice, you don’t have to figure out these exact numbers, and it suffices to look for a symmetrical pattern around the most intense center line, ascending from the left and descending to the right. You would need to amplify the spectrum to make sure that you don’t miss the outermost lines.

However, a symmetrical nonet is what is expected only if the coupling constants to the methyl and methylenes hydrogens, respectively, are the same.

• The sequential \( N + 1 \) rule applies if the \( J \) values to unequal neighbors differ. In that case, we first determine the splitting pattern expected if there was only one type of neighbor present. For example, if we pick the \( \text{CH}_3 \) groups, it would be 6 H, giving rise to a septet. We then apply the additional splitting caused by another neighbor, in our case the \( \text{CH}_2 \) group, and split each line of the original septet into a triplet. The result is a septet of triplets, 21 lines. This sequence is arbitrary and could have been reversed, resulting in a triplet of septets, the same 21 lines. In practice, the coupling pattern with the larger \( J \) value is quoted first, followed by the others, in order of decreasing size. You may be curious what the actual experimental splitting pattern looks like: It is a nonet, with \( J = 6.5 \) Hz.

Exercise 10-16

Try It Yourself

Predict the coupling patterns for the boldface hydrogens in the structures below, first according to the simple \( N + 1 \) rule and then according to the sequential \( N + 1 \) rule.

(a) \( \text{BrCH}_2\text{CH}_2\text{CH}_2\text{Cl} \)  \hspace{1cm} (b) \( \text{CH}_3\text{CHCHCl}_2 \)

(c) \( \text{Cl}_2\text{CHCHCH}_3 \)  \hspace{1cm} (d) 

Exercise 10-17

In Section 10-6 you learned how to distinguish among the three monochlorination products of 1-chloropropane—1,1-, 1,2-, and 1,3-dichloropropane—by using just chemical-shift data and chemical integration. Would you also expect to tell them apart on the basis of their coupling patterns?
Fast proton exchange decouples hydroxy hydrogens

With our knowledge of vicinal coupling, let us now return to the NMR of alcohols. We note in the NMR spectrum of 2,2-dimethyl-1-propanol (Figure 10-11) that the OH absorption appears as a single peak, devoid of any splitting. This is curious, because the hydrogen is adjacent to two others, which should cause its appearance as a triplet. The CH₂ hydrogens that show up as a singlet should in turn appear as a doublet with the same coupling constant. Why, then, do we not observe spin–spin splitting? The reason is that the weakly acidic OH hydrogens are rapidly transferring, both between alcohol molecules and to traces of water, on the NMR time scale at room temperature. As a consequence of this process, the NMR spectrometer sees only an average signal for the OH hydrogen. No coupling is visible, because the binding time of the proton to the oxygen is too short (about $10^{-2}$ s). It follows that the CH₂ nuclei are similarly uncoupled, a condition resulting in the observed singlet.

Absorptions of this type are said to be **decoupled** by fast proton exchange. The exchange may be slowed by removal of traces of water or acid or by cooling. In these cases, the OH bond retains its integrity long enough (more than 1 s) for coupling to be observed on the NMR time scale. An example is shown in Figure 10-29 for methanol. At 37°C, two singlets are observed, corresponding to the two types of hydrogens, both devoid of spin–spin splitting. However, at −65°C, the expected coupling pattern is detectable: a quartet and a doublet.

Rapid magnetic exchange “self-decouples” chlorine, bromine, and iodine nuclei

All halogen nuclei are magnetic. Therefore, the $^1$H NMR spectra of haloalkanes would be expected to exhibit spin–spin splitting owing to the presence of these nuclei (in addition to the normal H–H coupling). In practice, only fluorine exhibits this effect, in much the same way as the proton does but with much larger $J$ values. Thus, for example, the $^1$H NMR spectrum of CH₃F exhibits a doublet with $J = 81$ Hz. Because fluoroorganic compounds are a relatively specialised area, we shall not deal with their NMR spectroscopy any further.
Turning to the other halides, inspection of the spectra of the haloalkanes depicted in Figures 10-16, 10-21, 10-22, 10-24, 10-25, and 10-27 (fortunately) reveals the absence of any visible spin–spin splitting by these nuclei. The reason for this observation lies in their relatively fast internal magnetic equilibration on the NMR time scale, precluding their recognition by the adjacent hydrogens as having differing alignments with respect to the external magnetic field $H_0$. They “self-decouple,” in contrast with the “exchange decoupling” exhibited by the hydroxy protons.

In Summary The peak patterns in many NMR spectra are not first order, because the differences between the chemical shifts of nonequivalent hydrogens are close to the values of the corresponding coupling constants. Use of higher-field NMR instruments may improve the appearance of such spectra. Coupling to nonequivalent hydrogen neighbors occurs separately, with different coupling constants. In some cases, they are sufficiently dissimilar to allow for an analysis of the multiplets. In many simple alkyl derivatives, they are sufficiently similar ($J = 6–7$ Hz) that the spectra observed are simplified to those predicted in accordance with the $N + 1$ rule. Vicinal coupling through the oxygen in alcohols is frequently not observed because of decoupling by fast proton exchange.

10-9 Carbon-13 Nuclear Magnetic Resonance

Proton nuclear magnetic resonance is a powerful method for determining organic structures because most organic compounds contain hydrogens. Of even greater potential utility is NMR spectroscopy of carbon. After all, by definition, all organic compounds contain this element. In combination with $^1$H NMR, it has become the most important analytical tool in the hands of the organic chemist. We shall see in this section that $^{13}$C NMR spectra are much simpler than $^1$H NMR spectra, because we can avoid the complications of spin–spin splitting.

Carbon NMR utilizes an isotope in low natural abundance: $^{13}$C

Carbon NMR is possible. However, there is a complication: The most abundant isotope of carbon, carbon-12, is not active in NMR. Fortunately, another isotope, carbon-13, is present in nature at a level of about 1.1%. Its behavior in the presence of a magnetic field is the same as that of hydrogen. One might therefore expect it to give spectra very similar to those observed in $^1$H NMR spectroscopy. This expectation turns out to be only partly correct, because of a couple of important (and very useful) differences between the two types of NMR techniques.

Carbon-13 NMR ($^{13}$C NMR) spectra used to be much more difficult to record than hydrogen spectra, not only because of the low natural abundance of the nucleus under observation, but also because of the much weaker magnetic resonance of $^{13}$C. Thus, under comparable conditions, $^{13}$C signals are about $1/6000$ as strong as those for hydrogen. FT NMR (Sections 10-3 and 10-4) is particularly valuable here, because multiple radio-frequency pulsing allows the accumulation of much stronger signals than would normally be possible.

One advantage of the low abundance of $^{13}$C is the absence of carbon–carbon coupling. Just like hydrogens, two adjacent carbons, if magnetically nonequivalent (as they are in, e.g., bromoethane), split each other. In practice, however, such splitting is not observed. Why? Because coupling can occur only if two $^{13}$C isotopes come to lie next to each other. With the abundance of $^{13}$C in the molecule at 1.1%, this event has a very low probability (roughly 1% of 1%; i.e., 1 in 10,000). Most $^{13}$C nuclei are surrounded by only $^{12}$C nuclei, which, having no spin, do not give rise to spin–spin splitting. This feature simplifies $^{13}$C NMR spectra appreciably, reducing the problem of their analysis to a determination of the coupling patterns resulting from any attached hydrogens.

Figure 10-30 depicts the $^{13}$C NMR spectrum of bromoethane (for the $^1$H NMR spectrum, see Figure 10-21). The chemical shift $\delta$ is defined as in $^1$H NMR and is determined relative to an internal standard, normally the carbon absorption in $(\text{CH}_3)_4\text{Si}$. The chemical-shift range of carbon is much larger than that of hydrogen. For most organic compounds, it covers a distance of about 200 ppm, in contrast with the relatively narrow spectral “window” (10 ppm) of hydrogen. Figure 10-30 reveals the relative complexity of the absorptions caused by extensive $^{13}$C–$^1$H spin–spin splittings. Not surprisingly, directly bound hydrogens are most strongly coupled (~125–200 Hz). Coupling tapers off, however, with increasing
distance from the $^{13}$C nucleus under observation, such that the two-bond coupling constant $J_{^{13}C-H}$ is in the range of only 0.7–6.0 Hz.

You may wonder why it is that we observe hydrogen couplings in $^{13}$C NMR spectroscopy, yet we do not notice the converse, namely, carbon couplings, in $^1$H NMR. The answer lies in the low natural abundance of the NMR-active $^{13}$C isotope and the high natural abundance of the $^1$H nucleus. Thus, we could not detect $^{13}$C coupling in our proton spectra, because 99% of the attached carbons were $^{12}$C. On the other hand, the corresponding carbon

---

**Figure 10-30** $^{13}$C NMR spectrum of bromoethane, showing the complexity of $^{13}$C–H coupling. There is an upfield quartet ($\delta = 18.3$ ppm, $J = 126$ Hz) and a downfield triplet ($\delta = 26.6$ ppm, $J = 151$ Hz) resonance for the two carbon atoms. Note the large chemical-shift range. Tetramethylsilane, defined to be located at $\delta = 0$ ppm as in $^1$H NMR, absorbs as a quartet ($J = 118$ Hz) because of coupling of each carbon to three equivalent hydrogens. The inset shows a part of the spectrum expanded horizontally to reveal the fine splitting of each of the main peaks that is due to coupling of each $^{13}$C to protons on the neighboring carbon. Thus, each line of the upfield quartet (red) is split again into a triplet with $J = 3$ Hz, and each line of the downfield triplet (blue) is split again into a quartet with $J = 5$ Hz.
Hydrogen decoupling gives single lines

A technique that completely removes $^{13}\text{C}-\text{H}$ coupling is called **broad-band hydrogen** (or proton) **decoupling**. This method employs a strong, broad radio-frequency signal that covers the resonance frequencies of all the hydrogens and is applied at the same time as the $^{13}\text{C}$ spectrum is recorded. For example, in a magnetic field of 7.05 T, carbon-13 resonates at 75.3 MHz, hydrogen at 300 MHz (Figure 10-7). To obtain a proton-decoupled carbon spectrum at this field strength, we irradiate the sample at both frequencies. The first radio-frequency signal produces carbon magnetic resonance. Simultaneous exposure to the second signal causes all the hydrogens to undergo rapid $\alpha \leftrightarrow \beta$ spin flips, fast enough to average their local magnetic field contributions. The net result is the absence of coupling. Use of this technique simplifies the $^{13}\text{C}$ NMR spectrum of bromoethane to two single lines, as shown in Figure 10-31.

The power of proton decoupling becomes evident when spectra of relatively complex molecules are recorded. Every magnetically distinct carbon gives only one single peak in the $^{13}\text{C}$ NMR spectrum. Consider, for example, a hydrocarbon such as methylcyclohexane. Analysis by $^1\text{H}$ NMR is made very difficult by the close-lying chemical shifts of the eight different types of hydrogens. However, a proton-decoupled $^{13}\text{C}$ spectrum shows only five peaks, clearly depicting the presence of the five different types of carbons and revealing the twofold symmetry in the structure (Figure 10-32). These spectra also exhibit a limitation in $^{13}\text{C}$ NMR spectroscopy: Integration is not usually straightforward. As a consequence of the broad-band decoupling, peak intensities no longer correspond to numbers of nuclei.

Exercise 10-18

Predict the $^{13}\text{C}$ NMR spectral pattern of 1-bromopropane (for the $^1\text{H}$ NMR spectrum, see Figure 10-27). **(Hint:** Use the sequential $N+1$ rule.)
Table 10-6 shows that carbon, like hydrogen (Table 10-2), has characteristic chemical shifts depending on its structural environment. As in \(^1H\) NMR, electron-withdrawing groups cause deshielding, and the chemical shifts go up in the order primary < secondary < tertiary carbon. Apart from the diagnostic usefulness of such \(\delta\) values, knowing the number of different carbon atoms in the molecule can aid structural identification. Consider, for example, the difference between methylcyclohexane and its isomers with the molecular formula \(C_7H_{14}\). Many of them differ in the number of nonequivalent carbons and therefore give distinctly different carbon spectra. Notice how much the (lack of) symmetry in a molecule affects the complexity of the carbon spectrum.

**Exercise 10-19**

How many peaks would you expect in the proton-decoupled $^{13}$C NMR spectra of the following compounds? (Hint: Look for symmetry.)

(a) 2,2-Dimethyl-1-propanol

(b) [Diagram of 2,2-Dimethyl-1-propanol]

(c) [Diagram of a complex molecular structure]

(d) [Diagram of a complex molecular structure]

**Exercise 10-20**

**Working with the Concepts: Differentiating Isomers by $^{13}$C NMR**

In Exercise 2-16(a) you formulated the structures of the five possible isomers of hexane, C$_6$H$_{14}$. One of them shows three peaks in the $^{13}$C NMR spectrum at $\delta = 13.7, 22.7,$ and $31.7$ ppm. Deduce its structure.

**Strategy**

We need to write down all possible isomers and see to what extent symmetry (or the lack thereof) influences the number of peaks expected for each (using the labels $a$, $b$, $c$, and $d$.)

**Solution**

Hexane 2-Methylpentane 2,2-Dimethylbutane 2,3-Dimethylbutane 3-Methylpentane

- Only one isomer has only three different carbons: hexane.

**Exercise 10-21**

**Try It Yourself**

A researcher finds two unlabeled bottles in the stock room. She knows that one of them contains the sugar d-ribose, the other d-arabinose (both shown as Fischer projections below), but she does not know which bottle contains which sugar. Armed with a supply of Na$^{+}$BH$_4$ and equipped with an NMR spectrometer, how could she tell?

[d-Ribose Fischer projection]

[d-Arabinose Fischer projection]
Advances in FT NMR greatly aid structure elucidation:
DEPT $^{13}\text{C}$ and 2D-NMR

The FT technique for the measurement of NMR spectra is extremely versatile, allowing data to be collected and presented in a variety of ways, each providing information about the structure of molecules. Most recent advances are due to the development of sophisticated time-dependent pulse sequences, including the application of *two-dimensional NMR, or 2D NMR* (Chemical Highlight 10-4). With these methods, it is now possible to establish coupling (and therefore bonding) between close-lying hydrogens (*homonuclear correlation*) or connected carbon and hydrogen atoms (*heteronuclear correlation*). Thus, $^1\text{H}$ and $^{13}\text{C}$ NMR allow the determination of molecular connectivity by measuring the magnetic effect of neighboring atoms on one another along a carbon chain.

An example of such a pulse sequence, now routine in the research laboratory, is the **DEPT $^{13}\text{C}$ NMR spectrum (distortionless enhanced polarization transfer)**, which tells you what type of carbon gives rise to a specific signal in the normal $^{13}\text{C}$ spectrum: CH$_3$, CH$_2$, CH, or C$_{\text{quaternary}}$. It avoids the complications arising from a proton-coupled $^{13}\text{C}$ NMR spectrum (see Figure 10-30), particularly overlapping multiplets of close-lying carbon signals. The DEPT method consists of a combination of spectra run with differing pulse sequences: the normal broad-band decoupled spectrum and a set of spectra that reveals *signals only of carbons bound to three (CH$_3$), two (CH$_2$), and one hydrogen (CH)*, respectively. Figure 10-33 depicts a series of such spectra for limonene (see also Problem 5-29).

The first is the normal proton-decoupled spectrum (Figure 10-33A), which exhibits the expected number of lines (10) and groups them into the six alkyl and four alkenyl carbon signals at high and at low field, respectively. The remaining spectra specifically identify the three types of possible carbons bearing hydrogens, CH$_3$ (red; Figure 10-33B),

![Figure 10-33](image-url)

Figure 10-33 The DEPT $^{13}\text{C}$ NMR method applied to limonene: (A) broad-band decoupled spectrum revealing the six alkyl carbon signals at high field (20–40 ppm) and four alkenyl carbon signals at low field (108–150 ppm; see Table 10-6); (B) spectrum showing only the two CH$_3$ signals for C7 and C10 (red); (C) spectrum showing only the four CH$_2$ signals for C3, C5, C6, and C9 (blue); (D) spectrum showing only the two CH signals for C2 and C4 (green). The additional lines in (A) are assigned to the quaternary carbons C1 and C8 (black).
Correlated NMR Spectra: COSY and HETCOR

We have learned that NMR is of great help in proving the structure of molecules. It tells us what types of nuclei are present and how many of them are in a compound. It can also reveal connectivity by exploiting spin coupling through bonds. This last phenomenon can be exploited in a special type of plot, which is obtained by the application of sophisticated pulse techniques and the associated computer analysis: two-dimensional (2D) NMR. In this method, two spectra of the molecule are plotted on the horizontal and vertical axes. Mutually coupled signals are indicated as “blotches,” or correlation peaks, on the x–y graph. Because this plot correlates nuclei that are in close proximity (and therefore exhibit spin–spin splitting), this type of spectroscopy is also called correlation spectroscopy or COSY.

Let us pick an example we already know: 1-bromopropane (see Figure 10-27). The COSY spectrum is shown below.

The two spectra along the x and y axes are identical to that in Figure 10-27. The marks on the diagonal line correlate the same peaks in each spectrum (indicated by the colored “blotches”) and can be ignored. It is the off-diagonal correlations (indicated by the orange lines) that prove the connectivity of the hydrogens in the molecule. Thus, the (red) methyl triplet at δ = 1.05 ppm has a cross peak (indicated by the black “blotches”) with the (green) methylene sextet at  δ = 1.88 ppm, establishing their relation as neighbors. Similarly, the (blue) peaks for the methylene hydrogens, deshielded by the bromine to appear at  δ = 3.40 ppm, also correlate with the center signal at  δ = 1.88 ppm. Finally, the center absorption shows cross peaks with the signals of both of its neighbors, thus proving the structure.
Of course, the example of 1-bromopropane is overly simple and was chosen only to demonstrate the workings of this technique. Think of 1-bromohexane instead. Here, the rapid assignment of the individual methylene groups is made possible by COSY spectroscopy. Starting from either of the two signals that are readily recognized—namely, those due to the methyl (a unique high-field triplet) or the CH$_2$Br protons (a unique low-field triplet)—we can “walk along” the correlated signals from one methylene neighbor to the next until the complete connectivity of the structure is evident.

Connectivity is disclosed even more powerfully by heteronuclear correlation spectroscopy (HETCOR). Here, an $^1$H NMR spectrum is juxtaposed with a $^{13}$C spectrum. This allows the mapping of a molecule along its entire C–H framework by revealing the identity of C–H bonded fragments. The principle is illustrated again with 1-bromopropane in the spectrum shown below.

The $^{13}$C NMR spectrum is plotted on the $y$ axis and exhibits three peaks. On the basis of what we know about carbon NMR, we can readily assign the signal at $\delta = 13.0$ ppm to the methyl carbon, that at $\delta = 26.2$ ppm to the methylene, and that at $\delta = 36.0$ ppm to the bromine-bearing carbon. But even without this knowledge, these assignments are immediately evident from the cross-correlations of the respective hydrogen signals (which we have already assigned) with those of their bound carbon counterparts. Thus, the methyl hydrogen triplet correlates with the carbon signal at $\delta = 13.0$ ppm, the sextet for the methylenes has a cross peak with the carbon signal at $\delta = 26.2$ ppm, and the downfield proton triplet is connected to the carbon with a signal at $\delta = 36.0$ ppm.
Chapter 10
Using NMR Spectroscopy to Deduce Structure

CH2 (blue; Figure 10-33C), and CH (green; Figure 10-33D). The quaternary carbon signals (black) don’t show up in the last three experiments and are located by subtracting all of the lines in Figure 10-33B – D from the complete spectrum in Figure 10-33A.

For the remainder of the text, whenever the depiction or description of a 13C NMR spectrum includes spectral assignments to CH3CH2, CH, or C quaternary carbons, they are based on a DEPT experiment.

We can apply 13C NMR spectroscopy to the problem of the monochlorination of 1-chloropropane

In Section 10-6 we learned how we could use 1H NMR chemical shifts and integration to distinguish among the three isomers of dichloropropane arising from the chlorination of 1-chloropropane. Exercise 10-12 addressed the use of spin–spin splitting patterns as a complementary means of solving this problem. How does 13C NMR fare in this task? Our prediction is straightforward: Both 1,1- and 1,2-dichloropropane should exhibit three carbon signals each, but spaced significantly differently because the 1,1-isomer has the two electron-drawing chlorine atoms located on the same carbon (hence no chlorines on the remaining two), whereas 1,2-dichloropropane bears one chlorine each on C1 and C2. In contrast, 1,3-dichloropropane would be clearly distinct from the other two isomers because of its symmetry: Only two lines should be observed. The experimental data are shown in the margin and confirm our expectations. The specific assignments of the two deshielded chlorine-bearing carbons in 1,2-dichloropropane (as indicated in the margin) can be made on the basis of the DEPT technique: The signal at 49.5 ppm appears as a CH2, and that at 55.8 ppm as a CH in the DEPT-90 experiment.

CHEMICAL HIGHLIGHT 10-5
Structural Characterization of Natural Products: Antioxidants from Grape Seeds

The world of plants is a rich source of useful pharmacological, therapeutic, and chemoprotective substances. The 15-carbon compound viniferone (a sesquiterpene; see Section 4-7) was isolated from grape seeds in 2004. It is one of a variety of substances called grape seed proanthocyanidins, which are highly active against radicals (Chapter 3) and oxidative stress (see Section 22-9). Only 40 mg of the compound was obtained from 10.5 kg of grape seeds; therefore, elemental analysis, chemical tests, and any other procedures that would destroy the tiny amount of available material could not be used in structural elucidation. Instead, a combination of spectroscopic techniques (NMR, IR, MS, and UV) was employed, leading to the structure shown here, which was later confirmed by X-ray crystallography.

The characterization of viniferone relied in part on 1H and 13C NMR data. Proton chemical shifts provided evidence for key pieces of the structure. Thus, there were three signals in the range reserved for internal alkene and aromatic hydrogens (shown in orange in the structural drawings) between δ = 5.9 and 6.2 (consult Table 10-2 for typical proton chemical shifts). Another three signals were observed at δ > 3.8 ppm, reflecting the presence of three protons (red) attached to oxygen-bearing carbons. Finally, there were four absorptions with relatively low δ values between 2.5 and 3.1 ppm, assignable to the two pairs of (green) diastereotopic hydrogens (see Chemical Highlight 10-3). 13C NMR was equally helpful (consult Table 10-6 for
You can see from this example how $^1$H NMR and $^{13}$C NMR spectroscopy complement each other. $^1$H NMR spectra provide an estimate of the electronic environment (i.e., electron rich versus electron poor) of a hydrogen nucleus under observation ($\delta$), a measure of its relative abundance (integration), and an indication of how many neighbors (and their number of types) it has (spin–spin splitting). Proton-decoupled $^{13}$C NMR provides the total number of chemically distinct carbons, their electronic environment ($\delta$), and, in the DEPT mode, even the quantity of their attached hydrogens. Application of both techniques to the solution of a structural problem is not unlike the methods used to solve a crossword puzzle. The horizontal entries (such as the data provided by $^1$H NMR spectroscopy) have to fit the vertical ones (i.e., the corresponding $^{13}$C NMR information) to provide the correct answer.

The extracts of grape seeds are being touted in the prevention of a range of maladies, including heart disease, cancer, and psoriasis.
not observed, because the scarcity of the isotope in the sample renders the likelihood of neighboring 13C nuclei negligible. 13C–H coupling can be measured but is usually removed by broadband proton decoupling, providing single lines for each distinct carbon atom in the molecule under investigation. The 13C NMR chemical-shift range is large, about 200 ppm for organic structures. 13C NMR spectra cannot usually be integrated, but the DEPT experiment allows the identification of each signal as arising from CH3, CH2, CH, or Cquaternary units, respectively.

THE BIG PICTURE

In your study of organic chemistry so far, there may have been moments during which you wondered, how do chemists know this? How do they establish the veracity of a structure? How do they follow the kinetics of disappearance of a molecule? How is an equilibrium constant determined? When do they know that a reaction is over? The introduction of NMR spectroscopy provides a first glimpse of the variety of practical tools available to answer these questions. Other forms of spectroscopy can yield other important information about molecules. We shall introduce them in conjunction with the functional groups for which they are particularly diagnostic. Spectroscopy, especially NMR spectroscopy, is the key to identifying the different classes of organic compounds and is an important part of each subsequent chapter in the book. You may find it helpful to review the material in this chapter as you examine new spectra later on.

CHAPTER INTEGRATION PROBLEMS

10-23. A researcher executed the following reaction sequence in a preparation of (S)-2-chlorobutane:

Careful preparative gas chromatography of the reaction product (b.p. 68.2°C) allowed the separation of a very small amount of another compound, C5H9Cl (b.p. 68.5°C), which was optically inactive and exhibited the NMR spectra depicted below. What is the structure of this compound and how could it have been formed?
SOLUTION

As we did in Chapter Integration Problems 3-14 and 6-30, let us apply the WHIP approach to break down the process of solving this problem. Again, this strategy will be described in detail in the Interlude that follows Chapter 11.

**What is the problem asking?** We are first to deduce the structure of a minor product of the given reaction sequence. Subsequently, we are asked to explain “how” this compound forms. As mentioned earlier, “how” and “why” questions normally require some mechanistic insight. We’ll take things in order.

**How to begin?** The given molecular composition of the unknown compound, C₄H₉Cl, tells us that it is an isomer of the observed major product. We have both its ¹H and ¹³C NMR spectra available for analysis. We also know the reagents that convert the starting material to the major product. Which pieces of information are the most useful ones to help us get started? We could try to come up with alternative results of the two reactions in the sequence without examining the spectroscopic data at all, but, realistically, sooner or later it will be necessary to use the spectra to confirm any hypothetical structure we propose. It makes much more sense to start with them and at least find out whether they give us an unambiguous answer.

**Information needed?** Sections 10-4 through 10-7 reveal the information contained in an ¹H NMR spectrum; Section 10-9 covers ¹³C NMR. The carbon spectrum is simpler. As a general rule of strategy, try to extract the most information you can from the sources that are the *simplest* to analyze. Start with the ¹³C NMR spectrum; then proceed to the ¹H NMR spectrum.

**Proceed.** The formula of the unknown is C₄H₉Cl. It has four carbon atoms, but the ¹³C NMR spectrum (assignments by DEPT) displays only three lines. Therefore, one of these three lines must arise from two equivalent carbon atoms. The line farthest downfield, at δ = 51 (CH₂) ppm, is the most deshielded and therefore most likely to be the unique carbon bearing the chlorine atom (Table 10-6). This reasoning suggests the presence of substructure –CH₂Cl. The other two lines are in the alkyl region, at about δ = 20 (CH₃) and 31 (CH) ppm. One of these two must be due to two equivalent carbon nuclei. We can use the molecular formula and our knowledge of substructure –CH₂Cl to identify which one. Thus, if the signal (for CH) at δ = 31 ppm were due to two identical carbons, then we would arrive at a molecular formula of CH₃ + 2 CH + CH₂Cl = C₂H₅Cl, not a match for that given. On the other hand, if the signal at δ = 20 (CH₃) ppm corresponded to two carbons, then we have 2 CH₃ + CH + CH₂Cl = C₄H₉Cl, the correct formula. Therefore, the unknown contains two equivalent CH₃ groups. We could connect these fragments to give us an immediate likely solution, but let us exercise a little patience and see what the ¹H NMR spectrum has to tell us.

This spectrum reveals three types of hydrogens at about δ = 1.0, 1.9, and 3.4 ppm. Following the same logic as that applied in the above assignment of the most deshielded carbon atom, the most deshielded hydrogens must be those attached to the chlorine-bearing carbon (Section 10-4). The integrated values for the three hydrogen signals are 6, 1, and 2, respectively, totaling to the nine hydrogens present (Section 10-6). Finally, there is spin-spin splitting. Both the highest and lowest field signals are doublets, with almost identical J values. This means that each of these sets of hydrogens (6 + 1, or 8 in all) has a single neighbor (the ninth H). That hydrogen shows up in the middle as a nine-line pattern, as expected by the N + 1 rule (N = 8; Section 10-7).

Now let us combine this information in a structural assignment. As with most puzzles, one can arrive at the answer in several ways. In NMR spectral problems, it is often best to start with the formulation of partial structures, as dictated by the ¹H NMR spectrum, and use the other information as corroborating evidence. Thus, the high-field doublet integrating for 6 H indicates a (CH₃)₂CH– substructure. Similarly, the low-field counterpart points to –CH₂CH–. Combining the two provides –CH₂CH(CH₃)₂ and, adding the Cl atom, the solution: the achiral (hence optically inactive) ClCH₂CH(CH₃)₂. This assignment is confirmed by the ¹³C NMR spectrum, the highest field line being due to the presence of the two equivalent methyl carbons. The center line is due to the tertiary, the most deshielded absorption due to the chlorine-bearing carbon (Table 10-6). You can confirm your solution in another manner, taking advantage of the relatively small molecular formula; thus, there are only four possible chlorobutane isomers: CH₃CH₂CH₂CH₂Cl, CH₃CHCH₂CH₃ (our major product), (CH₃)₂CHCH₂Cl (the minor product), and (CH₃)₃CCl. They differ drastically in their ¹H and ¹³C NMR spectra with respect to number of signals, chemical shifts, integration, and multiplicities. (Verify.)
The second aspect of this problem is mechanistic. How do we get 1-chloro-2-methylpropane from the preceding reaction sequence? The answer presents itself on retrosynthetic analysis, using the reagents given in our initial scheme:

\[
\begin{align*}
\text{H}_3\text{C} - \text{C} - \text{CH}_2\text{Cl} & \xrightarrow{\text{SOCl}_2} \text{H}_3\text{C} - \text{C} - \text{CH}_2\text{OH} \\
& \xrightarrow{\text{CH}_3\text{Li}} \text{H}_3\text{C} - \text{C} - \text{OH}
\end{align*}
\]

The only way to obtain a product with two CH\textsubscript{3} groups attached to the same carbon is to have the methyl group of CH\textsubscript{3}Li add to the carbon of the oxacyclopropane that already contains one CH\textsubscript{3}. Therefore, the observed minor product is the result of nucleophilic ring opening of the starting compound by attack at the more hindered position, usually neglected because it is less favored.

10-24. a. A graduate student took the \textsuperscript{1}H and \textsuperscript{13}C NMR spectra of optically pure (1\textsubscript{R}, 2\textsubscript{R})-trans-1-bromo-2-methylcyclohexane (A) in deuterated nitromethane (CD\textsubscript{3}NO\textsubscript{2}) as a solvent (Table 6-5) and recorded the following values: \textsuperscript{1}H NMR spectrum: \(\delta = 1.06\) (d, 3 H), 1.42 (m, 6 H), 1.90 (m, 2 H), 2.02 (m, 1 H), 3.37 (m, 1 H); \textsuperscript{13}C NMR (DEPT): \(\delta = 16.0\) (CH\textsubscript{3}), 23.6 (CH\textsubscript{2}), 23.9 (CH\textsubscript{2}), 30.2 (CH\textsubscript{2}), 33.1 (CH\textsubscript{2}), 35.0 (CH), 43.2 (CH) ppm. Assign these spectra as best you can with the help of Tables 10-2 and 10-6, respectively.

**SOLUTION**

\textsuperscript{1}H NMR spectrum. All of the signals, with the exception of the highest field doublet, appear as complex multiplets. This is not surprising, considering that each hydrogen (except for the three CH\textsubscript{3} nuclei) is magnetically distinct, that there are multiple vicinal and geminal couplings all around the ring, and that the \(\delta\) values (except for those in the immediate vicinity of the bromine substituent) are close. The exception is the methyl group appearing at highest field, as expected, and as a doublet due to coupling to the neighboring tertiary hydrogen. To complete our assignments, we have to rely more than usual on chemical shifts and integration.

What is the expected effect of bromine on its vicinity? **Answer:** Br is deshielding (Section 10-4), mostly its direct neighbors, the effect tapering off with distance. Indeed, the \(\delta\) values divide into two groups. One set has higher (\(\delta = 3.37, 2.02, 1.90\) ppm), the other lower values (\(\delta = 1.42, 1.06\) ppm). The most deshielded single hydrogen at \(\delta = 3.37\) ppm is readily assignable to that at C1 next to bromine. The next most deshielded positions are its neighbors at C2 and C6. Since the signal at \(\delta = 2.02\) ppm integrates for only 1 H, it must be the single tertiary hydrogen at C2; the peak at \(\delta = 1.90\) ppm can then be assigned to the CH\textsubscript{2} group at C6. This choice is also consistent with the general appearance of secondary hydrogen signals at higher field than those of tertiary hydrogens (Table 10-2). The remaining six hydrogens at \(\delta = 1.42\) ppm are not resolved, and all absorb at around the same place.

\[
\begin{align*}
\text{H}_3\text{C} & \text{Br} \\
\text{CH}_3 & \text{H}
\end{align*}
\]

\textsuperscript{13}C NMR spectrum. Using the DEPT correlations in conjunction with the deshielding effect of bromine allows a ready assignment to the extent shown above.

b. To the student’s surprise, the optical activity of the sample decreased with time. Concurrently, the NMR spectrum of A diminished in intensity and new peaks appeared of an optically inactive isomer B. \textsuperscript{1}H NMR: \(\delta = 1.44\) (m, 6 H), 1.86 (m, 4 H), 1.89 (s, 3 H) ppm; \textsuperscript{13}C NMR: \(\delta = 20.8\) (CH\textsubscript{2}), 26.7 (CH\textsubscript{2}), 28.5 (CH\textsubscript{2}), 37.6 (C\textsubscript{quat}), 41.5 (CH\textsubscript{2}) ppm. Following the disappearance of A revealed a rate = \(k[A]\). What is B, and how is it formed?

**SOLUTION**

Let us analyze the spectra of B, particularly in comparison to those of A. In the \textsuperscript{1}H NMR spectrum, we note that the number of signals has decreased from five to only three. Moreover, the low-field peak at \(\delta = 3.37\) ppm for the hydrogen next to bromine in A has disappeared and the methyl doublet is now a singlet, moved to lower field relative to its original position. In the \textsuperscript{13}C NMR spectrum, we
recognize a similar simplification (hence symmetrization) from seven to five peaks. Moreover, the tertiary carbons (CH) have disappeared, there are only three types of CH₂, and a quaternary carbon has appeared. The relatively deshielded CH₃ carbon is also evident.

Conclusions. The bromine atom must now be located at the same position as the CH₃ substituent, as in the achiral 1-bromo-1-methylcyclohexane:

\[
\begin{array}{c}
\text{Br} \\
\text{CH}_3
\end{array}
\]  

\[
\begin{array}{c}
\text{Br} \\
\text{CH}_3
\end{array}
\]

How could that rearrangement have happened? Answer: We have a case of an SN₁ reaction (Section 7-2) proceeding through a rearranging carbocation (Section 9-3):

The mechanism explains all of the observations: The loss of optical activity, the first-order disappearance of A, and the formation of B.

Important Concepts

1. NMR is the most important spectroscopic tool in the elucidation of the structures of organic molecules.

2. Spectroscopy is possible because molecules exist in various energetic forms, those at lower energy being convertible into states of higher energy by absorption of discrete quanta of electromagnetic radiation.

3. NMR is possible because certain nuclei, especially \(^1\text{H}\) and \(^13\text{C}\), when exposed to a strong magnetic field, align with it (α) or against it (β). The α-to-β transition can be effected by radio-frequency radiation, leading to resonance and a spectrum with characteristic absorptions. The higher the external field strength, the higher the resonance frequency. For example, a magnetic field of 7.05 T causes hydrogen to absorb at 300 MHz, a magnetic field of 14.1 T causes it to absorb at 600 MHz.

4. High-resolution NMR allows for the differentiation of hydrogen and carbon nuclei in different chemical environments. Their characteristic positions in the spectrum are measured as the chemical shift, \(\delta\), in ppm from an internal standard, tetramethylsilane.

5. The chemical shift is highly dependent on the presence (causing shielding) or absence (causing deshielding) of electron density. Shielding results in relatively high-field peaks [to the right, toward (CH₃)₄Si], deshielding in low-field ones. Therefore, electron-donor substituents shield, and electron-withdrawing components deshield. The protons on the heteroatoms of alcohols, thiols, and amines show variable chemical shifts and often appear as broad peaks because of hydrogen bonding and exchange.

6. Chemically equivalent hydrogens and carbons have the same chemical shift. Equivalence is best established by the application of symmetry operations, such as those using mirror planes and rotations.

7. The number of hydrogens giving rise to a peak is measured by integration.

8. The number of hydrogen neighbors of a nucleus is given by the spin–spin splitting pattern of its NMR resonance, following the \(N+1\) rule. Equivalent hydrogens show no mutual spin–spin splitting.
9. When the chemical-shift difference between coupled hydrogens is comparable to their coupling constant, non-first-order spectra with complicated patterns are observed.

10. When the constants for coupling to nonequivalent types of neighboring hydrogens are different, the \( N + 1 \) rule is applied sequentially.

11. Carbon NMR utilizes the low-abundance \(^{13}\text{C}\) isotope. Carbon–carbon coupling is not observed in ordinary \(^{13}\text{C}\) spectra. Carbon–hydrogen coupling can be removed by proton decoupling, thereby simplifying most \(^{13}\text{C}\) spectra to a collection of single peaks.

12. DEPT \(^{13}\text{C}\) NMR allows the assignment of absorptions to \( \text{CH}_3 \), \( \text{CH}_2 \), \( \text{CH} \), and quaternary carbons, respectively.

**Problems**

25. Where on the chart presented in Figure 10-2 would the following be located: AM radio waves (\( \nu \sim 1 \text{ MHz} = 10^6 \text{ kHz} = 10^8 \text{ Hz} \), or cycles s\(^{-1}\)); FM broadcast frequencies (\( \nu \sim 100 \text{ MHz} = 10^8 \text{ s}^{-1} \))?

26. Convert each of the following quantities into the specified units. (a) 1050 cm\(^{-1}\) into \( \lambda \), in \( \mu\text{m} \); (b) 510 nm (green light) into \( \nu \), in s\(^{-1}\) (cycles s\(^{-1}\), or hertz); (c) 6.15 \( \mu\text{m} \) into \( \bar{\nu} \), in cm\(^{-1}\); (d) 2250 cm\(^{-1}\) into \( \nu \), in s\(^{-1}\) (Hz).

27. Convert each of the following quantities into energies, in kcal mol\(^{-1}\). (a) A bond rotation of 750 wavenumbers (cm\(^{-1}\)); (b) a bond vibration of 2900 wavenumbers (cm\(^{-1}\)); (c) an electronic transition of 350 nm (ultraviolet light, capable of sunburn); (d) the broadcast frequency of the audio signal of TV channel 6 (87.25 MHz; before the advent of digital TV in 2009); (e) a “hard” X-ray with a 0.07-nm wavelength.

28. Calculate to three significant figures the amount of energy absorbed by a hydrogen when it undergoes an \( \alpha \)-to-\( \beta \) spin flip in the field of (a) a 2.11-T magnet (\( \nu = 90 \text{ MHz} \)); (b) an 11.75-T magnet (\( \nu = 500 \text{ MHz} \)).

29. For each of the following changes, indicate whether it corresponds to moving to the right or to the left in an NMR spectrum. (a) Increasing radio frequency (at constant magnetic field strength); (b) increasing magnetic field strength (at constant radio frequency; moving “upfield”; Section 10-4); (c) increasing chemical shift; (d) increased shielding.

30. Sketch a hypothetical low-resolution NMR spectrum showing the positions of the resonance peaks for all magnetic nuclei for each of the following molecules. Assume an external magnetic field of 2.11 T. How would the spectra change if the magnetic field were 8.46 T?

(a) CFCl\(_3\) (Freon 11)  
(b) CH\(_3\)CFCl\(_2\) (HCFC-141b)  
(c) CF\(_3\)-C--H (Halothane)  
(d) Br

31. If the NMR spectra of the molecules in Problem 30 were recorded by using high resolution for each nucleus, what differences would be observed?

32. The \(^1\text{H}\) NMR spectrum of CH\(_3\)COCH\(_2\)C(CH\(_3\))\(_2\), 4,4-dimethyl-2-pentanone, taken at 300 MHz, shows signals at the following positions: 307, 617, and 683 Hz downfield from tetramethylsilane. (a) What are the chemical shifts (\( \delta \)) of these signals? (b) What would their positions be in hertz, relative to tetramethylsilane, if the spectrum were recorded at 90 MHz? At 500 MHz? (c) Assign each signal to a set of hydrogens in the molecule.

33. Order the \(^1\text{H}\) NMR signals of the following compounds by chemical-shift position (lowest to highest). Which one is the most upfield? The most downfield?

(a) H\(_2\)C—CH\(_3\)  
(b) H\(_2\)C=CH\(_2\)  
(c) H\(_2\)C—O—CH\(_3\)  
(d) H\(_2\)C—C—CH\(_3\)  
(e)  
(f) H\(_2\)C—N—CH\(_3\)
34. Which hydrogens in the following molecules exhibit the more downfield signal relative to \((\text{CH}_3)_4\text{Si}\) in the NMR experiment? Explain.

(a) \((\text{CH}_3)_2\text{O}\) or \((\text{CH}_3)_2\text{N}\)   (b) \text{CH}_3\text{COCH}_3\   (c) \text{CH}_3\text{CH}_2\text{OH}\   (d) \text{CH}_3\text{S}\) or \((\text{CH}_3)_2\text{S}\)

35. How many signals would be present in the \(^1\text{H}\) NMR spectrum of each of the cyclopropane derivatives shown below? Consider carefully the geometric environments around each hydrogen.

(a) \(\text{Br}\)   (b) \(\text{BrBr}\)   (c) \(\text{Br}\)\(\text{Br}\)\(\text{Br}\)\(\text{Br}\)\(\text{Br}\)\(\text{Br}\)

36. How many signals would be present in the \(^1\text{H}\) NMR spectrum of each of the following molecules? What would the *approximate* chemical shift be for each of these signals? Ignore spin–spin splitting.

(a) \text{CH}_3\text{CH}_2\text{CH}_3\   (b) \text{CH}_3\text{CHCH}_3\   (c) \text{HOCH}_2\text{CCl}\text{CH}_3\   (d) \text{CH}_3\text{CHCH}_2\text{CH}_3\n
(e) \text{CH}_3\text{CHNH}_2\   (f) \text{CH}_3\text{CHCH}_2\text{(CH}_2\text{CH}_3)_2\   (g) \text{CH}_3\text{OCH}_2\text{CH}_2\text{CH}_3\   (h) \text{H}_2\text{C}—\text{C}—\text{O}\n
(i) \text{CH}_3\text{CH}_2—\text{C}—\text{H}\   (j) \text{CH}_3\text{CH}—\text{C}—\text{CH}_3\n
37. For each compound in each of the following groups of isomers, indicate the number of signals in the \(^1\text{H}\) NMR spectrum, the *approximate* chemical shift of each signal, and the integration ratios for the signals. Ignore spin–spin splitting. Indicate whether all the isomers in each group can be distinguished from one another by these three pieces of information alone.

(a) \text{CH}_3\text{CHC}_2\text{CH}_3\   \text{BrCH}_2\text{CHCH}_2\text{CH}_3\   \text{CH}_3\text{CHCH}_2\text{CH}_2\text{Br}\n
(b) \text{ClCH}_2\text{CH}_2\text{CH}_2\text{OH}\   \text{CH}_3\text{CHCH}_2\text{OH}\   \text{CH}_3\text{CHCH}_2\text{OH}\n
(c) \text{ClCH}_2—\text{CHCH}_3\   \text{ClCH}_2—\text{CHC}_2\text{H}_3\   \text{ClCH}—\text{CHCH}_3\   \text{ClCH}_2\text{CHCH}_{3}\
38. $^1$H NMR spectra for two haloalkanes are shown below. Propose structures for these compounds that are consistent with the spectra. (a) $\text{C}_5\text{H}_{11}\text{Cl}$, spectrum A; (b) $\text{C}_4\text{H}_8\text{Br}_2$, spectrum B.

\[ \text{A} \quad \text{B} \]

39. The following $^1$H NMR signals are for three molecules with ether functional groups. All the signals are singlets (single, sharp peaks). Propose structures for these compounds. (a) $\text{C}_6\text{H}_{13}\text{O}_2$, $\delta = 3.3$ and 4.4 ppm (ratio 3:1); (b) $\text{C}_5\text{H}_{15}\text{O}_3$, $\delta = 3.3$ and 4.9 ppm (ratio 9:1); (c) $\text{C}_4\text{H}_{10}\text{O}_2$, $\delta = 1.2$ and 3.1 ppm (ratio 1:1). Compare and contrast these spectra with that of 1,2-dimethoxyethane (Figure 10-15B).

40. (a) The $^1$H NMR spectrum of a ketone with the molecular formula $\text{C}_6\text{H}_{12}\text{O}$ has $\delta = 1.2$ and 2.1 ppm (ratio 3:1). Propose a structure for this molecule. (b) Each of two isomeric molecules related to the ketone in (a) has the molecular formula $\text{C}_6\text{H}_ {12}\text{O}_2$. Their $^1$H NMR spectra are described as follows: isomer 1, $\delta = 1.5$ and 2.0 ppm (ratio 3:1); isomer 2, $\delta = 1.2$ and 3.6 ppm (ratio 3:1). All signals in these spectra are singlets. Propose structures for these compounds. To what compound class do they belong?

41. List the four important features of $^1$H NMR and the information you can derive from them. (Hint: See Sections 10-4 through 10-7.)

42. Describe in which ways the $^1$H NMR spectra of the compounds below would be similar and how they would differ. Address each of the four issues you listed in Problem 41. To which compound class does each of these compounds belong?

\[ \text{O} \quad \text{O} \quad \text{O} \]

\[ \text{CH}_3\text{CH}_2\text{C}—\text{O}—\text{CH}_3 \quad \text{CH}_3\text{C}—\text{O}—\text{CH}_2\text{CH}_3 \quad \text{CH}_3\text{CH}_2\text{C}—\text{C}—\text{CH}_3 \quad \text{CH}_3\text{CH}_2\text{CH}_2—\text{C}—\text{H} \]

43. Below are shown three $\text{C}_4\text{H}_8\text{Cl}_2$ isomers on the left and three sets of $^1$H NMR data that one would expect on application of the simple $N + 1$ rule on the right. Match the structures to the proper spectral data. (Hint: You may find it helpful to sketch the spectra on a piece of scratch paper.)

\[ \text{Cl} \quad \text{Cl} \]

(a) $\text{CH}_3\text{CH}_2\text{CH}_2\text{Cl}$

\[ \text{Cl} \quad \text{Cl} \]

(b) $\text{CH}_3\text{CHCHCH}_3$

\[ \text{Cl} \quad \text{Cl} \]

(c) $\text{CH}_3\text{CHCH}_2\text{CH}_2$

\[ (\text{a}) \quad \delta = 1.5 \text{ (d, 6 H) and 4.1 \text{ (q, 2 H) ppm}} \]

\[ (\text{i}) \quad \delta = 1.6 \text{ (d, 3 H), 2.1 \text{ (q, 2 H),} 3.6 \text{ (t, 2 H), and 4.2 \text{ (sex, 1 H) ppm}} \]

\[ (\text{ii}) \quad \delta = 1.0 \text{ (t, 3 H), 1.9 \text{ (quin, 2 H),} 3.6 \text{ (d, 2 H), and 3.9 \text{ (quin, 1 H) ppm}} \]

\[ (\text{iii}) \quad \delta = 1.5 \text{ (d, 6 H) and 4.1 \text{ (q, 2 H) ppm}} \]
44. Predict the spin–spin splitting that you would expect to observe in the NMR spectra of each compound in Problem 36. (Reminder: Hydrogens attached to oxygen and nitrogen do not normally exhibit spin–spin splitting.)

45. Predict the spin–spin splitting that you would expect to observe in the NMR spectra of each compound in Problem 37.

46. The $^1$H NMR chemical shifts are given for each of the following compounds. As best you can, assign each signal to the proper group of hydrogens in the molecule and sketch a spectrum for each compound, incorporating spin–spin splitting whenever appropriate. (a) Cl$_2$CHCH$_2$Cl, $\delta$ 4.0 and 5.8 ppm; (b) CH$_3$CHBrCH$_2$CH$_3$, $\delta$ 1.0, 1.7, 1.8, and 4.1 ppm; (c) CH$_3$CH$_2$CH$_2$COOCH$_3$, $\delta$ 1.0, 1.7, 2.3, and 3.6 ppm; (d) CICH$_2$CHOHCH$_3$, $\delta$ 1.2, 3.0, 3.4, and 3.9 ppm.

47. $^1$H NMR spectra C through F (see below) correspond to four isomeric alcohols with the molecular formula C$_3$H$_{12}$O. Try to assign their structures.

48. Sketch $^1$H NMR spectra for the following compounds. Estimate chemical shifts (see Section 10-4) and show the proper multiplets for peaks that exhibit spin–spin coupling. (a) CH$_3$CH$_2$OCH$_2$Br; (b) CH$_3$OCH$_2$CH$_2$Br; (c) CH$_3$CH$_2$CH$_2$OCH$_2$CH$_2$CH$_3$; (d) CH$_3$CH(OCH$_3$)$_2$. 
49. A hydrocarbon with the formula \( C_6H_{14} \) gives rise to \(^1H\) NMR spectrum G (margin). What is its structure? This molecule has a structural feature similar to that of another compound whose spectrum is illustrated in this chapter. What molecule is that? Explain the similarities and differences in the spectra of the two.

50. Treatment of the alcohol corresponding to NMR spectrum D in Problem 47 with hot concentrated HBr yields a substance with the formula \( C_5H_{11}Br \). Its \(^1H\) NMR spectrum exhibits signals at \( \delta = 1.0 \) (t, 3 H), 1.2 (s, 6 H), and 1.6 (q, 2 H) ppm. Explain. (Hint: See NMR spectrum C in Problem 42.)

51. The \(^1H\) NMR spectrum of 1-chloropentane is shown at 60 MHz (spectrum H) and 500 MHz (spectrum I). Explain the differences in appearance of the two spectra, and assign the signals to specific hydrogens in the molecule.

52. Describe the spin–spin splitting patterns that you expect for each signal in the \(^1H\) NMR spectra of the five bromocyclopropane derivatives illustrated in Problem 35. Note that in these compounds the geminal coupling constants (i.e., between nonequivalent hydrogens on the same carbon atom—Section 10-7) and trans vicinal coupling constants are smaller (ca. 5 Hz) than the cis vicinal coupling constants (ca. 8 Hz).
53. Can the three isomeric pentanes be distinguished unambiguously from their broad-band proton-decoupled $^{13}$C NMR spectra alone? Can the five isomeric hexanes be distinguished in this way?

54. Predict the $^{13}$C NMR spectra of the compounds in Problem 36, with and without proton decoupling.

55. Rework Problem 37 as it pertains to $^{13}$C NMR spectroscopy.

56. How would the DEPT $^{13}$C spectra of the compounds discussed in Problems 35 and 37 differ in appearance from the ordinary $^{13}$C spectra?

57. From each group of three molecules, choose the one whose structure is most consistent with the proton-decoupled $^{13}$C NMR data. Explain your choices. (a) CH$_3$(CH$_2$)$_2$CH$_3$, (CH$_3$)$_2$CHCH$_2$CH$_3$, (CH$_3$)$_2$CHCH(CH$_3$)$_2$; δ = 19.5 and 33.9 ppm. (b) 1-Chlorobutane, 1-chloropentane, 3-chloropentane; δ = 13.2, 20.0, 34.6, and 44.6 ppm. (c) Cyclopentanone, cycloheptanone, cyclononanone; δ = 24.0, 30.0, 43.5, and 214.9 ppm. (d) ClCH$_2$CHClCH$_2$Cl, CH$_3$CCl$_2$CH$_2$Cl, CH$_2$ = CHCH$_2$Cl; δ = 45.1, 118.3, and 133.8 ppm. (Hint: Consult Table 10-6.)

58. Propose a reasonable structure for each of the following molecules on the basis of the given molecular formula and of the $^1$H and proton-decoupled $^{13}$C NMR data. (a) C$_7$H$_{16}$O, spectra J and K (* = CH$_2$ by DEPT); (b) C$_7$H$_{16}$O$_2$, spectra L and M (the assignments in M were made by DEPT).
59. **[CHALLENGE]** The $^1$H NMR spectrum of cholesteryl benzoate (see Section 4-7) is shown as spectrum N. Although complex, it contains a number of distinguishing features. Analyze the absorptions marked by integrated values. The inset is an expansion of the signal at $\delta = 4.85$ ppm and exhibits an approximately first-order splitting pattern. How would you describe this pattern? ([**Hint**](#): The peak patterns at $\delta = 2.5, 4.85, \text{and } 5.4$ ppm are simplified by the occurrence of chemical shift and/or coupling constant equivalencies.)

60. **[CHALLENGE]** The terpene $\alpha$-terpineol has the molecular formula $\text{C}_{10}\text{H}_{18}\text{O}$ and is a constituent of pine oil. As the -ol ending in the name suggests, it is an alcohol. Use its $^1$H NMR spectrum (spectrum O, p. 443) to deduce as much as you can about the structure of $\alpha$-terpineol. ([**Hints**](#): (1) $\alpha$-Terpineol has the same 1-methyl-4-(1-methylethyl)cyclohexane framework found in a number of other terpenes (e.g., carvone, Problem 43 of Chapter 5). (2) In your analysis of spectrum O, concentrate on the most obvious features (peaks at $\delta = 1.1, 1.6, \text{and } 5.4$) and use chemical shifts, integrations, and the splitting of the $\delta 5.4$ signal (inset) to help you.)
Study of the solvolysis of derivatives of menthol [5-methyl-2-(1-methylethyl)-cyclohexanol] has greatly enhanced our understanding of these types of reactions. Heating the isomer of the 4-methylbenzenesulfonate ester shown below in 2,2,2-trifluoro-ethanol (a highly ionizing solvent of low nucleophilicity) leads to two products with the molecular formula C_{10}H_{18}.

(a) The major product displays 10 different signals in its $^{13}$C NMR spectrum. Two of them are at relatively low field, about $\delta = 120$ and 145 ppm, respectively. The $^1$H NMR spectrum exhibits a multiplet near $\delta = 5$ ppm (1 H); all other signals are upfield of $\delta = 3$ ppm. Identify this compound.

(b) The minor product gives only seven $^{13}$C signals. Again, two are at low field ($\delta \sim 125$ and 140 ppm), but, in contrast with the $^1$H NMR data on the major isomer, there are no signals at lower field than $\delta = 3$ ppm. Identify this product and explain its formation mechanistically.

(c) When the solvolysis is carried out starting with the ester labeled with deuterium at C2, the $^1$H spectrum of the resulting major product isomer in (a) reveals a significant reduction of the intensity of the signal at $\delta = 5$ ppm, a result indicating the partial incorporation of deuterium at the position associated with this peak. How might this result be explained? [Hint: The answer lies in the mechanism of formation of the minor product in (b).]

Team Problem

62. Your team is faced with a puzzle. Four isomeric compounds, A–D, with the molecular formula C_{4}H_{9}BrO react with KOH to produce E–G with the molecular formula C_{4}H_{8}O. Molecules A and B yield compounds E and F, respectively. The NMR spectra of compounds C and D are identical, and both furnish the same product, G. Although some of the starting materials are optically active, none of the products is. Moreover, each of E, F, and G displays only two $^1$H NMR signals of varying chemical shifts, none of them located between $\delta = 4.6$ and 5.7 ppm. Both the respective resonances of E and G are complex, whereas F exhibits two singlets. Proton-decoupled $^{13}$C NMR spectra for E and G show only two peaks, whereas F exhibits three. Using this spectral information, work together to determine which isomers of C_{4}H_{9}BrO will yield the respective isomers of C_{4}H_{8}O. When you have matched reactant and product, divide the task of predicting the proton and carbon NMR spectra of E, F, and G among yourselves. Estimate the $^1$H and $^{13}$C chemical shifts for all, and predict the respective DEPT spectra.
Preprofessional Problems

63. The molecule (CH₃)₄Si (tetramethylsilane) is used as an internal standard in ¹H NMR spectroscopy. One of the following properties makes it especially useful. Which one?
   (a) Highly paramagnetic    (b) Highly colored    (c) Highly volatile
   (d) Highly nucleophilic

64. One of the following compounds will show a doublet as part of its ¹H NMR spectrum. Which one?
   (a) CH₄    (b) ClCH(CH₃)₂    (c) CH₃CH₂CH₃    (d) H₂C=CH₂

65. In the ¹H NMR spectrum of 1-fluorobutane, the most deshielded hydrogens are those bound to
   (a) C₄    (b) C₃    (c) C₂    (d) C₁

66. One of the following compounds will have one peak in its ¹H NMR spectrum and two peaks in its ¹³C NMR spectrum. Which one?
   (a) [Diagram of a molecule]    (b) [Diagram of a molecule]    (c) CH₃—CH₃    (d) CH₃CHCHCH₃    (e) [Diagram of a molecule]
What differentiates solid shortening from liquid cooking oil? Remarkably, the only significant structural difference is that the liquid contains carbon–carbon double bonds and the solid does not. Cooking oils are derivatives of alkenes, the simplest organic compounds containing multiple bonds. In this chapter and in Chapter 12, we shall investigate the properties, generation, and reactivity of alkenes.

In the preceding several chapters, we learned that haloalkanes and alcohols, two major classes of compounds containing single-bonded functional groups, may undergo elimination under appropriate conditions to form alkenes. In this chapter we return to these processes and explore some additional features that affect their outcome. We shall then proceed in Chapter 12 to examine the reactions of alkenes, and we shall discover that they may be converted back into single-bonded substances by the process of addition. Thus, we shall see how alkenes can serve as intermediaries in many synthetic conversions. They are useful and economically valuable starting materials for plastics, synthetic fibers, construction materials, and many other industrially important substances. For example, addition reactions of many gaseous alkenes give oils as products, which is why this class of compounds used to be called “olefins” (from oleum facere, Latin, to make oil). Indeed, “margarine” is a shortened version of the original name, cis-9-Octadecenoic acid, also known as oleic acid, makes up more than 80% of natural olive oil extracted from the fruit of the European olive tree. It is acknowledged to be one of the most beneficial of all the food-derived fats and oils for human cardiovascular health. In contrast, the isomeric compound in which the double bond possesses trans instead of cis geometry has been found to have numerous adverse health effects.

\[ \text{Alkene double bond} \]
Because alkenes can undergo addition reactions, they are described as **unsaturated** compounds. In contrast, alkanes, which possess the maximum number of single bonds and thus are inert with respect to addition, are referred to as **saturated**.

We begin with the names and physical properties of the alkenes and show how we evaluate the relative stability of their isomers. A review of elimination reactions allows us to further our discussion of alkene preparation.

We also introduce two additional methods for determining molecular structure: a second type of spectroscopy — infrared (IR) spectroscopy — and a technique for determining the elemental composition of a molecule — mass spectrometry (MS). These methods complement NMR by ascertaining directly the presence or absence of functional groups and their characteristic bonds (O–H, C=O, etc.), as well as their arrangement in the overall structure.

### 11-1 Naming the Alkenes

A carbon–carbon double bond is the characteristic functional group of the alkenes. Their general formula is C\text{n}H\text{2n}, the same as that for the cycloalkanes.

Like other organic compounds, some alkenes are still known by common names, in which the `-ane` ending of the corresponding alkane is replaced by `-ylene`. Substituent names are added as prefixes.

#### Common Names of Typical Alkenes

<table>
<thead>
<tr>
<th>Chemical Structure</th>
<th>Common Name</th>
<th>Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>CH\text{2}=CH\text{2}</td>
<td>Ethylene</td>
<td>(Fruit-ripening hormone in plants)</td>
</tr>
<tr>
<td>CH\text{2}=CH\text{3}</td>
<td>Propylene</td>
<td>(Raw material for plastics)</td>
</tr>
<tr>
<td>Cl\text{2}=C\text{2}</td>
<td>Trichloroethylene</td>
<td>(Common cleaning solvent)</td>
</tr>
</tbody>
</table>

In IUPAC nomenclature, the simpler ending `-ene` is used instead of `-ylene`, as in ethene and propene. More complicated systems require adaptations and extensions of the rules for naming alkanes (Section 2-5).

**Rule 1.** To name the stem, find the longest chain that includes both carbons making up the double bond. The molecule may have longer carbon chains, but ignore them.

- **Methylmethylpentene**
- **Propylpropyloctene**
- **Ethylmethylene**

**Rule 2.** Indicate the location of the double bond in the main chain by number, starting at the end closer to the double bond. (Cycloalkenes do not require the numerical prefix, but the carbons making up the double bond are assigned the numbers 1 and 2, unless another group takes precedence; see rule 6.) Alkenes that have the same molecular formula but differ in the

*The name margarine itself originates indirectly from the Greek, *margaron*, pearl, and directly from margaric acid, the common name given to one of the constituent fatty acids of margarine, heptadecanoic acid, because of the shiny, “pearly” crystals it forms.*
location of the double bond (such as 1-butene and 2-butene) are constitutional isomers that are also called double-bond isomers. A 1-alkene is also referred to as a terminal alkene; the others are called internal. Note that alkenes are easily depicted in line notation.

**Rule 3.** Add substituents and their positions to the alkene name as prefixes. If the alkene stem is symmetric, begin from the end that gives the first substituent along the chain the lowest possible number.

**Exercise 11-1**

Name the following two alkenes.

(a)  
(b)  

**Rule 4.** Identify any stereoisomers. In a 1,2-disubstituted ethene, the two substituents may be on the same side of the molecule or on opposite sides. The first stereochemical arrangement is called cis and the second trans, in analogy to the cis-trans names of the disubstituted cycloalkanes (Section 4-1). Two alkenes of the same molecular formula differing only in their stereochemistry are called geometric or cis-trans isomers and are examples of diastereomers: stereoisomers that are not mirror images of each other.

**Exercise 11-2**

Name the following three alkenes.

(a)  
(b)  
(c)  

...
In the smaller substituted cycloalkenes, the double bond can exist only in the cis configuration. The trans arrangement is prohibitively strained (as building a model reveals). However, in larger cycloalkenes, trans isomers are stable.

\[
\begin{align*}
3\text{-Fluoro-1-methylcyclopentene} & \\
1\text{-Ethyl-2,4-dimethylcyclohexene} & \\
\text{trans-Cyclodecene}
\end{align*}
\]
(In both cases, only the cis isomer is stable)

**Rule 5.** The labels *cis* and *trans* cannot be applied when there are three or four different substituents attached to the double-bond carbons. An alternative system for naming such alkenes has been adopted by IUPAC: the *E,Z* system. In this convention, the sequence rules devised for establishing priority in *R,S* names (Section 5-3) are applied separately to the two groups on each double-bonded carbon. When the two groups of higher priority are on opposite sides, the molecule is of the *E* configuration (*E* from *entgegen*, German, opposite). When the two substituents of higher priority appear on the same side, the molecule is a *Z* isomer (*Z* from *zusammen*, German, together).

\[
\begin{align*}
(Z)-1\text{-Bromo-1,2-difluoroethene} & \\
(E)-1\text{-Chloro-3-ethyl-4-methyl-3-heptene}
\end{align*}
\]

**Exercise 11-3**

Name the following three alkenes.

(a) \[
\begin{align*}
\text{D} & \\
\text{H}_2\text{C} & \\
\text{C} & \\
\text{C} & \\
\text{D} & \\
\text{H}
\end{align*}
\]
(b) \[
\begin{align*}
\text{F} & \\
\text{H}_2\text{C} & \\
\text{C} & \\
\text{C} & \\
\text{CH}_2\text{CH}_3 & \\
\text{OCH}_3
\end{align*}
\]
(c) \[
\begin{align*}
\text{Cl} & \\
\text{CH}_2\text{CH}_2\text{CH}_3 & \\
\text{CH}_2\text{CH}_3 & \\
\text{Cl}\text{CH}_2\text{CH}_2 & \\
\text{CH}_3
\end{align*}
\]

**Rule 6.** With the alkenes, we are introducing a new functional group after the alcohols. This rule addresses the problem that arises when we have both functions in a compound: Do we call it an alkene or an alcohol? The answer is that we give the hydroxy functional group precedence over the double bond. Therefore, we name alcohols containing double bonds *alkenols*, and the stem *incorporating both functions* is numbered to give the carbon bearing the OH group the lowest possible assignment. Note that the last *e* in alkene is dropped in the naming of alkenols.

\[
\begin{align*}
\text{2-Propen-1-ol} & \\
\text{(Not 1-propen-3-ol)} & \\
\text{(Z)-5-Chloro-3-ethyl-4-hexen-2-ol} & \\
\text{(The two stereocenters are unspecified)} & \\
\text{3-Cyclohexen-1-ol} & \\
\text{(Not 1-cyclohexen-4-ol)} & \\
\end{align*}
\]

**Exercise 11-4**

Draw the structures of the following molecules: (a) *trans*-3-penten-1-ol; (b) 2-cyclohexen-1-ol.
Rule 7. Substituents containing a double bond are named alkenyl; for example, ethenyl (common name, vinyl), 2-propenyl (allyl), and cis-1-propenyl.

As usual, the numbering of a substituent chain begins at the point of attachment to the basic stem. The example below constitutes an alkenol. However, we cannot incorporate both functional groups into the stem name. Therefore, the double bond is part of the substituent to the cyclooctanol.

Exercise 11-5
(a) Draw the structure of trans-2-ethenylcyclopropanol. (b) Name the structure shown in the margin.

11-2 Structure and Bonding in Ethene: The Pi Bond

The carbon–carbon double bond in alkenes has special electronic and structural features. This section reviews the hybridization of the carbon atoms in this functional group, the nature of its two bonds (σ and π), and their relative strengths. We consider ethene, the simplest of the alkenes.

The double bond consists of sigma and pi components

Ethene is planar, with two trigonal carbon atoms and bond angles close to 120° (Figure 11-1). Therefore, both carbon atoms are best described as being sp² hybridized (Section 1-8; Figure 1-21). Two sp² hybrids on each carbon atom overlap with hydrogen 1s orbitals to form the four C–H σ bonds. The remaining sp² orbitals, one on each carbon, overlap with each other to form the carbon–carbon σ bond. Each carbon also possesses a 2p orbital; these are aligned parallel to each other and are close enough to overlap, forming the π bond (Figure 11-2A). The electron density in a π bond is distributed over both carbons above and below the molecular plane, as indicated in Figure 11-2B.
The pi bond in ethene is relatively weak

How much do the $\sigma$ and $\pi$ bonds each contribute to the total double-bond strength? We know from Section 1-7 that bonds are made by overlap of orbitals and that their relative strengths depend on the effectiveness of this overlap. Therefore, we can expect overlap in a $\sigma$ bond to be considerably better than that in a $\pi$ bond, because the $sp^2$ orbitals lie along the internuclear axis (Figure 11-2). This situation is illustrated in energy-level-interaction diagrams (Figures 11-3 and 11-4) analogous to those used to describe the bonding in the hydrogen molecule (Figures 1-11 and 1-12). Figure 11-5 summarizes our predictions of the relative energies of the molecular orbitals that make up the double bond in ethene.

**Figure 11-3** Overlap between two $sp^2$ hybrid orbitals (containing one electron each; shown in red) determines the relative strength of the $\sigma$ bond of ethene. In-phase interaction between regions of the wave function having the same sign reinforces bonding (compare in-phase overlap of waves, Figure 1-4B) and creates a bonding molecular orbital. [Recall: These signs do not refer to charges; the + designations are chosen arbitrarily (see Figure 1-11).] Both electrons end up occupying this orbital and have a high probability of being located near the internuclear axis. The orbital stabilization energy, $\Delta E_{\sigma}$, corresponds to the $\sigma$-bond strength. The out-of-phase interaction, between regions of opposite sign (compare Figure 1-4C), results in an unfilled antibonding molecular orbital (designated $\sigma^*$) with a node.

**Thermal isomerization allows us to measure the strength of the pi bond**

How do these predictions of the $\pi$-bond strength compare with experimental values? We can measure the energy required to interconvert the cis form of a substituted alkene—say, 1,2-dideuterioethene—with its trans isomer. In this process, called thermal isomerization,
the two \( p \) orbitals making up the \( \pi \) bond are rotated 180°. At the midpoint of this rotation—90°—the \( \pi \) (but not the \( \sigma \)) bond has been broken (Figure 11-6). Thus, the activation energy for the reaction can be roughly equated with the \( \pi \) energy of the double bond.

Thermal isomerization occurs, but only at high temperatures (>400°C). Its activation energy is 65 kcal mol\(^{-1}\) (272 kJ mol\(^{-1}\)), a value we may assign to the strength of the \( \pi \) bond. Below 300°C, double bonds are configurationally stable; that is, cis stays cis and trans stays

![Figure 11-4](image)

**Figure 11-4** Compare this picture of the formation of the \( \pi \) bond in ethene with Figure 11-3. In-phase interaction between two parallel \( p \) orbitals (containing one electron each; shown in blue) results in positive overlap and a filled bonding \( \pi \) orbital. The representation of this orbital indicates the probability of finding the electrons between the carbons above and below the molecular plane. Because \( \pi \) overlap is less effective than \( \sigma \), the stabilization energy, \( \Delta E_{\pi} \), is smaller than \( \Delta E_{\sigma} \). The \( \pi \) bond is therefore weaker than the \( \sigma \) bond. The out-of-phase interaction results in the antibonding molecular orbital \( \pi^* \).

![Figure 11-5](image)

**Figure 11-5** Energy ordering of the molecular orbitals making up the double bond. The four electrons occupy only bonding orbitals.

![Figure 11-6](image)

**Figure 11-6** Thermal isomerization of cis-dideuterioethene to the trans isomer requires breaking the \( \pi \) bond. The reaction proceeds from starting material (A) through rotation around the C–C bond until it reaches the point of highest energy, the transition state (B). At this stage, the two \( p \) orbitals used to construct the \( \pi \) bond are perpendicular to each other. Further rotation in the same direction results in a product in which the two deuterium atoms are trans (C).

**Remember:**
The symbol \( \dagger \) in Figure 11-6 denotes a transition state.
trans. The strength of the double bond in ethene—the energy required for dissociation into two CH₂ fragments—is 173 kcal mol⁻¹ (724 kJ mol⁻¹). Consequently the C–C σ bond amounts to about 108 kcal mol⁻¹ (452 kJ mol⁻¹, Figure 11-7). Note that the other σ bonds to the alkenyl carbon are also stronger than the analogous bonds in alkanes (Table 3-2). This effect is due largely to improved bonding overlap involving the relatively compact \( sp^2 \) orbitals.

As one consequence, the strongly bound alkenyl hydrogens are not abstracted in radical reactions. Instead, additions to the weaker \( \pi \) bond characterize the reactivity of alkenes (Chapter 12).

In Summary The characteristic hybridization scheme for the double bond of an alkene accounts for its physical and electronic features. Alkenes contain a planar double bond, incorporating trigonal carbon atoms. Their hybridization explains the strong \( \sigma \) and weaker \( \pi \) bonds, stable cis and trans isomers, and the strength of the alkenyl-substituent bond. Alkenes are prone to undergo addition reactions, in which the weaker \( \pi \) bond but not the C–C \( \sigma \) bond is broken.

### 11-3 Physical Properties of Alkenes

The carbon–carbon double bond alters many of the physical properties of alkenes relative to those of alkanes. Exceptions are boiling points, which are very similar, primarily a result of similar London forces (Figure 2-6C). Like their alkane counterparts, ethene, propene, and the butenes are gases at room temperature. Melting points, however, depend in part on the packing of molecules in the crystal lattice, a function of molecular shape. The double bond in cis-disubstituted alkenes imposes a U-shaped bend in the molecule that disrupts packing and reduces the melting point, usually below that of either the corresponding alkane or isomeric trans alkene (Table 11-1). A cis double bond is responsible for the sub-room-temperature melting point of vegetable oil.

Depending on their structure, alkenes may exhibit weak dipolar character. Why? Bonds between alkyl groups and an alkenyl carbon are polarized in the direction of the \( sp^2 \)-hybridized atom, because the degree of \( s \) character in an \( sp^3 \) hybrid orbital is greater than that in an \( sp^2 \). Electrons in orbitals with increased \( s \) character are held closer to the nucleus than those in orbitals containing more \( p \) character. This effect makes the \( sp^2 \) carbon relatively electron withdrawing (although much less so than strongly electronegative atoms such as O and Cl) and creates a weak dipole along the substituent weak–alkenyl carbon bond.

In cis-disubstituted alkenes, the two individual dipoles combine to give a net molecular dipole. These dipoles are opposed in trans-disubstituted alkenes and tend to cancel each other. The more polar cis-disubstituted alkenes often have slightly higher boiling points than their trans counterparts. The boiling-point difference is greater when the individual bond dipoles are larger, as in the case of the two 1,2-dichloroethene isomers, whose highly electronegative chlorine atoms also cause the direction of the bond dipoles to be reversed.

Another consequence of the electron-attracting character of the \( sp^3 \) carbon is the increased acidity of the alkenyl hydrogen. Whereas ethane has an approximate \( pK_a \) of 50,
ethene is somewhat more acidic with a $pK_a$ of 44. Even so, ethene is a very weak acid compared with other compounds, such as the carboxylic acids or alcohols.

![Acidity of the Ethenyl Hydrogen]

**Exercise 11-6**

Ethenyllithium (vinylithium) is not generally prepared by direct deprotonation of ethene but rather from chloroethene (vinyl chloride) by metallation (Section 8-7).

$$\text{CH}_2=\text{CHCl} + 2 \text{Li} \rightarrow \text{CH}_2=\text{CHLi} + \text{LiCl}$$

Upon treatment of ethenyllithium with acetone followed by aqueous work-up, a colorless liquid is obtained in 74% yield. Propose a structure.

**In Summary** The presence of the double bond does not greatly affect the boiling points of alkenes, compared with alkanes, but cis-disubstituted alkenes usually have lower melting points than their trans isomers, because the cis compounds pack less well in the solid state. Alkenyl hydrogens are more acidic than those in alkanes because of the electron-withdrawing character of the $sp^2$-hybridized alkenyl carbon.

### 11-4 Nuclear Magnetic Resonance of Alkenes

The double bond exerts characteristic effects on the $^1H$ and $^{13}C$ chemical shifts of alkenes (see Tables 10-2 and 10-6). Let’s see how to make use of this information in structural assignments.

**The pi electrons exert a deshielding effect on alkenyl hydrogens**

Figure 11-8 shows the $^1H$ NMR spectrum of trans-2,2,5,5-tetramethyl-3-hexene. Only two signals are observed, one for the 18 equivalent methyl hydrogens and one for the 2 alkenyl protons. The absorptions appear as singlets because the methyl hydrogens are too far away from the alkenyl hydrogens to produce detectable coupling. The low-field resonance of the alkenyl hydrogens ($\delta = 5.30$ ppm) is typical of hydrogen atoms bound to alkenyl carbons. Terminal alkenyl hydrogens (RR'C=CH$_2$) resonate at $\delta = 4.6$–5.0 ppm, their internal counterparts (RCH=CHR') at $\delta = 5.2$–5.7 ppm.

Why is deshielding so pronounced for alkenyl hydrogens? Although the electron-withdrawing character of the $sp^2$-hybridized carbon is partly responsible, another phenomenon is more important: the movement of the electrons in the $\pi$ bond. When subjected to an external magnetic field perpendicular to the double-bond axis, these electrons enter into a circular motion. This motion induces a local magnetic field that reinforces the external
**Figure 11-8** 300-MHz $^1$H NMR spectrum of trans-2,2,5,5-tetramethyl-3-hexene, illustrating the deshielding effect of the π bond in alkenes. It reveals two sharp singlets for two sets of hydrogens: the 18 methyl hydrogens at $\delta = 0.97$ ppm and 2 highly deshielded alkenyl protons at $\delta = 5.30$ ppm.

**Figure 11-9** Movement of electrons in the π bond causes pronounced deshielding of alkenyl hydrogens. An external field, $H_0$, induces a circular motion of the π electrons (shown in red) above and below the plane of a double bond. This motion in turn induces a local magnetic field (shown in green) that opposes $H_0$ at the center of the double bond but reinforces it in the regions occupied by the alkenyl hydrogens.

Field at the edge of the double bond (Figure 11-9). As a consequence, the alkenyl hydrogens are strongly deshielded (Section 10-4).

**Exercise 11-7**

The hydrogens on methyl groups attached to alkenyl carbons resonate at about $\delta = 1.6$ ppm (see Table 10-2). Explain the deshielding of these hydrogens relative to hydrogens on methyl groups in alkanes. (Hint: Try to apply the principles in Figure 11-9.)

**Cis coupling through a double bond is different from trans coupling**

When a double bond is not substituted symmetrically, the alkenyl hydrogens are nonequivalent, a situation leading to observable spin–spin coupling such as that shown in the spectra of cis- and trans-3-chloropropenoic acid (Figure 11-10). Note that the coupling constant
Figure 11-10 300-MHz
$^1$H NMR spectra of (A) \textit{cis}-3-chloropropenoic acid and (B) the corresponding \textit{trans} isomer. The two alkenyl hydrogens are non-equivalent and coupled. The broad carboxylic acid proton (–CO$_2$H) resonates at $\delta = 10.80$ ppm and is shown in the inset.

for the hydrogens situated \textit{cis} ($J = 9$ Hz) is different from that for the hydrogens arranged \textit{trans} ($J = 14$ Hz). Table 11-2 gives the magnitudes of the various possible couplings around a double bond. Although the range of $J_{\text{cis}}$ overlaps that of $J_{\text{trans}}$, within a set of isomers $J_{\text{cis}}$ is always smaller than $J_{\text{trans}}$. In this way cis and trans isomers can be readily distinguished.

Coupling between hydrogens on adjacent carbon atoms, such as $J_{\text{cis}}$ and $J_{\text{trans}}$, is called \textit{vicinal}. Coupling between nonequivalent hydrogens on the same carbon atom is referred to as \textit{geminal}. In alkenes, geminal coupling is usually small (Table 11-2). Coupling to neighboring alkyl hydrogens (\textit{allylic}, see Section 11-1) and across the double bond (1,4- or \textit{long-range}) also is possible, sometimes giving rise to complicated spectral patterns. Thus,

Further coupling leads to more complex spectra

The spectra of 3,3-dimethyl-1-butene and 1-pentene illustrate the potential complexity of the coupling patterns. In both spectra, the alkenyl hydrogens appear as complex multiplets. In 3,3-dimethyl-1-butene (Figure 11-11A), \(H_a\), located on the more highly substituted carbon atom, resonates at lower field (\(\delta = 5.86\) ppm) and in the form of a doublet of doublets with two relatively large coupling constants (trans \(J_{ab} = 18\) Hz, cis \(J_{ac} = 10.5\) Hz). Hydrogens \(H_b\) and \(H_c\) also absorb as a doublet of doublets each because of their respective coupling to \(H_a\) and their small mutual coupling (geminal \(J_{bc} = 1.5\) Hz). In the spectrum of 1-pentene (Figure 11-11B), additional coupling due to the attached alkyl group (see Table 11-2) creates a relatively complex pattern for the alkenyl hydrogens, although the two sets (terminal and internal) are clearly differentiated. In addition, the electron-withdrawing effect of the \(sp^2\) carbon and the movement of the \(\pi\) electrons (Figure 11-9) cause a slight deshielding of the directly attached (allylic) \(\text{CH}_2\) group. The magnitude of the coupling between these hydrogens and the neighboring alkenyl hydrogen is about the same (6–7 Hz) as the coupling with the two \(\text{CH}_2\) hydrogens on the other side. As a result, the multiplet for this allylic \(\text{CH}_2\) group appears as a quartet (with additional long-range couplings to the terminal alkenyl hydrogens), in accordance with the simple \(N + 1\) rule: \(N = (2\ \text{H from } \text{CH}_2) + (1\ \text{H from } \text{C} = \text{C}) = 3\).
Exercise 11-8

Working with the Concepts: Interpreting NMR Spectra of Alkenes

Ethyl 2-butoenoate (ethyl crotonate), $\text{CH}_2\text{CH}=$CHCO$_2\text{CH}_2\text{CH}_3$, in CCl$_4$ has the following $^1$H NMR spectrum: $\delta = 6.95$ (dq, $J = 16$, 6.8 Hz, 1 H), 5.81 (dq, $J = 16$, 1.7 Hz, 1 H), 4.13 (q, $J = 7$ Hz, 2 H), 1.88 (dd, $J = 6.8$, 1.7 Hz, 3 H), and 1.24 (t, $J = 7$ Hz, 3 H) ppm; dd denotes a doublet of doublets, dq a doublet of quartets. Assign the various hydrogens and indicate whether the double bond is substituted cis or trans (consult Table 11-2).

**Strategy**

You are given both the compound’s structure and the NMR data. Therefore, this problem consists of deciphering the information. The $^1$H NMR spectrum shows five signals, one for each of the five
distinct hydrogen environments in the molecule. Each signal has an integration value telling us the number of hydrogens giving rise to that signal, and that is where we start. Then we analyze the location and splitting (if any) of each signal in turn.

**Solution**

- Beginning with the highest-field (smallest δ ppm value) signal, at δ = 1.24 ppm, it integrates as 3 H; therefore, it must arise from one of the two CH3 groups in the molecule. Looking further, we see that it is split into a triplet, three lines. According to the N + 1 rule for spin–spin splitting, this tells us that the CH3 group giving rise to this signal is adjacent to a carbon bearing two hydrogens, the CH2 group in the structure (2 neighboring hydrogens + 1 = 3 lines). We can find the signal for this CH2 at δ = 4.13; as expected, it is a quartet (3 neighboring methyl hydrogens + 1 = 4 lines). By a process of elimination, the CH3 group on the alkene carbon must be responsible for the signal at δ = 1.88. This signal is split as a doublet of doublets, indicative of splitting to two distinct single hydrogens: the two different alkene hydrogens.

- We now turn to these final two hydrogens, which give signals at δ = 5.81 and 6.95 ppm, respectively. Both are doublets of quartets—in other words, eight-line patterns that appear as pairs of quartets. What does this imply? Each is evidently split into a quartet by the CH3 on the alkene carbon (3 + 1 = 4). Also, because the two alkene hydrogens are neighbors and in dissimilar environments, they split each other, causing the doublet splitting of each pattern (1 neighbor + 1 = 2 lines). Which is which? The alkene hydrogen at δ = 6.95 ppm shows the larger quartet splitting, 6.8 Hz, suggesting that it is the one adjacent to the CH3 group. The other alkene hydrogen, at δ = 5.81 ppm, shows a much smaller quartet splitting of 1.7 Hz, consistent with its increased distance to the methyl. Notice that the order in which the information is presented allows us to assign each coupling constant to each splitting: given “dq, J = 16, 6.8 Hz,” we infer that the first splitting (d) corresponds to the first J value (16 Hz), and the second (q) to the second J (6.8 Hz).

- Finally, with J = 16 Hz for the mutual splitting of the alkene hydrogens, we conclude from the data in Table 11-2 that they are trans to each other. In problems such as this, it is often instructive to reproduce all the information pictorially, as shown below. Notice that this representation is especially useful in revealing the mutual couplings by their identical J values, for example, 6.8 Hz for both the methyl hydrogens and the alkenyl hydrogen on the left. Identify the others on your own.

\[
\begin{align*}
\delta &= 1.88 \text{ (dd, } J = 6.8, 1.7 \text{ Hz, } 3 \text{ H)} \\
\delta &= 6.95 \text{ (dq, } J = 16, 6.8 \text{ Hz, } 1 \text{ H)} \\
\delta &= 4.13 \text{ (q, } J = 7 \text{ Hz, } 2 \text{ H)} \\
\delta &= 5.81 \text{ (dq, } J = 16, 1.7 \text{ Hz, } 1 \text{ H)} \\
\delta &= 4.97 \text{ (dd, } J = 14.4, 1.6 \text{ Hz, } 1 \text{ H)} \\
\delta &= 3.86 \text{ (dd, } J = 6.8, 1.6 \text{ Hz, } 1 \text{ H)} \\
\delta &= 2.10 \text{ (s, } 3 \text{ H)}
\end{align*}
\]

**Exercise 11-9**

**Try It Yourself**

Ethenyl acetate, CH3COCH═CH2, displays the following 1H NMR data: δ = 7.23 (dd, J = 14.4, 6.8 Hz, 1 H), 4.73 (dd, J = 14.4, 1.6 Hz, 1 H), 4.52 (dd, J = 6.8, 1.6 Hz, 1 H), 2.10 (s, 3 H). Interpret this spectrum.

**Alkenyl carbons are deshielded in 13C NMR**

The carbon NMR absorptions of the alkenes also are highly revealing. Relative to alkanes, the corresponding alkenyl carbons (with similar substituents) absorb at about 100 ppm lower field (see Table 10-6). Two examples are shown in Table 11-3, in which the carbon chemical shifts of an alkene are compared with those of its saturated counterpart. Recall that, in broad-band decoupled 13C NMR spectroscopy, all magnetically unique carbons absorb as sharp single lines (Section 10-9). It is therefore very easy to determine the presence of sp2 carbons by this method.
CHEMICAL HIGHLIGHT 11-1

Prostaglandins

NMR analysis is widely used to determine the structures of complex molecules containing multiple functional groups. The first three compounds shown are members of the prostaglandin (PG) family of naturally occurring, biologically active substances. The \(^1\)H NMR spectra of these PGs reveal some aspects of their structures, but overall they are quite complicated, with many overlapping signals. In contrast, \(^1\)C NMR permits rapid distinction between PG derivatives, merely by counting the peaks in three chemical-shift ranges. For example, PGE\(_2\) is readily distinguished by the presence of two signals near \(\delta = 70\) ppm for two hydroxy carbons, four alkene \(^1\)C resonances between \(\delta = 125\) and 140 ppm, and two carbonyls above \(\delta = 170\) ppm.

Prostaglandins are extremely potent hormonelike substances with many biological functions, including muscle stimulation, inhibition of platelet aggregation, lowering of blood pressure, enhancement of inflammatory reactions, and induction of labor in childbirth. Indeed, the anti-inflammatory effects of aspirin (see Chemical Highlight 22-2) are due to its ability to suppress prostaglandin biosynthesis. An undesirable side effect of aspirin use is gastric ulceration, because some prostaglandins function to protect the stomach lining. The synthetic prostaglandin-like substance misoprostol exhibits a similar protective effect and is frequently administered together with aspirin or other anti-inflammatory agents to prevent ulcer formation.

In Summary Hydrogen NMR is highly effective in establishing the presence of double bonds in organic molecules. Alkenyl hydrogens and carbons are strongly deshielded. The order of coupling is \(J_{\text{gem}} < J_{\text{cis}} < J_{\text{trans}}\). Coupling constants for allylic substituents display characteristic values as well. \(^1\)C NMR identifies alkenyl carbons by their unusually low-field chemical shifts, compared with those of alkane carbons.

11-5 Catalytic Hydrogenation of Alkenes: Relative Stability of Double Bonds

When an alkene and hydrogen gas are mixed in the presence of catalysts such as palladium or platinum, two hydrogen atoms add to the double bond to give the saturated alkane (see Section 12-2). This reaction, which is called hydrogenation, is very exothermic. The heat released, called heat of hydrogenation, is typically about \(-30\) kcal mol\(^{-1}\) (\(-125\) kJ mol\(^{-1}\)) per double bond.

\[
\begin{align*}
\text{Hydrogenation of an Alkene} \\
\text{C\_C} + \text{H\_H} & \xrightarrow{\text{Pd or Pt}} \text{C\_C} \\
\Delta H^\circ & \approx -30 \text{ kcal mol}^{-1}
\end{align*}
\]
Heats of hydrogenation can be measured so accurately that they may be used to determine the relative energy contents, and therefore the thermodynamic stabilities, of alkenes. Let us see how this is done.

The heat of hydrogenation is a measure of stability

In Section 3-10 we presented one method for determining relative stability: measuring heat of combustion. The less stable the molecule, the greater its energy content, and the more energy is released in this process. A very similar connection can be established using heats of hydrogenation.

For example, what are the relative stabilities of the three isomers 1-butene, cis-2-butene, and trans-2-butene? Hydrogenation of each isomer leads to the same product: butane. If their respective energy contents are equal, their heats of hydrogenation should also be equal; however, as the reactions in Figure 11-12 illustrate, they are not. The most heat is evolved by hydrogenation of the terminal double bond, the next most exothermic reaction is that with cis-2-butene, and finally the trans isomer gives off the least heat. Therefore, the thermodynamic stability of the butenes increases in the order 1-butene < cis-2-butene < trans-2-butene (Figure 11-12).

Highly substituted alkenes are most stable; trans isomers are more stable than cis isomers

The results of the preceding hydrogenation reactions may be generalized: The relative stability of the alkenes increases with increasing substitution, and trans isomers are usually more stable than their cis counterparts. The first trend is due in part to hyperconjugation. Just as the stability of a radical increases with increasing alkyl substitution (Section 3-2),

![Image of chemical structures and heats of hydrogenation](image-url)

**Figure 11-12** The relative energy contents of the butene isomers, as measured by their heats of hydrogenation, tell us their relative stabilities. The diagram is not drawn to scale.
Chapter 11

461

the $p$ orbitals of a $\pi$ bond can be stabilized by alkyl substituents. The second finding is easily understood by looking at molecular models. In cis-disubstituted alkenes, the substituent groups frequently crowd each other.

![Molecular model of trans-Cyclooctene](image)

**Relative Stabilities of the Alkenes**

CH$_2$=CH$_2$ < RCH=CH$_2$ < \(\text{(cis)}\) \(\text{(trans)}\) < \(\text{(cis)}\) \(\text{(trans)}\) < \(\text{(cis)}\) \(\text{(trans)}\) < \(\text{(cis)}\) \(\text{(trans)}\)

Least stable

Increasing alkene stability

Decreasing heat of hydrogenation

Most stable

This steric interference is energetically unfavorable and absent in the corresponding trans isomers (Figure 11-13).

**Exercise 11-10**

Rank the following alkenes in order of stability of the double bond to hydrogenation (order of $\Delta H^\circ$ of hydrogenation): 2,3-dimethyl-2-butene, cis-3-hexene, trans-4-octene, and 1-hexene.

Cycloalkenes are exceptions to the generalization that trans alkenes are more stable than their cis isomers. In the medium-ring and smaller members of this class of compounds (Section 4-2), the trans isomers are much more strained (Section 11-1). The smallest isolated simple trans cycloalkene is trans-cyclooctene. It is 9.2 kcal mol$^{-1}$ (38.5 kJ mol$^{-1}$) less stable than the cis isomer and has a highly twisted structure.

**Exercise 11-11**

Alkene A hydrogenates to compound B with an estimated release of 65 kcal mol$^{-1}$, more than double the values of the hydrogenations shown in Figure 11-12. Explain.

\[ \text{A} \quad \text{H}_2\text{, catalyst} \quad \text{B} \quad \Delta H^\circ = -65 \text{ kcal mol}^{-1} \]

**In Summary** The relative energies of isomeric alkenes can be estimated by measuring their heats of hydrogenation. The more energetic alkene has a higher $\Delta H^\circ$ of hydrogenation. Stability increases with increasing substitution because of hyperconjugation. Trans alkenes are more stable than their cis isomers because of steric hindrance. Exceptions are the small- and medium-ring cycloalkenes, in which cis substitution is more stable than trans substitution because of ring strain.
11-6 Preparation of Alkenes from Haloalkanes and Alkyl Sulfonates: Bimolecular Elimination Revisited

With the physical aspects of alkene structure and stability as a background, let us now return to the various ways in which alkenes can be made. The most general approach is by elimination, in which two adjacent groups on a carbon framework are removed. The E2 reaction (Section 7-7) is the most common laboratory source of alkenes. Another method of alkene synthesis, the dehydration of alcohols, is described in Section 11-7.

Regioselectivity in E2 reactions depends on the base

In Chapter 7 we discussed how haloalkanes (or alkyl sulfonates) in the presence of strong base can undergo elimination of the elements of HX with simultaneous formation of a carbon–carbon double bond. With many substrates, removal of a hydrogen can take place from more than one carbon atom in a molecule, giving rise to constitutional (double-bond) isomers. In such cases, can we control which hydrogen is removed—that is, the regioselectivity of the reaction (Section 9-9)? The answer is yes, to a limited extent. A simple example is the elimination of hydrogen bromide from 2-bromo-2-methylbutane. Reaction with sodium ethoxide in hot ethanol furnishes mainly 2-methyl-2-butene, but also some 2-methyl-1-butene.

In our example, the major product contains a trisubstituted double bond, so it is thermodynamically more stable than the minor product. Indeed, many eliminations are regioselective in this way, with the more stable product predominating. This result can be explained by analysis of the transition state of the reaction (Figure 11-14). Elimination of HBr proceeds through attack by the base on one of the neighboring hydrogens situated anti to the leaving group. In the transition state, there is partial C–H bond rupture, partial C–C double-bond formation, and partial cleavage at C–Br (compare Figure 7-8). The transition state leading to 2-methyl-2-butene is slightly more stabilized than that generating 2-methyl-1-butene (Figure 11-15A). The more stable product is formed faster because the structure of the transition state of the reaction resembles that of the products. Elimination reactions of this type that lead to the more highly substituted alkene are said to follow the Saytzev* rule: The

*Alexander M. Saytzev (also spelled Zaitsev or Saytzeff; 1841–1910), Russian chemist.
double bond forms preferentially between the carbon that contained the leaving group and the most highly substituted adjacent carbon that bears a hydrogen. A different product distribution is obtained when a more hindered base is used; more of the thermodynamically less favored terminal alkene is generated.

**E2 Reaction of 2-Bromo-2-methylbutane with tert-Butoxide, a Hindered Base**

More accessible primary hydrogens

\[
\text{CH}_3\text{CH}_2\text{C} = \text{CH}_3 + (\text{CH}_3\text{CO})^-\text{K}^+ \rightarrow \text{H}_2\text{C} = \text{C} - \text{HCH}_3 + \text{CH}_3\text{CH}_2\text{C} = \text{CH}_2
\]

27% 73%
To see why the terminal alkene is now favored, we again examine the transition state. Removal of a secondary hydrogen (from C3 in the starting bromide) is sterically more difficult than abstracting one of the more exposed methyl hydrogens. When the bulky base tert-butoxide is used, the energy of the transition state leading to the more stable product is increased by steric interference relative to that leading to the less substituted isomer; thus, the less substituted isomer becomes the major product (Figure 11-15B). An E2 reaction that generates the thermodynamically less favored isomer is said to follow the Hofmann rule,* named after the chemist who investigated a series of eliminations that proceeded with this particular mode of regioselectivity (Section 21-8).

**Exercise 11-12**

**Working with the Concepts: Regioselectivity in Elimination**

When the following reaction is carried out with tert-butoxide in 2-methyl-2-propanol (tert-butyl alcohol), two products, A and B, are formed in the ratio 23:77. When ethoxide in ethanol is used, this ratio changes to 82:18. What are products A and B, and how do you explain the difference in their ratios in the two experiments?

![Reaction diagram](image)

**Strategy**

The difference between the two experiments is the use of a hindered base (tert-butoxide) in one and an unhindered base (ethoxide) in the other. Following the ideas presented in the text, we should expect A and B to be regiosomeric products of E2 reactions, arising from the removal of hydrogens from different carbon atoms adjacent to the one bearing the sulfonate leaving group.

**Solution**

- The bulky tert-butoxide is more likely to abstract a hydrogen atom from the less hindered adjacent (methyl) carbon atom, giving mostly B, the Hofmann-rule product:

![Major (Hofmann) product](image)

- On the other hand, ethoxide preferentially removes a hydrogen from the tertiary carbon atom on the other side, because the result is the more stable trisubstituted alkene A, the Saytzev product:

![Major (Saytzev) product (More stable)](image)

*Professor August Wilhelm von Hofmann (1818–1892), University of Berlin.
**Exercise 11-13**

**Try It Yourself**

(a) E2 reaction of 2-bromo-2,3-dimethylbutane, \((\text{CH}_3)_2\text{CBrCH(CH}_3)_2\), gives two products, A and B, in a 79:21 ratio using ethoxide in ethanol but a 27:73 ratio with tert-butoxide in 2-methyl-2-propanol. What are A and B? (b) Use of \((\text{CH}_3\text{CH}_2)_3\text{CO}^-\) as the base gives an 8:92 ratio of A and B. Explain.

---

**E2 reactions often favor trans over cis**

Depending on the structure of the alkyl substrate, the E2 reaction can lead to cis-trans alkene mixtures, in some cases with selectivity. For example, treatment of 2-bromopentane with sodium ethoxide furnishes 51% trans- and only 18% cis-2-pentene, the remainder of the product being the terminal regioisomer. The outcome of this and related reactions appears to be controlled again to some extent by the relative thermodynamic stabilities of the products, the more stable trans double bond being formed preferentially.

![Stereoselective Dehydrobromination of 2-Bromopentane](image)

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{Br} \
\text{H} \quad \xrightarrow{\text{CH}_3\text{CH}_2\text{O}^-\text{Na}} \quad \text{CH}_3\text{CH}_2\text{H} \quad + \quad \text{CH}_3\text{CH}_2\text{H} \quad + \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{H} \quad = \quad \text{CH}_2
\]

51%  
18%  
31%

Unfortunately from a synthetic viewpoint, complete trans selectivity is rare in E2 reactions. Chapter 13 deals with alternative methods for the preparation of stereochemically pure cis and trans alkenes.

---

**Some E2 processes are stereospecific**

Recall (Section 7-7) that the preferred transition state of elimination places the proton to be removed and the leaving group anti with respect to each other. Thus, before an E2 reaction takes place, bond rotation to an anti conformation occurs. This fact has additional consequences when reaction may lead to Z or E stereoisomers. For example, the E2 reaction of the two diastereomers of 2-bromo-3-methylpentane to give 3-methyl-2-pentene is stereospecific. Both the \((R,R)\) and the \((S,S)\) isomer yield exclusively the \((E)\) isomer of the alkene. Conversely, the \((R,S)\) and \((S,R)\) diastereomers give only the \((Z)\) alkene. (Build models!)

As shown in the three-dimensional structures on the next page, anti elimination of HBr dictates the eventual configuration around the double bond. The reaction is stereospecific: One diastereomer (and its mirror image) produces only one stereoisomeric alkene, the other diastereomer furnishing the opposite configuration.

---

**Exercise 11-14**

Which diastereomer of 2-bromo-3-deuteriobutane gives \((E)-2\)-deuterio-2-butene, and which diastereomer gives the \((Z)\) isomer?

---

**In Summary** Alkenes are most generally made by E2 reactions. Usually, the thermodynamically more stable internal alkenes are formed faster than the terminal isomers (Saytzev rule). Bulky bases may favor the formation of the products with thermodynamically less stable (e.g., terminal) double bonds (Hofmann rule). Elimination may be stereoselective, producing greater quantities of trans isomers than their cis counterparts from racemic starting materials. It also may be stereospecific, certain haloalkane diastereomers furnishing only one of the two possible stereoisomeric alkenes.
Preparation of Alkenes by Dehydration of Alcohols

We have seen that treatment of alcohols with mineral acid at elevated temperatures results in alkene formation by loss of water, a process called dehydration, which proceeds by E1 or E2 pathways (Chapters 7 and 9). This section reviews this chemistry, now from the perspective of the alkene product. The usual way in which to dehydrate an alcohol is to heat it in the presence of sulfuric or phosphoric acid at relatively high temperatures (120–170°C).

Acid-Mediated Dehydration of Alcohols

The ease of elimination of water from alcohols increases with increasing substitution of the hydroxy-bearing carbon.
Relative Reactivity of Alcohols (ROH) in Dehydration Reactions

Increasing ease of dehydration

Secondary and tertiary alcohols dehydrate by the unimolecular elimination pathway (E1), discussed in Sections 7-6 and 9-2. Protonation of the weakly basic hydroxy oxygen forms an alkoxonium ion, now containing water as a good potential leaving group. Loss of H₂O supplies the respective secondary or tertiary carbenium ions and deprotonation furnishes the alkene. The reaction is subject to all the side reactions of which carbenium ions are capable, particularly hydrogen and alkyl shifts (Section 9-3).

Exercise 11-15

Referring to Sections 7-6 and 9-3, write a mechanism for the preceding reaction. **(Caution:** As emphasized repeatedly, when writing mechanisms, use “arrow pushing” to depict electron flow; write out every step separately; formulate complete structures, including charges and relevant electron pairs; and draw explicit reaction arrows to connect starting materials or intermediates with their respective products. Don’t use shortcuts, and don’t be sloppy!)

Typically, the thermodynamically most stable alkene or alkene mixture results from unimolecular dehydration in the presence of acid. Thus, whenever possible, the most highly substituted system is generated; if there is a choice, trans-substituted alkenes predominate over the cis isomers. For example, acid-catalyzed dehydration of 2-butanol furnishes the equilibrium mixture of butenes, consisting of 74% trans-2-butene, 23% of the cis isomer, and only 3% 1-butene.

Treatment of primary alcohols with mineral acids at elevated temperatures also leads to alkenes; for example, ethanol gives ethene and 1-propanol yields propene (Section 9-7).
The mechanism of this reaction begins with the initial protonation of oxygen. Then, attack by hydrogen sulfate ion or another alcohol molecule effects bimolecular elimination of a proton from one carbon atom and a water molecule from the other.

**In Summary** Alkenes can be made by dehydration of alcohols. Secondary and tertiary systems proceed through carbocation intermediates, whereas primary alcohols can undergo E2 reactions from the intermediate alkyl oxonium ions. All systems are subject to rearrangement and thus frequently give mixtures.

### 11-8 Infrared Spectroscopy

The remaining sections in this chapter deal with two additional methods for the determination of the structures of organic compounds: infrared (IR) spectroscopy and mass spectrometry (MS). IR spectroscopy is a very useful tool because it is capable of detecting the characteristic bonds of many functional groups through their absorption of infrared light. IR spectroscopy measures the vibrational excitation of atoms around the bonds that connect them. The positions of the absorption lines associated with this excitation depend on the types of functional groups present, and the IR spectrum as a whole displays a pattern unique for each individual substance.

**Absorption of infrared light causes molecular vibrations**

At energies slightly lower than those of visible radiation, light causes vibrational excitation of the bonds in a molecule. This part of the electromagnetic spectrum is the infrared region (see Figure 10-2). The intermediate range, or middle infrared, is most useful to the organic chemist. IR absorption bands are described by either the wavelength, \( \lambda \), of the absorbed light in micrometers \( (10^{-6} \text{ m}; \lambda = 2.5–16.7 \mu \text{m}) \); see Figure 10-2) or its reciprocal value, called wavenumber, \( \tilde{\nu} \) (in units of \( \text{cm}^{-1} \); \( \tilde{\nu} = 1/\lambda \)). Thus, a typical infrared spectrum ranges from \( \tilde{\nu} = 600 \) to \( 4000 \text{ cm}^{-1} \), and the energy changes associated with absorption of this radiation range from 1 to 10 kcal mol\(^{-1} \) (4 to 42 kJ mol\(^{-1} \)).

Figure 10-3 described the general principles of a spectrometer, which apply also to an infrared instrument. Modern systems use sophisticated rapid-scan techniques and are linked with computers. This equipment allows for data storage, spectra manipulation, and computer library searches, so that unknown compounds can be matched with stored spectra.

We can envision vibrational excitation simply by thinking of two atoms, A and B, linked by a flexible bond. Picture the atoms as two masses connected by a bond that stretches and compresses at a certain frequency, \( \nu \), like a spring (Figure 11-16). In this picture, the frequency of the vibrations between two atoms depends both on the strength of the bond between them and on their atomic weights. In fact, it is governed by Hooke’s* law, just like the motion of a spring.

---

*Professor Robert Hooke (1635–1703), physicist at Gresham College, London.
11-8 Infrared Spectroscopy

Hooke’s Law and Vibrational Excitation

\[ \nu = k \sqrt{\frac{f (m_1 + m_2)}{m_1 m_2}} \]

- \( \nu \) = vibrational frequency in wavenumbers (cm\(^{-1}\))
- \( k \) = constant
- \( f \) = force constant, indicating the strength of the spring (bond)
- \( m_1, m_2 \) = masses of attached atoms

This equation might lead us to expect every individual bond in a molecule to show one specific absorption band in the infrared spectrum. However, in practice, an interpretation of the entire infrared spectrum is considerably more complex and beyond the needs of the organic chemist. This is because molecules that absorb infrared light undergo not only stretching, but also various bending motions (Figure 11-17), as well as combinations of the two. The bending vibrations are mostly of weaker intensity, they overlap with other absorptions, and they may show complicated patterns. In addition, for a bond to absorb infrared light, its vibrational motion must cause a change in the molecular dipole. Therefore, vibrations of polar bonds give strong infrared absorption bands, whereas absorptions associated with nonpolar bonds may be weak or entirely absent. The practicing organic chemist can find good use for IR spectroscopy for two reasons: The vibrational bands of many functional groups appear at characteristic frequencies; furthermore, the entire infrared spectrum of any given compound is unique in its pattern and can be distinguished from that of any other substance.

Functional groups have typical infrared absorptions

Table 11-4 lists the characteristic stretching wavenumber values for the bonds (shown in red) in some common structural units. Notice how most absorb in the region above 1500 cm\(^{-1}\). We shall show the IR spectra typical of new functional groups when we introduce each of the corresponding compound classes in subsequent chapters.

Figures 11-18 and 11-19 show the IR spectra of pentane and hexane. Above 1500 cm\(^{-1}\), we see only the C–H stretching absorptions typical of alkanes, in the range from 2840 to 3000 cm\(^{-1}\); no functional groups are present, and the two spectra are very similar in this

![Figure 11-17 Various vibrational modes around tetrahedral carbon. The motions are labeled symmetric and asymmetric stretching or bending, scissoring, rocking, twisting, and wagging.](image-url)
Figure 11-18 IR spectrum of pentane. Note the format: Wavenumber is plotted (decreasing from left to right) against percentage of transmittance. A 100% transmittance means no absorption; therefore “peaks” in an IR spectrum point downward. The spectrum shows absorbances at $\tilde{\nu}_{\text{C-H stretch}} = 2960, 2930, \text{and } 2870 \text{ cm}^{-1}$; $\tilde{\nu}_{\text{C-H bend}} = 1460, 1380, \text{and } 730 \text{ cm}^{-1}$. The region between 600 and 1300 cm$^{-1}$ is also shown recorded at higher sensitivity (in red), revealing details of the pattern in the fingerprint region.
region. However, below 1500 cm\(^{-1}\), the spectra differ, as the scans at higher sensitivity show. This is the **fingerprint region**, in which absorptions due to C–C bond stretching and C–C and C–H bending motions overlap to give complicated patterns. Bands at approximately 1460, 1380, and 730 cm\(^{-1}\) are common to all saturated hydrocarbons.

Figure 11-20 shows the IR spectrum of 1-hexene. A characteristic feature of alkenes when compared with alkanes is the stronger C\(_{sp^2}\)-H bond, which should therefore have a band at higher energy in the IR spectrum. Indeed, as Figure 11-20 shows, there is a sharp spike at 3080 cm\(^{-1}\), due to this stretching mode, at a slightly higher wavenumber than the remainder of the C–H stretching absorptions. A useful rule of thumb is that C\(_{sp^3}\)-H bonds give rise to peaks below 3000 cm\(^{-1}\), whereas C\(_{sp^2}\)-H bonds absorb above 3000 cm\(^{-1}\). According to Table 11-4, the C=C stretching band should appear between about 1620 and 1680 cm\(^{-1}\). Figure 11-20 shows a sharp band at 1640 cm\(^{-1}\) assigned to this vibration. The other major peaks are the result of bending motions. For example, the two signals at 915 and 995 cm\(^{-1}\) are typical of a terminal alkene.
Approximate Infrared Frequencies of Major Bending Modes for Alkenes

Two other strong bending modes may be used as a diagnostic tool for the substitution pattern in alkenes. One mode results in a single band at 890 cm\(^{-1}\) and is characteristic of 1,1-dialkylethenes; the other gives a sharp band at 970 cm\(^{-1}\) and is produced by the C\(_{\pi}\)-H bending mode of a trans double bond. The C\(=\)C stretching absorption of internal alkenes is usually less intense than that in terminal alkenes, because vibration of an internal C\(=\)C bond causes less change in the molecular dipole. In highly symmetric molecules, such as trans-3-hexene, the band for the C\(=\)C vibration may be too weak to be observed readily. However, the alkanyl C\(=\)H bend in trans-3-hexene still gives a very strong, sharp absorption at 970 cm\(^{-1}\). In conjunction with NMR (Section 11-4), the presence or absence of such bands allows for fairly reliable structural assignments of specifically substituted double bonds.

The O–H stretching absorption is the most characteristic band in the IR spectra of alcohols (Chapters 8 and 9), appearing as a readily recognizable intense, broad absorption over a wide range (3200–3650 cm\(^{-1}\), Figure 11-21). The broadness of this band is due to hydrogen bonding to other alcohol molecules or to water. Dry alcohols in dilute solution exhibit sharp, narrow bands in the range from 3620 to 3650 cm\(^{-1}\). In contrast, the C–X bonds of haloalkanes (Chapters 6 and 7) possess IR stretching frequencies at energies too low (<800 cm\(^{-1}\)) to be generally useful for characterization.

**Exercise 11-17**

Three alkenes with the formula C\(_4\)H\(_8\) exhibit the following IR absorptions: alkene A, 964 cm\(^{-1}\); alkene B, 908 and 986 cm\(^{-1}\); alkene C, 890 cm\(^{-1}\). Assign a structure to each alkene.

**In Summary** The presence of specific functional groups can be ascertained by infrared spectroscopy. Infrared light causes the vibrational excitation of bonds in molecules. Strong bonds and light atoms vibrate at relatively high stretching frequencies measured in wavenumbers (reciprocal wavelengths). Conversely, weak bonds and heavy atoms absorb at lower wavenumbers, as would be expected from Hooke’s law. Highly polar bonds tend to exhibit more intense absorption bands. Because of the variety of stretching and bending modes, infrared spectra usually show complicated patterns. However, these patterns are diagnostic fingerprints for particular compounds. The presence of variously substituted alkenes may be detected by stretching signals at about 3080 (C–H) and 1640 (C\(=\)C) cm\(^{-1}\) and by bending modes between 890 and 990 cm\(^{-1}\). Alcohols show a characteristic band for the OH group in the range from 3200 to 3650 cm\(^{-1}\). As a general rule, bands in the left half of the IR spectrum (above 1500 cm\(^{-1}\)) identify functional groups, whereas absorptions in the right half (below 1500 cm\(^{-1}\)) characterize specific compounds.
11-9 Measuring the Molecular Mass of Organic Compounds: Mass Spectrometry

In the examples and problems dealing with structure determinations of organic compounds, we have so far been given the molecular formula of the “unknown.” How is this information obtained? Elemental analysis (Section 1-9) gives us an empirical formula, which tells us the ratios of the different elements in a molecule. However, empirical and molecular formulas are not necessarily identical. For example, elemental analysis of cyclohexane merely reveals the presence of carbon and hydrogen atoms in a 1:2 ratio; it does not tell us that the molecule contains six carbons and twelve hydrogens.

To determine molecular masses, the chemist turns to another important physical technique used to characterize organic molecules: mass spectrometry. This section begins with a description of the apparatus used and the physical principle on which it is based. Subsequently, we shall consider processes by which molecules fragment under the conditions required for molecular mass measurement, giving rise to characteristic recorded patterns called mass spectra. Mass spectra can help chemists distinguish between constitutional isomers and identify the presence of many functions such as hydroxy and alkenyl groups.

The mass spectrometer distinguishes ions by mass

Mass spectrometry is not a form of spectroscopy in the conventional sense, because no radiation is absorbed (Section 10-2). A sample of an organic compound is introduced into an inlet chamber (Figure 11-22, upper left). It is vaporized, and a small quantity is allowed to leak into the source chamber of the spectrometer. Here the neutral molecules (M) pass through a beam of high-energy [usually 70 eV, or about 1600 kcal mol\(^{-1}\) (6700 kJ mol\(^{-1}\))] electrons. Upon electron impact, some of the molecules lose an electron to form the corresponding radical cation, \(M^{+}\), called the parent or molecular ion. Most organic molecules undergo only a single ionization.
Ionization of a Molecule on Electron Impact

\[
\text{M} + e (70 \text{ eV}) \rightarrow \text{M}^{+} + 2e
\]

As charged particles, the molecular ions are next accelerated to high velocity by an electric field. (Molecules that are not ionized remain in the source chamber to be pumped away.) The accelerated \( \text{M}^{+} \) ions are then subjected to a magnetic field, which deflects them from a linear to a circular path. The curvature of this path is a function of the strength of the magnetic field. Much as in an NMR spectrometer (Section 10-3), the strength of the magnetic field can be varied and therefore adjusted to give the exact degree of curvature to the path of the ions necessary to direct them through the collector slit to the collector, where they are detected and counted. Because lighter species are deflected more than heavier ones, the strength of the field necessary to direct the ions through the slit to the collector is a function of the mass of \( \text{M}^{+} \) and therefore of the original molecule \( \text{M} \). Thus, at a given magnetic field strength, \textit{only ions of a specific mass can pass through the collector slit}. All others will collide with the internal walls of the instrument. Finally, the arrival of ions at the collector is translated electronically into a signal and recorded on a chart. The chart plots mass-to-charge ratio, \( m/z \) (on the abscissa), versus peak height (on the ordinate); peak height measures the relative number of ions with a given \( m/z \) ratio. Because only singly charged species are normally formed, \( z = 1 \), and \( m/z \) equals the mass of the ion being detected.

### Molecular Masses of Organic Molecules

- \( \text{CH}_4 \quad m/z = 16 \)
- \( \text{CH}_3\text{OH} \quad m/z = 32 \)
- \( \text{O} \)
- \( \text{CH}_2\text{COCH}_3 \quad m/z = 74 \)

### Exercise 11-18

Three unknown compounds containing only C, H, and O give rise to the following molecular weights. Draw as many reasonable structures as you can. (a) \( m/z = 46 \); (b) \( m/z = 30 \); (c) \( m/z = 56 \).

### High-resolution mass spectrometry reveals molecular formulas

Consider substances with the following molecular formulas: \( \text{C}_7\text{H}_{14} \), \( \text{C}_6\text{H}_{10}\text{O} \), \( \text{C}_5\text{H}_6\text{O}_2 \), and \( \text{C}_5\text{H}_{10}\text{N}_2 \). All possess the same \textit{integral mass}; that is, to the nearest integer, all four would be expected to exhibit a molecular ion at \( m/z = 98 \). However, the atomic weights of the elements are composites of the masses of their naturally occurring isotopes, which are \textit{not} integers. Thus, if we use the atomic masses for the most abundant isotopes of C, H, O, and N (Table 11-5) to calculate the \textit{exact mass} corresponding to each of the aforementioned molecular formulas, we see significant differences.

### Exact Masses of Four Compounds with \( m/z = 98 \)

<table>
<thead>
<tr>
<th>Compound</th>
<th>Exact Mass</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \text{C}<em>7\text{H}</em>{14} )</td>

<td>( \text{C}<em>5\text{H}</em>{10}\text{N}_2 )</td>
<td>98.0845</td>
</tr>
</tbody>
</table>

Can we use mass spectrometry to differentiate these species? Yes. Modern \textbf{high-resolution mass spectrometers} are capable of distinguishing among ions that differ in mass by as little as a few thousandths of a mass unit. We can therefore measure the exact mass of any molecular ion. By comparing this experimentally determined value with that calculated for each species possessing the same integral mass, we can assign a molecular formula to the unknown ion. High-resolution mass spectrometry is the most widely used method for determining the molecular formulas of unknowns.

### Exercise 11-19

Choose the molecular formula that matches the exact mass. (a) \( m/z = 112.0888 \), \( \text{C}_8\text{H}_{16} \), \( \text{C}_7\text{H}_{12}\text{O} \), or \( \text{C}_6\text{H}_4\text{O}_2 \); (b) \( m/z = 86.1096 \), \( \text{C}_6\text{H}_{14} \), \( \text{C}_6\text{H}_6\text{O}_2 \), or \( \text{C}_5\text{H}_{10}\text{N}_2 \).
Molecular ions undergo fragmentation

Mass spectrometry gives information not only about the molecular ion, but also about its component structural parts. Because the energy of the ionizing beam far exceeds that required to break typical organic bonds, some of the molecular ions break apart into virtually all possible combinations of neutral and ionized fragments. This fragmentation gives rise to a number of additional mass-spectral peaks, all of lower mass than the molecular ion from which they are derived. The spectrum that results is called the mass-spectral fragmentation pattern. The most intense peak in the spectrum is called the base peak. Its relative intensity is defined to be 100, and the intensities of all other peaks are described as a percentage of the intensity of the base peak. The base peak in a mass spectrum may be the molecular ion peak or it may be the peak of one of the fragment ions.

For example, the mass spectrum of methane contains, in addition to the molecular ion peak, lines for CH$_3^+$, CH$_2^+$, CH$^+$, and C$^+$ (Figure 11-23). These lines are formed by the processes shown in the margin. The relative abundances of these species, as indicated by the heights of the peaks, give a useful indication of the relative ease of their formation. It can be seen that the first C–H bond is cleaved readily, the m/z = 15 peak reaching 85% of the abundance of the molecular ion, which in this case is the base peak. The breaking of additional C–H bonds is increasingly difficult, and the corresponding ions have lower relative abundance. Section 11-10 considers the process of fragmentation in more detail and reveals how fragmentation patterns may be used as an aid to molecular structure determination.
Mass spectra reveal the presence of isotopes

An unusual feature in the mass spectrum of methane is a small (1.1%) peak at \( m/z = 17 \); it is designated \((M + 1)_{1}\)\(^{+}\). How is it possible to have an ion present that has an extra mass unit? The answer lies in the fact that carbon is not isotopically pure. About 1.1% of natural carbon is the \(^{13}\)C isotope (see Table 10-1), giving rise to the additional peak. In the mass spectrum of ethane, the height of the \((M + 1)_{1}\)\(^{+}\) peak, at \( m/z = 31 \), is about 2.2% that of the parent ion. The reason for this finding is statistical. The chance of finding a \(^{13}\)C atom but readily detectable: After the steroids are separated from the samples by GC, they undergo combustion to \( \text{CO}_2 \), and the mass spectrometer measures the ratio of \(^{13}\text{CO}_2\) to \(^{12}\text{CO}_2\). A \(^{13}\text{C}:^{12}\text{C}\) ratio that departs significantly from that found in normal human steroids and that approaches that found in plant-derived synthetics is considered to be strong evidence of “doping.”

---

**CHEMICAL HIGHLIGHT 11-3**

**Detecting Performance-Enhancing Drugs Using Mass Spectrometry**

Recent and rather notorious cases of using illicit substances to enhance athletic performance have highlighted the technology that has made the detection of these substances possible (see Chapter 4 Opening). An instrument called a gas chromatograph (GC) separates a test sample into its individual components, each of which is analyzed by high-resolution mass spectrometry. The success of this method in detecting “cheating” rests in its exquisite sensitivity and extremely high quantitative precision.

In cases of suspected administration of anabolic steroids such as testosterone (Section 4-7), two approaches are used. The first compares the ratio of testosterone (T) to its stereoisomer, epitestosterone (E; identical to T except that the hydroxy group on the five-membered ring is “down” instead of “up”). E and T occur naturally in humans in roughly equal amounts, but E, unlike T, does not enhance performance. Taking synthetic T alters the T:E ratio and is easily detected. Therefore, some athletes have taken synthetic T and E together, to maintain a T:E ratio within normal limits. Mass spectrometry identifies these situations, because of a quirk of biology: Synthetic steroids are made from plant-derived precursors, which have a slightly lower \(^{13}\text{C}\) content (relative to \(^{12}\text{C}\)) than do steroids biosynthesized naturally in the human body. The differences are quite small (parts per thousand)
in a compound containing two carbons is double that expected of a one-carbon molecule. For a three-carbon moiety, it would be threefold, and so on.

Other elements, too, have naturally occurring higher isotopes: Hydrogen (deuterium, \( ^2\text{H} \), about 0.015% abundance), nitrogen (0.366% \( ^{15}\text{N} \)), and oxygen (0.038% \( ^{17}\text{O} \), 0.200% \( ^{18}\text{O} \)) are examples. These isotopes also contribute to the intensity of peaks at masses higher than \( M^+ \), but less so than \( ^{13}\text{C} \).

Fluorine and iodine are isotopically pure. However, chlorine (75.53% \( ^{35}\text{Cl} \); 24.47% \( ^{37}\text{Cl} \)) and bromine (50.54% \( ^{79}\text{Br} \); 49.46% \( ^{81}\text{Br} \)) each exist as a mixture of two isotopes and give rise to readily identifiable isotopic patterns. For example, the mass spectrum of 1-bromopropane (Figure 11-24) shows two peaks of nearly equal intensity at \( m/z = 122 \) and 124. Why? The isotopic composition of the molecule is a nearly 1:1 mixture of \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \) and \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \). Similarly, the spectra of monochloroalkanes exhibit ions two mass units apart in a 3:1 intensity ratio, because of the presence of about 75% \( ^{35}\text{Cl} \) and 25% \( ^{37}\text{Cl} \). Peak patterns such as these are useful in revealing the presence of chlorine or bromine.

**Figure 11-24** Mass spectrum of 1-bromopropane. Note the nearly equal heights of the peaks at \( m/z = 122 \) and 124, owing to the almost equal abundances of the two bromine isotopes.

### Exercise 11-20
What peak pattern do you expect for the molecular ion of dibromomethane?

### Exercise 11-21
Nonradical compounds containing C, H, and O have even molecular weights, those containing C, H, O, and an odd number of N atoms have odd molecular weights, but those with an even number of N atoms are even again. Explain.

**In Summary** Molecules can be ionized by an electron beam at 70 eV to give radical cations that are accelerated by an electric field and then separated by the different deflections that they undergo in a magnetic field. In a mass spectrometer, this effect is used to measure the molecular masses of molecules. At high resolution, the mass of the molecular ion permits the determination of the molecular formula. The molecular ion is usually accompanied by less massive fragments and isotopic “satellites,” owing to the presence of less abundant isotopes. In some cases, such as with Cl and Br, more than one isotope may be present in substantial quantities.
11-10 Fragmentation Patterns of Organic Molecules

Upon electron impact, molecules dissociate by breaking weaker bonds first and then stronger ones. Because the original molecular ion is positively charged, its dissociation typically gives one neutral fragment and one that is cationic. Normally the cationic fragment that forms bears its charge at the center that is most capable of stabilizing a positive charge. This section illustrates how the preference to break weaker bonds and to form more stable carbocationic fragments combines to make mass spectrometry a powerful tool for molecular structure determination.

Fragmentation is more likely at a highly substituted center

The mass spectra of the isomeric hydrocarbons pentane, 2-methylbutane, and 2,2-dimethylpropane (Figures 11-25, 11-26, and 11-27) reveal the relative ease of the several possible C–C bond-dissociation processes. In each case, the molecular ion produces a relatively weak peak; otherwise, the spectra of the three compounds are very different.

**Figure 11-25** Mass spectrum of pentane, revealing that all C–C bonds in the chain have been ruptured.

**Figure 11-26** Mass spectrum of 2-methylbutane. The peaks at \( m/z = 43 \) and 57 result from preferred fragmentation around C2 to give secondary carbocations.
Pentane fragments by C–C bond-breaking in four possible ways, each of which gives a carbocation and a radical. Only the positively charged cation is observed in the mass spectrum (see margin); the radical, being neutral, is “invisible.” For example, one process breaks the C1–C2 bond to give a methyl cation and a butyl radical. The peak at \( m/z = 15 \) for \( \text{CH}_3^+ \) in the mass spectrum (Figure 11-25) is very weak, consistent with the instability of this carbocation (Section 7-5). Similarly, the peak at \( m/z = 57 \) is weak, because it derives from fragmentation into a butyl cation and a methyl radical, and although the primary butyl cation is more stable than \( \text{CH}_3^+ \), the methyl radical is a high-energy species. Thus this mode of fragmentation is not favored. The favored bond cleavages give peaks at \( m/z = 29 \) and 43, for the ethyl and propyl cations, respectively. Each of these fragmentations generates both a primary cation and a primary radical, and avoids formation of a methyl fragment. Each peak is surrounded by a cluster of smaller lines because of the presence of \(^{13}\text{C}\), which results in a peak at one mass unit higher, and the loss of hydrogens, which produces peaks at masses one or more units lower. Note that loss of \( \text{H}^- \) does not give a strong peak even if the carbocation left behind is stable: The hydrogen atom is a high-energy species (Section 3-1).

The mass spectrum of 2-methylbutane (Figure 11-26) shows a pattern similar to that of pentane; however, the relative intensities of the various peaks differ. Thus, the peak at \( m/z = 71 \) (\( \text{M} - 1^+ \)) is larger, because loss of \( \text{H}^- \) from C2 gives a tertiary cation. The signals at \( m/z = 43 \) and 57 are more intense, because both arise from loss of an alkyl radical from C2 to form a secondary carbocation.

**Preferred Fragmentation of 2-Methylbutane**

\[
\begin{align*}
\text{CH}_3^+ & \quad \text{propyl cation} \\
\text{C}_3\text{H}_7^+ & \quad \text{primary butyl cation} \\
[\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3]^+ & \quad \text{tertiary cation}
\end{align*}
\]

\[
\begin{align*}
\text{CH}_3^- & \quad \text{methyl radical} \\
\text{C}_2\text{H}_5^+ & \quad \text{primary ethyl cation} \\
\text{C}_4\text{H}_9^+ & \quad \text{primary propyl cation}
\end{align*}
\]

\[
\begin{align*}
\text{CH}_3^- & \quad \text{methyl radical} \\
\text{C}_2\text{H}_5^+ & \quad \text{primary ethyl cation} \\
\text{C}_4\text{H}_9^+ & \quad \text{primary propyl cation}
\end{align*}
\]

Figure 11-27 Mass spectrum of 2,2-dimethylpropane. Only a very weak molecular ion peak is seen, because the fragmentation to give a tertiary cation is favored.
Chapter 11
Alkenes; Infrared Spectroscopy and Mass Spectrometry

The preference for fragmentation at a highly substituted center is even more pronounced in the mass spectrum of 2,2-dimethylpropane (Figure 11-27). Here, loss of a methyl radical from the molecular ion produces the 1,1-dimethylethyl (tert-butyl) cation as the base peak at \( m/z = 57 \). This fragmentation is so easy that the molecular ion is barely visible. The spectrum also reveals peaks at \( m/z = 41 \) and 29, the result of complex structural rearrangements, such as the carbocation rearrangements considered in Section 9-3.

**Fragmentations also help to identify functional groups**

Particularly easy fragmentation of relatively weak bonds is also seen in the mass spectra of the haloalkanes. The fragment ion \( (M - X)^+ \) is frequently the base peak in these spectra. A similar phenomenon is observed in the mass spectra of alcohols, which eliminate water to give a large \( (M - H_2O)^+ \) peak 18 mass units below the parent ion (Figure 11-28). The bonds to the C–OH group also readily dissociate in a process called \( \alpha \) cleavage, leading to resonance-stabilized hydroxycarbocations:

\[
R + \overset{\cdots}{C} - \overset{\cdots}{OH} \xrightarrow{70 \text{ eV}} \overset{\cdots}{C} - \overset{\cdots}{OH} \quad \overset{\cdots}{C} = \overset{\cdots}{OH}
\]

The strong peak at \( m/z = 31 \) in the mass spectrum of 1-butanol is due to the hydroxymethyl cation, \( ^+\text{CH}_2\text{OH} \), which arises from \( \alpha \) cleavage.

**Alcohol Fragmentation by Dehydration and \( \alpha \) Cleavage**

\[
\begin{align*}
\left[ \text{HO} - \overset{\cdots}{C} - \overset{\cdots}{R} \right]^{**} & \to [\text{RCH} = \overset{\cdots}{C} + \overset{\cdots}{R'}]^{**} + \text{H}_2\text{O} \\
\text{M}^{**} & \to (M - 18)^{**} \\
\end{align*}
\]

**Figure 11-28** Mass spectrum of 1-butanol. The parent ion, at \( m/z = 74 \), gives rise to a small peak because of ready loss of water to give the ion at \( m/z = 56 \). Other fragment ions due to \( \alpha \) cleavage are propyl \( (m/z = 43) \), 2-propenyl (allyl) \( (m/z = 41) \), and hydroxymethyl \( (m/z = 31) \).
Alkenes fragment to give resonance-stabilized cations

The fragmentation patterns of alkenes also reflect a tendency to break weaker bonds and to form more stable cationic species. The bonds one atom removed from the alkene function—the so-called allylic bonds—are relatively easily broken, because the result is a resonance-stabilized carbocation. For example, the mass spectra of terminal straight-chain alkenes such as 1-butene reveal formation of the 2-propenyl (allyl) cation, at \( m/z = 41 \), the base peak in the spectrum (Figure 11-29A).

\[
\begin{align*}
&\text{Allylic bond} \\
&\left[ \text{CH}_2=\text{CH}-\text{CH}_2+\text{CH}_3 \right]_+ \xrightarrow{\text{CH}_3} \\
&\text{2-Propenyl (allyl) cation} \\
&\left[ \text{CH}_2=\text{CH}=\text{CH}_2 \right]_+ \\
&\text{CH}_3 \\
&\text{CH}_2 \\
&\text{CH}_3
\end{align*}
\]

\( m/z = 56 \)

Branched and internal alkenes fragment similarly at allylic bonds. Figure 11-29B shows the mass spectrum of 2-hexene, in which the base peak at \( m/z = 55 \) corresponds to formation of the resonance-stabilized 2-butenyl cation.

\[
\begin{align*}
&\text{2-Butenyl cation} \\
&\left[ \text{CH}_3=\text{CH}=\text{CH}=\text{CH}_2 \right]_+ \xrightarrow{\text{C}_2\text{H}_5} \\
&\text{CH}_3 \\
&\text{CH}_2 \\
&\text{CH}_3 \\
&\text{CH}_3
\end{align*}
\]

\( m/z = 84 \)

\( m/z = 55 \)

\[\text{Exercise 11-22} \]

Try to predict the appearance of the mass spectrum of 3-methyl-3-heptanol.

\[\text{Figure 11-29} \]

Mass spectra of (A) 1-butene, showing a peak at \( m/z = 41 \) from cleavage to give the resonance-stabilized 2-propenyl (allyl) cation; (B) 2-hexene, showing similar cleavage between C4 and C5 to give the 2-butenyl cation, with \( m/z = 55 \).
In Summary

Fragmentation patterns can be interpreted for structural elucidation. For example, the radical cations of alkanes cleave to form the most stable positively charged fragments, haloalkanes fragment by rupture of the carbon–halogen bond, alcohols readily dehydrate and undergo \( \alpha \) cleavage, and alkenes break an allylic bond to form a resonance-stabilized carbocation.

### 11-11 Degree of Unsaturation: Another Aid to Identifying Molecular Structure

NMR and IR spectroscopy and mass spectrometry are important tools for determining the structure of an unknown. However, concealed in the molecular formula of every compound is an additional piece of information that can make the job easier. Consider a saturated, acyclic alkane: Its molecular formula is \( \text{C}_n\text{H}_{2n+2} \). In contrast, an alkene containing one double bond contains two hydrogens less: \( \text{C}_n\text{H}_{2n} \); it is called unsaturated. Cycloalkanes also have the general formula \( \text{C}_n\text{H}_{2n} \). You can see that hydrocarbons containing several double bonds and/or rings will deviate from the “saturated” formula \( \text{C}_n\text{H}_{2n+2} \) by the appropriate number of fewer hydrogens. The **degree of unsaturation** is defined as the sum of the numbers of rings and \( \pi \) bonds present in the molecule. Table 11-6 illustrates the relation between molecular formula, structure, and degree of unsaturation for several hydrocarbons.

As Table 11-6 shows, each increase in the degree of unsaturation corresponds to a decrease of two hydrogens in the molecular formula. Therefore, starting with the general formula for acyclic alkanes (saturated; degree of unsaturation = 0), \( \text{C}_n\text{H}_{2n+2} \) (Section 2-4), the degree of unsaturation may be determined for any hydrocarbon merely by comparing the actual number of hydrogens present with the number required for the molecule to be saturated, namely, \( 2n + 2 \), where \( n = \) the number of carbon atoms present. For example, what is the degree of unsaturation in a hydrocarbon of the formula \( \text{C}_5\text{H}_8 \)? A saturated compound with five carbons has the formula \( \text{C}_5\text{H}_{12} \) (\( \text{C}_n\text{H}_{2n+2} \) with \( n = 5 \)). Because \( \text{C}_5\text{H}_8 \) is four hydrogens short of being saturated, the degree of unsaturation is \( 4/2 = 2 \). All molecules with this formula contain a combination of rings and \( \pi \) bonds adding up to two.

### Table 11-6 Degree of Unsaturation as a Key to Structure

</tbody>
</table>
The presence of heteroatoms may affect the calculation. Let us compare the molecular formulas of several saturated compounds: ethane, C₂H₆, and ethanol, C₂H₅O, have the same number of hydrogen atoms; chloroethane, C₂H₅Cl, has one less; ethanamine, C₂H₇N, one more. The number of hydrogens required for saturation is reduced by the presence of halogen, increased when nitrogen is present, and unaffected by oxygen. We can generalize the procedure for determination of the degree of unsaturation from a molecular formula as follows.

**Step 1.** Determine from the number of carbons \(n_C\), halogens \(n_X\), and nitrogens \(n_N\) in the molecular formula the number of hydrogens required for the molecule to be saturated, \(H_{\text{sat}}\).

\[
H_{\text{sat}} = 2n_C + 2 - n_X + n_N \quad \text{(Oxygen and sulfur are disregarded.)}
\]

**Step 2.** Compare \(H_{\text{sat}}\) with the actual number of hydrogens in the molecular formula, \(H_{\text{actual}}\), to determine the degree of unsaturation.

\[
\text{Degree of unsaturation} = \frac{H_{\text{sat}} - H_{\text{actual}}}{2}
\]

Alternatively, these steps may be combined into one formula:

\[
\text{Degree of unsaturation} = \frac{2n_C + 2 + n_N - n_X}{2}
\]

### Exercise 11-24

Calculate the degree of unsaturation indicated by each of the following molecular formulas.

(a) C₅H₁₀; (b) C₉H₁₂O; (c) C₈H₇ClO; (d) C₈H₁₅N; (e) C₄H₈Br₂.

### Exercise 11-25

**Working with the Concepts: Degree of Unsaturation in Structure Determination**

Spectroscopic data for three compounds with the molecular formula C₅H₈ are given below; \(m\) denotes a complex multiplet. Assign a structure to each compound. (Hint: One is acyclic; the others each contain one ring.)

(a) IR 910, 1000, 1650, 3100 cm⁻¹; \(^1\)H NMR \(\delta = 2.79\) (t, \(J = 8\) Hz), 4.8–6.2 (m) ppm, integrated intensity ratio of the signals = 1:3.

(b) IR 900, 995, 1650, 3050 cm⁻¹; \(^1\)H NMR \(\delta = 0.5–1.5\) (m), 4.8–6.0 (m) ppm, integrated intensity ratio of the signals = 5:3.

(c) IR 1611, 3065 cm⁻¹; \(^1\)H NMR \(\delta = 1.5–2.5\) (m), 5.7 (m) ppm, integrated intensity ratio of the signals = 3:1. Is there more than one possibility?

**Strategy**

Find the degree of unsaturation in order to set limits on the numbers of \(\pi\) bonds and rings. Use IR data to determine the presence or absence of \(\pi\) bonds. Then continue by using NMR data to define a reasonable structure possibility.

- The molecular formula C₅H₈ corresponds to a degree of unsaturation = 2. Therefore, all molecules must contain a combination of \(\pi\) bonds and rings adding up to two. Taking each in turn:
  - (a) Four bands are listed in the IR spectrum; those at 1650 and 3100 cm⁻¹ correspond unambiguously to alkene C=–C and alkenyl C–H stretching motions. The bands at 910 and 1000 cm⁻¹ are strongly suggestive of the presence of the terminal –CH=CH₂ group (Section 11-8). The NMR spectrum displays two signals in an intensity ratio of 1:3. Because the molecule contains eight hydrogens total, this information implies two groups of hydrogens, one containing two and the other six. The two-hydrogen signal, showing a triplet at \(\delta = 2.79\), would appear to be due to a –CH₂– unit, coupled to two neighboring hydrogens on the surrounding carbon atoms. The signal for six hydrogens is in the range \(\delta = 4.8–6.2\), typical of alkenyl hydrogens and must therefore correspond to two –CH=CH₂ groups. Combining these fragments, we obtain the structure CH₂=CH–CH₂–CH=CH₂.
  - (b) The IR data are essentially identical to those in (a), implying the presence of a –CH=CH₂ unit. The NMR spectrum shows a five-hydrogen signal at high field and a three-hydrogen signal in the alkenyl region. The three-hydrogen signal is consistent with –CH=CH₂, leaving us with a
The degree of unsaturation is equal to the sum of the numbers of rings and \( \pi \) bonds in a molecule. Calculation of this parameter makes solving structure problems from spectroscopic data easier.

**THE BIG PICTURE**

In this chapter, we looked at alkenes, a compound class characterized by the carbon–carbon double bond. In Chapters 7 and 9, we learned that alkenes are prepared synthetically by elimination reactions of haloalkanes and alcohols. In this chapter, we examined these reactions in more depth. We saw that the structure of the base determines what products will form in E2 elimination from haloalkanes. Similarly, the structure of an alcohol undergoing acid-catalyzed dehydration determines what mechanism takes place and how easily it occurs.

We also examined three additional methods that organic chemists use for determining molecular structure: calculation of the degree of unsaturation from a molecular formula, infrared (IR) spectroscopy, and mass spectrometry (MS). Mass spectrometry is the most important method for deriving the molecular formula; the degree of unsaturation tells us the total number of rings and \( \pi \) bonds in a molecule; IR spectra help identify the presence of the characteristic bonds of many functional groups. Combined with NMR spectra, this information is normally enough to determine a molecule’s structure. In later chapters, we shall cover ultraviolet (UV) spectroscopy, which provides information on multiple \( \pi \) bonds.

In the next chapter, we turn to the reactions of alkenes, to see how their unsaturated structure defines their chemical behavior and the compounds into which they may be converted.

**CHAPTER INTEGRATION PROBLEMS**

**11-27.** The relative rates of E2 reaction of bromoethane, 2-bromopropane, and 2-bromo-2-methylpropane with sodium ethoxide in ethanol at 25°C (at identical concentrations of substrate and base) are as follows: \( \text{CH}_3\text{CH}_2\text{Br}, 1; \text{CH}_3\text{CHBrCH}_3, 5; (\text{CH}_3)_3\text{CBr}, 40. \) Explain these data qualitatively.

**SOLUTION**

The E2 reaction is a one-step process. Therefore, its rate depends on the activation energy for this step, which in turn is related to the energy of the E2 transition state (Section 11-6). In addition, if some other reaction competes with the E2 process, the observed rate of elimination is diminished to the extent that some of the substrate molecules prefer to react via the alternative reaction pathway. For example, recall that bromoethane, a primary halide, reacts with ethoxide, a basic but nonbulky
nucleophile, predominantly by the \( S_N \)2 mechanism (Section 7-9). Comparison with 2-bromopropane, a secondary substrate, illustrates two points: (i) increased steric hindrance in 2-bromopropane interferes with substitution, reducing the competition from the \( S_N \)2 mechanism; and (ii) the E2 transition state, which resembles ethene in the case of bromoethane, drops in energy in the case of 2-bromopropane, because it now resembles propene, a more stable alkene. Both arguments may be carried forward to the case of 2-bromo-2-methylpropane, a tertiary halide, because (i) the \( S_N \)2 mechanism is sterically prohibited from taking place, and (ii) the E2 transition state now resembles 2-methylpropene, an even more stable alkene. Although unimolecular processes are now possible, at moderate to high concentrations of the strong base the tertiary substrate reacts preferentially via the E2 pathway.

11-28. Acid-catalyzed dehydration of 2-methyl-2-pentanol (dilute \( H_2S\)O\(_4\), 50° C) gives one major product and one minor product. Elemental analysis reveals that both contain only carbon and hydrogen in a 1:2 atom ratio, and high-resolution MS gives a mass of 84.0940 for the molecular ions of both compounds. Spectroscopic data for these substances are as follows:

1. Major product: IR 1660 and 3080 cm\(^{-1}\); \( ^1H \) NMR \( \delta = 0.91 \) (t, \( J = 7 \) Hz, 3 H), 1.60 (s, 3 H), 1.70 (s, 3 H), 1.98 (quin, \( J = 7 \) Hz, 2 H), and 5.08 (t, \( J = 7 \) Hz, 1 H) ppm.

2. Minor product: IR 1640 and 3090 cm\(^{-1}\); \( ^1H \) NMR \( \delta = 0.92 \) (t, \( J = 7 \) Hz, 3 H), 1.40 (sex, \( J = 7 \) Hz, 2 H), 1.74 (s, 3 H), 2.02 (t, \( J = 7 \) Hz, 2 H), and 4.78 (s, 2 H) ppm.

Deduce the structures of the products, suggest mechanisms for their formation, and discuss why the major product forms in the greater amount.

**SOLUTION**

First, we write the structure of the starting material (alcohol nomenclature, Section 8-1) and what we know about the reaction:

\[
\begin{align*}
\overset{\text{OH}}{\text{2-Methyl-2-pentanol}} & \quad \text{Dilute } H_2SO_4, 50^\circ C
\end{align*}
\]

This is an acid-catalyzed reaction of a tertiary alcohol (Section 11-7). Even though we may know enough to be able to make a sensible prediction, let us proceed by interpretation of the spectra first, and see if the answer that we get is consistent with our expectations.

Both compounds have the same molecular formula—they are isomers. The elemental analysis gives the empirical formula of CH\(_2\). The exact mass of CH\(_2\) is 12.000 \( \pm \) (1.00783) \( \times \) 14.01566. Thus, the MS data tell us that the molecular formula is 6(CH\(_2\)) = C\(_6\)H\(_{12}\), because 84.0940/14.01566 = 6.

For the major product, peaks at 1660 and 3080 cm\(^{-1}\) in the IR spectrum are in the ranges for the alkene C–C and C–H bond-stretching frequencies (1620–1680 and 3050–3150 cm\(^{-1}\), Table 11-3). Armed with this information, we turn to the NMR spectrum and immediately look for signals in the region characteristic of alkene hydrogens, \( d = 4.6–5.7 \) ppm (Table 10-2 and Section 11-4). Indeed, we find one at \( d = 5.08 \) ppm. The information following the chemical shift position (t, \( J = 7 \) Hz, 1 H) tells us that the signal is split into a triplet with a coupling constant of 7 Hz and has a relative integrated intensity corresponding to one hydrogen. The spectrum also shows three signals with integrations of 3 H each; it is usually reasonable to assume that simple signals with intensities of 3 between \( d = 0–4 \) ppm indicate the presence of methyl groups, unless information to the contrary appears. Two of the methyl groups are singlets, and the other appears as a triplet. Finally, a signal integrating for 2 H at \( d = 1.98 \) ppm is split into five lines. Assuming that a CH\(_2\) group gives rise to the latter signal, we have the following fragments to consider in piecing together a structure: CH–C, 3 CH\(_3\), and CH\(_2\). The sum of atoms in these fragments is C\(_6\)H\(_{12}\), in agreement with the formula given for the product and giving us confidence that we are on the right track. There is only a limited number of ways in which to connect these pieces into a proper structure:

\[
\begin{align*}
\text{CH}_3 & \quad \text{and} \quad \text{CH}_3
\end{align*}
\]

We can either use our chemical knowledge or, again, turn to the spectroscopy to determine which is correct. With the use of the splitting patterns in the NMR spectrum, a quick decision may be made. Using the \( N + 1 \) rule (Section 10-7), we see that, under ideal conditions, an NMR signal will be split by \( N \) neighboring hydrogens into \( N + 1 \) lines. In the first structure, the alkenyl hydrogen is neighbor to a CH\(_3\) group and should therefore appear with 3 + 1 = 4 lines, a quartet. The actual spectrum shows this signal as a triplet. Furthermore, this structure contains three methyl groups, but they have
0, 1, and 2 neighboring hydrogens, respectively, and should appear as one singlet, one doublet, and one triplet—again, in disagreement with the actual spectrum. In contrast, the second structure fits: the alkenyl hydrogen has two neighbors, consistent with the observed triplet splitting, and two of the three CH₃ groups are on an alkene carbon lacking a neighboring hydrogen and should be singlets. Using our chemical knowledge, we note that this correct structure has the same carbon connectivity as that of the starting material, whereas the incorrect one would have required a rearrangement.

Turning to the minor product, we use the same logic: Again, the IR spectrum shows an alkene C=C stretch (at 1640 cm⁻¹) and an alkanyl C–H stretch at 3090 cm⁻¹. The NMR spectrum contains a singlet at δ = 4.78, integrating for 2 H: two alkenyl hydrogens. It also shows two methyl signals, as well as two others integrating 2 H for each. Therefore, we have 2 CH₃, 2 CH₂, and 2 alkenyl H, adding again (with the two alkenyl carbons) to C₆H₁₂. Even though many possible combinations can be devised at this point, we can make use of NMR splitting information to close in rapidly on the answer. One of the CH₃ groups is a singlet, meaning that it must be attached to a carbon that lacks hydrogens. If we look at the preceding array of fragments, this latter carbon can only be an alkenyl carbon. Thus, we have CH₃–C=CH₂, in which the bold carbon is not attached to hydrogen. Therefore, by process of elimination, both alkenyl hydrogens must be attached to the other alkenyl carbon:

CH₃–C=CH₂. The remaining fragments can be attached to this piece in only one way, giving the final structure:

Thus, we can complete the equation stated at the beginning of the problem as follows:

Is this result in accord with our chemical expectations? Let us consider the mechanism (Section 11-7). Dehydration of a secondary or a tertiary alcohol under acidic conditions begins with protonation of the oxygen atom, giving a good potential leaving group (water). Departure of the leaving group results in a carbocation, and removal of a proton from a neighboring carbon atom (most likely by a second molecule of alcohol acting as a Lewis base) gives the alkene, overall an E1 process:

The major product is the one with the more substituted double bond, the thermodynamically more stable alkene (Sections 11-5 and 11-7), as is typical in E1 dehydrations.

**New Reactions**

1. **Hydrogenation of Alkenes (Section 11-5)**

   \[ \text{C} = \text{C} + \text{H}_2 \xrightarrow{\text{Pd or Pt}} \text{C} - \text{C} \quad \Delta H^\circ \approx -30 \text{ kcal mol}^{-1} \]

   Order of stability of the double bond

   \[ \text{R} \text{C}=\text{CH}_2 < \text{R} \text{C} = \text{C} \text{H} < \text{R} \text{C} = \text{C} \text{H} < \text{more substituted alkene} \]
Preparation of Alkenes

2. From Haloalkanes, E2 with Unhindered Base (Section 11-6)

\[
\begin{align*}
\text{H} & \quad - \quad \text{C} \quad - \quad \text{CH}_3 \\
\text{X} & \quad \text{CH}_3\text{CH}_2\text{O} \cdot \text{Na}^+, \text{CH}_3\text{CH}_2\text{OH} \\
\text{HX} & \quad \rightarrow \quad \text{C} \quad = \quad \text{C} \quad \text{CH}_3
\end{align*}
\]

Saytzev rule

More substituted (more stable) alkene

3. From Haloalkanes, E2 with Sterically Hindered Base (Section 11-6)

\[
\begin{align*}
\text{H} & \quad - \quad \text{C} \quad - \quad \text{CH}_3 \\
\text{X} & \quad \text{(CH}_3\text{)}_3\text{CO} \cdot \text{K}^+, \text{(CH}_3\text{)}_3\text{COH} \\
\text{HX} & \quad \rightarrow \quad \text{C} \quad = \quad \text{C} \quad \text{CH}_2
\end{align*}
\]

Hofmann rule

Less substituted (less stable) alkene

4. Stereochemistry of E2 Reaction (Section 11-6)

\[
\begin{align*}
\text{H} & \quad - \quad \text{C} \quad - \quad \text{R}' \\
\text{R}'' & \quad \text{R}''' & \quad \text{X} \quad \text{Base} \\
\text{HX} & \quad \rightarrow \quad \text{R}' \quad \text{R}'' \quad \text{R}''' & \quad \text{C} \quad = \quad \text{C} \quad \text{Base}
\end{align*}
\]

Anti elimination

5. Dehydration of Alcohols (Section 11-7)

\[
\begin{align*}
\text{H} & \quad - \quad \text{C} \quad - \quad \text{OH} \\
\text{H}_2\text{SO}_4, \Delta & \quad \rightarrow \quad \text{C} \quad = \quad \text{C} \quad \text{H}_2\text{O}
\end{align*}
\]

Most stable alkene is major product

Primary: E2 mechanism
Secondary, tertiary: E1 mechanism
Carbocations may rearrange

Order of reactivity: primary < secondary < tertiary

Important Concepts

1. Alkenes are unsaturated molecules. Their IUPAC names are derived from alkanes, the longest chain incorporating the double bond serving as the stem. Double-bond isomers include terminal, internal, cis, and trans arrangements. Tri- and tetrasubstituted alkenes are named according to the E,Z system, in which the R,S priority rules apply.

2. The double bond is composed of a \( \sigma \) bond and a \( \pi \) bond. The \( \sigma \) bond is obtained by overlap of the two \( sp^3 \) hybrid lobes on carbon, the \( \pi \) bond by interaction of the two remaining \( p \) orbitals. The \( \pi \) bond is weaker (~65 kcal mol\(^{-1}\)) than its \( \sigma \) counterpart (~108 kcal mol\(^{-1}\)) but strong enough to allow for the existence of stable cis and trans isomers.

3. The functional group in the alkenes is flat, \( sp^2 \) hybridization being responsible for the possibility of creating dipoles and for the relatively high acidity of the alkenyl hydrogen.

4. Alkenyl hydrogens and carbons appear at low field in \( ^1\text{H} \) NMR (\( \delta = 4.6–5.7 \) ppm) and \( ^{13}\text{C} \) NMR (\( \delta = 100–140 \) ppm) experiments, respectively. \( J_{\text{trans}} \) is larger than \( J_{\text{cis}} \), \( J_{\text{geminal}} \) is very small, and \( J_{\text{allylic}} \) is variable but small.

5. The relative stability of isomeric alkenes can be established by comparing heats of hydrogenation. It decreases with decreasing substitution; trans isomers are more stable than cis.

6. Elimination of haloalkanes (and other alkyl derivatives) may follow the Saytzev rule (nonbulky base, internal alkene formation) or the Hofmann rule (bulky base, terminal alkene formation). Trans alkenes as products predominate over cis alkenes. Elimination is stereospecific, as dictated by the anti transition state.

7. Dehydration of alcohols in the presence of strong acid usually leads to a mixture of products, with the most stable alkene being the major constituent.
8. Infrared spectroscopy measures vibrational excitation. The energy of the incident radiation ranges from about 1 to 10 kcal mol\(^{-1}\) (\(\lambda \approx 2.5 - 16.7 \text{ \mu m}\); \(\nu \approx 600 - 4000 \text{ cm}^{-1}\)). Characteristic peaks are observed for certain functional groups, a consequence of stretching, bending, and other modes of vibration, and their combination. Moreover, each molecule exhibits a characteristic infrared spectral pattern in the fingerprint region below 1500 cm\(^{-1}\).

9. Alkanes show IR bands characteristic of C–H bonds in the range from 2840 to 3000 cm\(^{-1}\). The C=C stretching absorption for alkenes is in the range from 1620 to 1680 cm\(^{-1}\), that for the alkenyl C–H bond is about 3100 cm\(^{-1}\). Bending modes sometimes give useful peaks below 1500 cm\(^{-1}\). Alcohols are usually characterized by a broad peak for the O–H stretch between 3200 and 3650 cm\(^{-1}\).

10. Mass spectrometry is a technique for ionizing molecules and separating the resulting ions magnetically by molecular mass. Because the ionizing beam has high energy, the ionized molecules also fragment into smaller particles, all of which are separated and recorded as the mass spectrum of a compound. High-resolution mass spectral data allow determination of molecular formulas from exact mass values. The presence of certain elements (such as Cl, Br) can be detected by their isotopic patterns. The presence of fragment-ion signals in mass spectra can be used to deduce the structure of a molecule.

11. Degree of unsaturation (number of rings + number of \(\pi\) bonds) is calculated from the molecular formula by using the equation

\[
\text{Degree of unsaturation} = \frac{H_{\text{sat}} - H_{\text{actual}}}{2}
\]

where \(H_{\text{sat}} = 2n_C + 2 - n_X + n_N\) (disregard oxygen and sulfur).

**Problems**

29. Draw the structures of the molecules with the following names.

(a) 4,4-Dichloro-trans-2-octene
(b) (Z)-4-bromo-2-iodo-2-pentene
(c) 5-Methyl-cis-3-hexen-1-ol
(d) (R)-1,3-Dichlorocycloheptene
(e) (E)-3-Methoxy-2-methyl-2-buten-1-ol

30. Name each of the following molecules in accord with the IUPAC system of nomenclature.

31. Name each of the compounds below. Use cis/trans and/or \(E/Z\) designations, if appropriate, to designate stereochemistry.

32. Of each pair of the following compounds, which one should have the higher dipole moment? The higher boiling point? (a) \text{cis-} or \text{trans-}1,2-Difluoroethene; (b) \text{Z-} or \text{E-}1,2-difluoropropene; (c) \text{Z-} or \text{E-}2,3-difluoro-2-butene

33. Draw the structures of each of the following compounds, rank them in order of acidity, and circle the most acidic hydrogen(s) in each: cyclopentane, cyclopentanol, cyclopentene, 3-cyclopenten-1-ol.
34. Assign structures to the following molecules on the basis of the indicated $^1$H NMR spectra A–E. Consider stereochemistry, where applicable.

(a) C$_4$H$_7$Cl, NMR spectrum A; (b) C$_5$H$_8$O$_2$, NMR spectrum B;
(c) C$_4$H$_8$O, NMR spectrum C; (d) another C$_4$H$_8$O, NMR spectrum D (next page);
(e) C$_3$H$_4$Cl$_2$, NMR spectrum E (next page).

![A: 300-MHz $^1$H NMR spectrum ppm (δ)]

![B: 300-MHz $^1$H NMR spectrum ppm (δ)]

![C: 300-MHz $^1$H NMR spectrum ppm (δ)]
35. Explain the splitting patterns in \(^1\text{H NMR}\) spectrum D in detail. The insets are fivefold expansions.

36. For each of the pairs of alkenes below, indicate whether measurements of polarity alone would be sufficient to distinguish the compounds from one another. Where possible, predict which compound would be more polar.

(a) \(\text{CH}_3\text{CH}=\text{CH}_2\) and \(\text{CH}_3\text{CH}_2\text{CH}=\text{CH}_2\)

(b) \(\text{CH}_3\text{C}_=\text{C}\text{CH}_2\text{CH}_3\) and \(\text{CH}_3\text{CH}_2\text{C}_=\text{C}\text{CH}_3\)

(c) \(\text{CH}_3\text{C}_=\text{C}\text{CH}_2\text{CH}_3\) and \(\text{CH}_3\text{CH}=\text{CH}_2\text{CH}_3\)
37. Place the alkenes in each group in order of increasing stability of the double bond and increasing heat of hydrogenation.

(a) CH₂=CH₂
(b) H₂C=C=H
(c) H₂C=CH(CH₃)₂
(d) H₂C=CH(CH₂)₃

38. Write the structures of as many simple alkenes as you can that, upon catalytic hydrogenation with H₂ over Pt, will give as the product (a) 2-methylbutane; (b) 2,3-dimethylbutane; (c) 3,3-dimethylpentane; (d) 1,1,4-trimethylcyclohexane. In each case in which you have identified more than one alkene as an answer, rank the alkenes in order of stability.

39. The reaction between 2-bromobutane and sodium ethoxide in ethanol gives rise to three E2 products. What are they? Predict their relative amounts.

40. What key structural feature distinguishes haloalkanes that give more than one stereoisomer on E2 elimination (e.g., 2-bromobutane, Problem 39) from those that give only a single isomer exclusively (e.g., 2-bromo-3-methylpentane, Section 11-6)?

41. Write the most likely major product(s) of each of the following haloalkanes with sodium ethoxide in ethanol or potassium tert-butoxide in 2-methyl-2-propanol (tert-butyl alcohol). (a) Chloromethane; (b) 1-bromopentane; (c) 2-bromopentane; (d) 1-chloro-1-methylcyclohexane; (e) (1-bromoethyl)-cyclopentane; (f) (2R,3R)-2-chloro-3-ethylhexane; (g) (2R,3S)-2-chloro-3-ethylhexane; (h) (2S,3R)-2-chloro-3-ethylhexane.

42. Referring to the data in Chapter Integration Problem 11-27, predict how the rate of E2 reaction between 1-bromopropane and sodium ethoxide in ethanol would compare with those of the three substrates discussed in that problem under the same reaction conditions.

43. Draw Newman projections of the four stereoisomers of 2-bromo-3-methylpentane in the conformation required for E2 elimination. (See the structures labeled “Stereospecificity in the E2 Reaction of 2-Bromo-3-methylpentane” on p. 466.) Are the reactive conformations also the most stable conformations? Explain.

44. Referring to the answer to Problem 38 of Chapter 7, predict (qualitatively) the relative amounts of isomeric alkenes that are formed in the elimination reactions shown.

45. Referring to the answers to Problem 30 of Chapter 9, predict (qualitatively) the relative yields of all the alkenes formed in each reaction.

46. Compare and contrast the major products of dehydrohalogenation of 2-chloro-4-methylpentane with (a) sodium ethoxide in ethanol and (b) potassium tert-butoxide in 2-methyl-2-propanol (tert-butyl alcohol). Write the mechanism of each process. Next consider the reaction of 4-methyl-2-pentanol with concentrated H₂SO₄ at 130˚C, and compare its product(s) and the mechanism of its (their) formation with those from the dehydrohalogenations in (a) and (b). (Hint: The dehydration gives as its major product a molecule that is not observed in the dehydrohalogenations.)

47. Referring to Problem 59 of Chapter 7, write the structure of the alkene that you would expect to be formed as the major product from E2 elimination of each of the chlorinated steroids shown.

48. 1-Methylenecyclohexene is more stable than methylenecyclohexane (A, in the margin), but methylenecyclopropane (B) is more stable than 1-methyl-cyclopropene. Explain.
49. Give the products of bimolecular elimination from each of the following isomeric halogenated compounds.

(a) \[
\begin{array}{c}
\text{Br} \\
\text{C}_6\text{H}_5 \\
\text{H} \\
\text{C}_6\text{H}_5
\end{array}
\]

(b) \[
\begin{array}{c}
\text{Br} \\
\text{C}_6\text{H}_5 \\
\text{H} \\
\text{C}_6\text{H}_5
\end{array}
\]

One of these compounds undergoes elimination 50 times faster than the other. Which compound is it? Why? (Hint: See Problem 41.)

50. Explain in detail the differences between the mechanisms giving rise to the following two experimental results.

\[
\begin{array}{c}
\text{CH}_3 \\
\text{Cl} \\
\text{CH(CH}_3)_2 \\
\text{Na}^-\text{OCH}_2\text{CH}_3, \text{CH}_3\text{CH}_2\text{OH}
\end{array}
\]

\[
\begin{array}{c}
\text{CH}_3 \\
\text{Cl} \\
\text{CH(CH}_3)_2 \\
\text{Na}^-\text{OCH}_2\text{CH}_3, \text{CH}_3\text{CH}_2\text{OH}
\end{array}
\]

51. The molecular formulas and \(^{13}\text{C}\) NMR data (in ppm) for several compounds are given here. The type of carbon, as revealed from DEPT spectra, is specified in each case. Deduce a structure for each compound. (a) \(\text{C}_4\text{H}_6\): 30.2 (CH\(_2\)), 136.0 (CH); (b) \(\text{C}_4\text{H}_6\text{O}\): 18.2 (CH\(_3\)), 134.9 (CH), 153.7 (CH), 193.4 (CH); (c) \(\text{C}_4\text{H}_8\): 13.6 (CH\(_3\)), 25.8 (CH\(_2\)), 112.1 (CH\(_2\)), 139.0 (CH); (d) \(\text{C}_5\text{H}_{10}\text{O}\): 17.6 (CH\(_3\)), 25.4 (CH\(_3\)), 58.8 (CH\(_2\)), 125.7 (CH), 133.7 (C\(_\text{quaternary}\)); (e) \(\text{C}_5\text{H}_8\): 15.8 (CH\(_2\)), 31.1 (CH\(_2\)), 103.9 (CH\(_2\)), 149.2 (C\(_\text{quaternary}\)); (f) \(\text{C}_7\text{H}_{10}\): 25.2 (CH\(_2\)), 41.9 (CH), 48.5 (CH\(_2\)), 135.2 (CH). (Hint: This one is difficult. The molecule has one double bond. How many rings must it have?)

52. Data from both ordinary and DEPT \(^{13}\text{C}\) NMR spectra for several compounds with the formula \(\text{C}_5\text{H}_{10}\) are given here. Deduce a structure for each compound. (a) 25.3 (CH\(_2\)); (b) 13.3 (CH\(_3\)), 17.1 (CH\(_3\)), 25.5 (CH\(_3\)), 118.7 (CH), 131.7 (C\(_\text{quaternary}\)); (c) 12.0 (CH\(_3\)), 13.8 (CH\(_3\)), 20.3 (CH\(_2\)), 122.8 (CH), 132.4 (CH).

53. From the Hooke’s law equation, would you expect the C–X bonds of common haloalkanes (X = Cl, Br, I) to have IR bands at higher or lower wavenumbers than are typical for bonds between carbon and lighter elements (e.g., oxygen)?

54. Convert each of the following IR frequencies into micrometers.

(a) 1720 cm\(^{-1}\) (C=O)    (b) 1650 cm\(^{-1}\) (C=C)    (c) 3300 cm\(^{-1}\) (O–H)
(d) 890 cm\(^{-1}\) (alkene bend)    (e) 1100 cm\(^{-1}\) (C=O)    (f) 2260 cm\(^{-1}\) (C=N)

55. Match each of the following structures with the IR data that correspond best. Abbreviations: w, weak; m, medium; s, strong; br, broad. (a) 905 (s), 995 (m), 1040 (m), 1640 (m), 2850–2980 (s), 3090 (m), 3400 (s, br) cm\(^{-1}\); (b) 2840 (s), 2930 (s) cm\(^{-1}\); (c) 1665 (m), 2890–2990 (s), 3030 (m) cm\(^{-1}\); (d) 1040 (m), 2810–2930 (s), 3300 (s, br) cm\(^{-1}\).

56. You have just entered the chemistry stockroom to look for several isomeric bromopentanes. There are three bottles on the shelf marked \(\text{C}_5\text{H}_1\text{Br}\), but their labels have fallen off. The NMR machine
is broken, so you devise the following experiment in an attempt to determine which isomer is in which bottle: You first treat a sample of the contents in each bottle with NaOH in aqueous ethanol, and then you determine the IR spectrum of each product or product mixture. Here are the results:

(i) $C_5H_{11}Br$ isomer in bottle A $\xrightarrow{\text{NaOH}}$ IR bands at 1660, 2850–3020, and 3350 cm$^{-1}$

(ii) $C_5H_{11}Br$ isomer in bottle B $\xrightarrow{\text{NaOH}}$ IR bands at 1670 and 2850–3020 cm$^{-1}$

(iii) $C_5H_{11}Br$ isomer in bottle C $\xrightarrow{\text{NaOH}}$ IR bands at 2850–2960 and 3350 cm$^{-1}$

(a) What do the data tell you about each product or product mixture?

(b) Suggest possible structures for the contents of each bottle.

57. An organic compound exhibits IR spectrum F. From the group of structures below, choose the one that matches the spectrum best.

58. The three compounds hexane, 2-methylpentane, and 3-methylpentane correspond to the three mass spectra shown below. Match each compound with the spectrum that best fits its structure on the basis of the fragmentation pattern.

59. Assign as many peaks as you can in the mass spectrum of 1-bromopropane (Figure 11-24).
60. The following table lists selected mass-spectral data for three isomeric alcohols with the formula $C_5H_{12}O$. On the basis of the peak positions and intensities, suggest structures for each of the three isomers. A dash means that the peak is very weak or absent entirely.

61. Determine the molecular formulas corresponding to each of the following structures. For each structure, calculate the number of degrees of unsaturation from the molecular formula and evaluate whether your calculations agree with the structures shown.

(a) \[ \begin{array}{c} \text{structure} \end{array} \]
(b) \[ \begin{array}{c} \text{structure} \end{array} \]
(c) \[ \begin{array}{c} \text{structure} \end{array} \]
(d) \[ \begin{array}{c} \text{structure} \end{array} \]
(e) \[ \begin{array}{c} \text{structure} \end{array} \]
(f) \[ \begin{array}{c} \text{structure} \end{array} \]
(g) \[ \begin{array}{c} \text{structure} \end{array} \]
(h) \[ \begin{array}{c} \text{structure} \end{array} \]

62. Calculate the degree of unsaturation that corresponds to each of the following molecular formulas.
- (a) $C_7H_{12}$;
- (b) $C_6H_7NO_2$;
- (c) $C_6Cl_6$;
- (d) $C_{10}H_{22}O_{11}$;
- (e) $C_6H_{10}S$;
- (f) $C_{18}H_{28}O_2$.

63. A hydrocarbon with an exact molecular mass of 96.0940 exhibits the following spectroscopic data: $^1H$ NMR $\delta = 1.3$ (m, 2 H), 1.7 (m, 4 H), 2.2 (m, 4 H), and 4.8 (quin, $J = 3$ Hz, 2 H) ppm; $^1C$ NMR $\delta = 26.8, 28.7, 35.7, 106.9,$ and 149.7 ppm. The IR spectrum is shown below (spectrum G). Hydrogenation furnishes a product with an exact molecular mass of 98.1096. Suggest a structure for the compound consistent with these data.
64. The isolation of a novel form of molecular carbon, C_{60}, was reported in 1990. The substance has the shape of a soccer ball of carbon atoms and possesses the nickname “buckyball” (you don’t want to know the IUPAC name). Hydrogenation produces a hydrocarbon with the molecular formula C_{60}H_{36}. What is the degree of unsaturation in C_{60}? In C_{60}H_{36}? Does the hydrogenation result place limits on the numbers of π bonds and rings in “buckyball”? (More on C_{60} is found in Chemical Highlight 15-1.)

65. You have just been named president of the famous perfume company, Scents “R” Us. Searching for a hot new item to market, you run across a bottle labeled only C_{10}H_{20}O, which contains a liquid with a wonderfully sweet rose aroma. You want more, so you set out to elucidate its structure. Do so from the following data. (i) 1H NMR: clear signals at δ = 0.94 (d, J = 7 Hz, 3 H), 1.63 (s, 3 H), 1.71 (s, 3 H), 3.68 (t, J = 7 Hz, 2 H), 5.10 (t, J = 6 Hz, 1 H) ppm; the other 8 H have overlapping absorptions in the range δ = 1.3 – 2.2 ppm. (ii) 13C NMR (1H decoupled): δ = 60.7, 125.0, 130.9 ppm; seven other signals are upfield of δ = 40 ppm. (iii) IR: ν = 1640 and 3350 cm^{-1}. (iv) Oxidation with buffered PCC (Section 8-6) gives a compound with the molecular formula C_{10}H_{18}O. Its spectra show the following changes compared with the starting material: 1H NMR: signal at δ = 3.68 ppm is gone, but a new signal is seen at δ = 9.64 ppm; 13C NMR: signal at δ = 60.7 ppm is gone, replaced by one at δ = 202.1 ppm; IR: loss of signal at ν = 3350 cm^{-1}; new peak at ν = 1728 cm^{-1}. (v) Hydrogenation gives C_{10}H_{22}O, identical with that formed on hydrogenation of the natural product geraniol (see margin).

66. Using the information in Table 11-4, match up each set of the following IR signals with one of these naturally occurring compounds: camphor; menthol; chrysanthemic ester; epiandrosterone. You can find the structures of the natural products in Section 4-7. (a) 3355 cm^{-1}; (b) 1630, 1725, 3030 cm^{-1}; (c) 1730, 3410 cm^{-1}; (d) 1738 cm^{-1}.

67. Identify compounds A, B, and C from the following information and explain the chemistry that is taking place. Reaction of the alcohol shown in the margin with 4-methylbenzenesulfonyl chloride in pyridine produced A (C_{15}H_{20}O_{3}S). Reaction of A with lithium diisopropylamide (LDA, Section 7-8) produces a single product, B (C_{8}H_{12}), which displays in its 1H NMR a two-proton multiplet at about δ = 5.6 ppm. If, however, compound A is treated with NaI before the reaction with LDA, two products are formed: B and an isomer, C, whose NMR shows a multiplet at δ = 5.2 ppm that integrates as only one proton.

68. The citric acid cycle is a series of biological reactions that plays a central role in cell metabolism. The cycle includes dehydration reactions of both malic and citric acids, yielding fumaric and aconitic acids, respectively (all common names). Both proceed strictly by enzyme-catalyzed anti-elimination mechanisms.

(a) In each dehydration, only the hydrogen identified by an asterisk is removed, together with the OH group on the carbon below. Write the structures for fumaric and aconitic acids as they are formed in these reactions. Make sure that the stereochemistry of each product is clearly indicated. (b) Specify the stereochemistry of each of these products, using either cis-trans or E,Z notation, as appropriate. (c) Isocitric acid (shown in the margin) also is dehydrated by aconitase. How many stereoisomers can exist for isocitric acid? Remembering that this reaction proceeds through anti elimination, write the structure of a stereoisomer of isocitric acid that will give on dehydration the same isomer of aconitic acid that is formed from citric acid. Label the chiral carbons in this isomer of isocitric acid, using R,S notation.
Team Problem

69. The following data indicate that the dehydration of certain amino acid derivatives is stereospecific.

\[
\begin{array}{cccc}
\text{CCHO} & R^2 \text{CO}_2\text{CH}_2\text{C}_6\text{H}_5 \\
\text{H} & \text{NHCO}_2\text{CH}_2\text{C}_6\text{H}_5 \\
\end{array}
\]

1. \(\text{CH}_2\text{SO}_2\text{Cl}, \text{pyridine}\)
2. \(\text{R}_3\text{N base}\)

\[
\begin{array}{cccc}
\text{R}^1 & \text{R}^2 \\
a & \text{CH}_3 & \text{H} \\
b & \text{H} & \text{CH}_3 \\
c & \text{CH}(\text{CH}_3)_2 & \text{H} \\
d & \text{H} & \text{CH}(\text{CH}_3)_2 \\
\end{array}
\]

Divide the task of analyzing these data among yourselves to determine the nature of the stereocontrolled eliminations. Assign the absolute configuration (\(R,S\)) to compounds 1a–1d and the \(E,Z\) configuration to compounds 2a–2d. Draw a Newman projection of the active conformation of each starting compound (1a–1d). As a team, apply your understanding of this information to determine the absolute configuration of the unassigned stereocenter (marked by an asterisk) in compound 3, which was dehydrated to afford compound 4, an intermediate in an approach to the synthesis of compound 5, an antitumor agent.

\[
\begin{array}{cccc}
\text{OCH}_3 & \text{N} & \text{H} \\
\text{O} & \text{NH} & \text{H} \\
\text{O} & \text{NH} & \text{H} \\
\end{array}
\]

(P\(^1\) and P\(^2\) are protecting groups)
Preprofessional Problems

70. What is the empirical formula of compound A (see margin)?
   (a) C₈H₁₄; (b) C₈H₁₆; (c) C₈H₁₂; (d) C₄H₇

71. What is the degree of unsaturation in cyclobutane?
   (a) Zero; (b) one; (c) two; (d) three

72. What is the IUPAC name for compound B (see margin)?
   (a) (E)-2-Methyl-3-pentene; (b) (E)-3-methyl-2-pentene; (c) (Z)-2-methyl-3-pentene;
   (d) (Z)-3-methyl-2-pentene

73. Which of the following molecules would have the lowest heat of hydrogenation?

74. A certain hydrocarbon containing eight carbons was found to have two degrees of unsaturation but no absorption bands in the IR spectrum at 1640 cm⁻¹. The best structure for this compound is
With approximately one-third of the year’s course in organic chemistry behind you, let’s take stock of your ability to solve problems, and look to possible remedies for the difficulties you may have encountered. This interlude has the following structure:

**Understanding the Question**

**Types of Problems in Organic Chemistry**

A General Approach to Problem Solving: The “WHIP” Strategy

Solving Problems That Ask “What”

* Nomenclature
* Acidity
* Energy
* Stability
* Spectroscopy

Solving Problems That Ask “How” and/or “Why”

* What is the product of a reaction?
* How does the product form?
* What reagent(s) do you need to convert one molecule into a specific other?

**Understanding the question**

Perhaps the most common statement made by students coming to office hours is “I don’t understand!” When we ask them to elaborate, we frequently find that it is the question that they do not understand—never mind the solution. In fact, this situation is common in science and science-related classes. Exams not only test students’ knowledge; they also evaluate their ability to understand a written question and to rearrange it into a form that can be solved.

**Types of problems in organic chemistry**

What kind of question is it? It is somewhat of an oversimplification, but there are essentially two categories of questions in organic chemistry. Categorizing the question is the first step in understanding it and defining what is being asked of you.

**The “What?” question**

* What is the IUPAC name?
* Which is the strongest acid?
* Calculate $\Delta H^\circ$ and determine which way the equilibrium lies.
* What is the most stable conformation?
* Interpret the following spectra of a molecule and suggest a possible structure for it.
These are all “What?” questions. They ask you (1) to recall information and (2) to apply it to a relatively uncomplicated situation. As we shall soon see, approaches to solving “What” questions are usually straightforward (which does not necessarily mean that they are easy).

**The “How” or “Why” question**

What about the second type of questions? These are the ones that focus on one or more chemical reactions from any of several perspectives:

- What is the product?
- What is the mechanism by which it forms?
- What reagent(s) do you need to convert one molecule into a specific other?

These may sound like “What” queries, but they really have a lot more to do with “How” and “Why” things happen in organic chemistry. A more sophisticated approach is usually needed, compared to the typical “What” enquiry. *You can often recognize a “How” or a “Why” question by asking yourself: “Is something happening?” If the answer is yes, then the question is very likely asking you “How” or “Why.”*

Before we proceed to some examples, let us present a general approach to problem solving.

**A general approach to problem solving: the “WHIP” strategy**

To succeed in organic chemistry requires time, commitment, and hard work. It also requires the development of organized problem-solving skills. To “WHIP” the challenge of solving a problem, proceed step by step:

- **What does the problem ask?**
  
  *Read* the text describing the problem, and don’t start working on the answer until you understand everything it wants to know. Is it unclear? Read the question slowly and out loud to yourself. Look for key words that characterize the type of problem. Is it just looking for a piece of information (What?), or does it ask you to work out something more involved (How? Why?)?

- **How to start?**
  
  What is your starting point? Where do you need to go? Ponder both of these questions to figure out what you need to accomplish. For example, to deduce the product of a reaction, you must identify both the relevant structural features of the starting material(s) (such as functional groups) and the chemical nature of the reagent that is acting on it (electrophile? nucleophile? oxidizing or reducing agent?). Evaluate in a general sense what might result.

- **Information needed?**
  
  Have you forgotten something critical, such as the identity of a reagent? Or are you uncertain about a detail that might be important, such as primary vs secondary vs tertiary for a reacting carbon? *Look it up*—in the book, in your notes, or just ask—*before* you get too far into trying to work the problem. When you “solve” exercises incorrectly because of faulty information, it puts you in the position of having to “unlearn” a wrong approach in addition to still having to recognize the correct one. Under the stress of an exam situation, confusion becomes much more likely.

- **Proceed logically—no shortcuts!**
  
  *Do not skip steps* in formulating a solution to a problem! Be pedantic in your accuracy: Write out each structure fully, if necessary in its Lewis form; complete your arrow pushing; add reaction arrows and reagents for each step; “doodle” on a separate piece of paper—organic chemistry is very visual and even a wrong structure, when drawn, may trigger your mind to lead you to the right one. Practice your problem-solving skills in front of others. Finally, trust the various processes that you have learned to lead you to the answers.
Solving problems that ask “What?”

• **Nomenclature:** Nomenclature problems may ask you to give a name to a structure or to draw a structure that corresponds to a name. For example:

**Problem I-1.** Provide the IUPAC name for the molecule given below.

```
   OH
   Br
```

Your **What** is straightforward: Name the molecule.

**How to start?** Before naming a structure, you need to “read” it to determine connectivity and (if applicable) stereochemistry.

**Information needed?** You’ll need to know the rules of choosing a parent chain (or ring), numbering it, and naming its substituents. Thus:

```
   OH
   Br
```

Proceed, step by step. Apply the naming rules: (1) It is a “hexanol.” (2) Numbering begins at the end closer to the (highest-precedence) OH group. (3) Use alphabetical ordering to construct the name (“di-” is not counted—it is just a multiplier for “methyl”).

The answer: **5-Bromo-2,2-dimethyl-3-hexanol**

• **Acidity:**

**Problem I-2.** Which is the stronger acid, CH₃NH₂ or CH₃OH?

Again, a straightforward **What**.

**How to start?** When you are asked to evaluate the strength of an acid, look at its conjugate base. The most stable conjugate base (on the basis of atom electronegativity as well as stabilizing inductive and resonance effects) corresponds to the strongest acid (Section 2-2).

So, draw all the possible conjugate bases by removing a proton (H⁺) from every location in each molecule:

```
H⁻:CH₂NH₂   CH₃NH⁻   H⁻:CH₂OH   CH₃O⁻
```

Which is the most stable conjugate base? These four species have negative charges on three different atoms: C, N, and O. How do these atoms differ?

**Information needed!** The three atoms differ in their respective electronegativity: O > N > C (Table 1-2). The more electronegative an atom is, the better it is at attracting electrons. The most electronegative atom therefore stabilizes best the extra electron pair and negative charge in the corresponding conjugate base.

Finally, **Proceed logically:** (1) Oxygen is the most electronegative in the trio, so, with the extra electron pair and negative charge on O, CH₃O⁻ is the most stable of the four conjugate bases above. (2) Given that conclusion, CH₃OH must be the stronger acid, and the hydrogen on the oxygen must be the most acidic of its four hydrogen atoms.

• **Energy:** Energy change is one of the fundamental principles governing chemical reactions. Breaking bonds requires energy input; making bonds releases energy. \( \Delta H^\circ = \text{(energy in)} - \text{(energy out)} \). The equilibrium is favored in the direction of reaction for which \( \Delta G^\circ \) is negative, which will often be determined by a negative \( \Delta H^\circ \) (at least when \( \Delta S^\circ \) is small).
Problem I-3. Hydrogenation of alkenes typically displays $\Delta H^\circ = -30$ kcal mol$^{-1}$. Which of the following statements are always true? (a) Mixing an alkene with H$_2$ results in a fast reaction; (b) reaction of an alkene with H$_2$ is exothermic; (c) all alkenes react equally favorably with H$_2$.

What? This is a three-part true–false question. You must think about each statement individually.

(a) Start: Does energetic (thermodynamic) favorability necessarily determine how fast a reaction will go? Information: No. What does? Remember kinetics? Activation energies (Sections 3-3 and 11-5)? So, Proceed: False.

(b) Start: Define exothermic. Information: Exothermic corresponds to a negative $\Delta H^\circ$ (Section 2-1). Proceed: This statement is true.

(c) Start: Read carefully! The problem says equally favorably, which means that, if the statement is true, the hydrogenations of all alkenes will have exactly the same $\Delta H^\circ$. Information: Look at Figure 11-12. They don’t. Proceed: False! So the only true statement is (b).

• Stability:

Problem I-4. Rank the following four isomeric hydrocarbons in order of decreasing stability: (a) 1-cyclopropylpentane; (b) cis-1-ethyl-2-propylcyclopropane; (c) ethylcyclohexane; (d) cis-1,4-dimethylcyclohexane.

What does the problem ask? To establish an approximate order of energy content for the four molecules and thus estimate relative stability.

How to start? Careful structural drawings will help you recognize what features may stabilize or destabilize each hydrocarbon relative to the others. Notice that this problem includes a nomenclature component: Each name must be converted to a structure. Finally, to make the comparison fair, we need to draw the most stable possible conformation of each one.

Information: The lower the energy content of a structure, the more stable it is. Steric crowding raises energy content and decreases stability (Section 2-8). So, a staggered conformation is more stable than an eclipsed one; anti is more stable than gauche; equatorial is more stable than axial (Section 4-4). In each case, the more stable option has less steric crowding. Note any other destabilizing effects (such as bond-angle strain).

Proceed: As shown above, we identify the structural features that affect stability. How important is each one? Find the quantitative information: Bond-angle strain in cyclopropanes is the largest destabilizing factor (27.6 kcal mol$^{-1}$; Section 4-2). Next we add the enforced eclipsing in (b), which is at least as bad as the 4.9 kcal mol$^{-1}$ in the highest-energy conformation of butane (Figure 2-13). Cyclohexanes do not suffer from bond-angle strain, but (d) cannot avoid one axial substituent (1.7 kcal mol$^{-1}$, Table 4-3). With these data in hand, apply the logic: Higher energy content = less stable. The stability order is therefore (c) most stable, then (d), then (a), and finally (b) least stable. (If needed, you could even give approximate energy differences by adding the energy-content increments for each compound.)
**Spectroscopy**: Spectroscopy is our most powerful tool for determining the structure of an organic compound. Solving spectroscopic problems is rather like identifying and combining the pieces of a puzzle to construct a final “picture.” As in solving any other sort of puzzle, there are efficiencies of strategy that you can learn to employ.

**Problem I-5.** What is the structure of a molecule that displays the following spectroscopic data: 

- **$^1$H NMR**: $\delta = 1.30$ (broad s, 1 H), $3.89$ (d, $J = 7.8$ Hz, 2 H), $5.49$ (t, $J = 7.8$ Hz, 1 H) ppm;
- **IR**: $1670$ (weak), $3310$ (strong, broad) cm$^{-1}$;
- **MS**: $m/z = 88$ (M$^+$). A straightforward What.

Start by recognizing what each type of spectrum reveals. Ideally, we would like to know:

(a) Composition (molecular formula), either given or from mass spectrometry

(b) Functional groups present, from an infrared spectrum

(c) Number and location of hydrogens from the $^1$H NMR spectrum

**Information:**

(a) The composition of the molecule is not given. You do have mass data, a molecular weight of 88, and you could try to figure out by trial and error some combinations of common atoms that would add up to a molecular mass of 88, but that would be inefficient. Put this information aside for now and turn to the IR and $^1$H NMR spectra.

(b) The IR spectrum is diagnostic of the OH functional group because of the strong, broad absorption at 3310 cm$^{-1}$; the weaker one at 1670 cm$^{-1}$ suggests a C=CH double bond (Section 11-8).

(c) Now for the $^1$H NMR spectrum: The broad singlet at $\delta = 1.30$ ppm is almost certainly due to the OH hydrogen (Section 10-8). The signal at $\delta = 5.49$ ppm gives away the presence of an alkenyl hydrogen. Finally, at $\delta = 3.89$ ppm we have the signal for two hydrogens evidently deshielded by a neighboring OH group (Table 10-2).

Proceed, logically, and step by step: We have some molecular fragments—our “puzzle pieces.” How do we put them together? The pieces are an OH—evidently attached to a CH$_2$—and a double bond bearing a hydrogen: C=CH. On the basis of the integrations and spin–spin splittings of the $^1$H NMR signals (the alkenyl H is split into a triplet and the CH$_2$OH into a doublet, so they must be neighbors; Section 10-7), we must have something like the following substructure:

![Substructure](image)

This is obviously not a whole molecule. Furthermore, adding up the atomic masses gives us only 44. Atoms are clearly missing, but there are no additional signals in the $^1$H NMR spectrum. What to do? The molecular weight of this substructure gives us a strong hint: It is exactly half the value observed for the entire molecule. Thus, the molecule is symmetrical: It contains another set of hydrogen atoms (and carbons and oxygens) in identical environments as the ones already shown. This line of reasoning gets us to this structure:

![Final Structure](image)

Does this answer fit the data? The composition is C$_4$H$_8$O$_2$, giving a mass of 48 + 8 + 32 = 88. The IR spectrum fits well. How about the $^1$H NMR spectrum? The integrations given were 1 H, 2 H, and 1 H, suggesting a molecule with only four hydrogens, but we saw above that this interpretation was a dead end. Recall, however, that NMR integrations give us only relative numbers of hydrogen atoms in each environment (Section 10-6). The values given above are one-half of the actual numbers of hydrogens responsible for each signal. It is not uncommon to be given a spectroscopic problem involving a simple organic molecule with such symmetry, so you should be aware of the possibility.
At this stage, we have established that all the data fit our suggested structure. Are there any alternatives? The answer is yes, the trans isomer. However, careful scrutiny of Section 11-8 reveals that trans alkenes exhibit a sharp IR bending vibration at 970 cm$^{-1}$. Since such a band is not given, our answer stands as the best available.

A final note: The problem would have been much easier if we had been given the molecular composition. Even an exact molecular mass from a high-resolution mass spectrum would have been helpful (Section 11-9): This molecule’s exact mass of 88.0524 tells us that its formula is C$_4$H$_8$O$_2$ (by adding atomic masses from Table 11-5), as opposed to other alternatives with an approximate mass of 88, such as C$_4$H$_{12}$N$_2$ (88.1002) or C$_5$H$_{12}$O (88.0889).

**Solving problems that ask “How?” and/or “Why?”**

Let us turn now to the second type of question. These are the ones that address chemical reactions: the processes through which molecules change.

- **What is the product of a reaction?** Even if you have memorized everything you can, you will still need to recognize a reaction type and apply the relevant mechanism to arrive at a product structure. This kind of question is rarely just “What?” For example, consider the following mock exam question and follow its analysis:

**Problem I-6.** (5 points) Write the major product(s) of the following reaction.

![Reaction Diagram]

At first glance, this is a simple What-type problem. But is it? Let us see.

**How to start?** Identify the starting organic molecule and the reagent by the compound categories to which they belong. See if that leads you to a solution.

- Hydroxide—good nucleophile—do you immediately think of nucleophilic substitution?
- Do you write OH as your answer and quickly move on?
- If so, you just lost most of those 5 points.

Slow down! Take a second look: The substrate is tertiary, and OH is a strong base as well.

**Information:** Table 7-4 tells you how a reaction between a tertiary substrate and a strong base proceeds: through elimination, by the E2 mechanism. But you are still not finished. More than one isomer can be formed. Section 11-6 covers the regiochemistry of elimination: Unhindered bases (such as hydroxide) give the more stable alkene (Saytzev rule).

Now, finally, you can **Proceed:**

- **How does the product form? Why? Explain!** These are the buzz words for “Write the mechanism.” If you have not addressed the reaction mechanism, you have not answered a “How” or a “Why” question, nor have you “explained” anything about a chemical reaction. Individual reaction steps are the words in the language of organic chemistry—the vocabulary. However, you need grammar in order to put the words together. The mechanisms constitute that grammar.
Problem I-7. Which reaction below proceeds faster, (a) or (b)? What is the product? Explain.

What does the question ask? “Explain!” There’s your cue: This is a mechanism problem.

How to start? As in the preceding example, characterize the substrates: Here they are secondary chloroalkanes, with additional steric hindrance on the adjacent carbon. Again, the reagent is a strong nucleophile and base.

Information: Displacement by S_N2 is unlikely; as in Problem I-6, E2 should be favored (Table 7-4). What next?

Proceed, logically: Use the question as a clue to how to proceed. Why should these two reactions proceed at different rates? How do the substrates differ? Answer: stereoisomerically. So, redraw both starting materials in the more instructive cyclohexane chair forms:

The E2 mechanism proceeds most readily from a geometry that aligns the leaving group and the hydrogen atom to be removed from an adjacent carbon atom in an anti manner (Section 11-6). Only the substrate in reaction (a) is capable of attaining this arrangement. Transformation (a) will therefore be the faster one, eliminating to give the cyclic alkene as the major product.

Should you be asked specifically to show a mechanism for this transformation, base your answer on the Information relating to the E2 process presented in Section 7-7 and Figure 7-8. The carbon atom bearing the Cl is polarized δ+. The reaction takes place in a single step, by simultaneous movement of three electron pairs. The first originates from hydroxide ion, the base, which attacks the hydrogen atom β to the leaving group. The second emanates from the breaking C–H bond and moves toward the δ+ carbon atom to form the new π bond. The third leaves with the departing chloride ion, the leaving group. Using curved arrows to depict electron flow, we draw:

• What reagent(s) do you need to effect the conversion of one molecule into a specific other? Synthesis requires you to have a command of your reaction vocabulary so that you know whether, and exactly how, one kind of compound can be transformed into another. The Reaction Road Maps preceding the end-of-chapter Problem sections in many of the chapters are designed to help you organize your studying for this purpose. Retrosynthetic analysis (Section 8-9) provides a framework for designing solutions for synthesis problems.
Problem I-8. Design a synthesis of \( \text{OB} \) (3-hexanone), beginning with any organic molecules containing no more than three carbons.

What does the problem ask? Actually, several things. The product is a ketone, so you have to make that functional group. It has six carbons, and you are only allowed starting molecules with three, so you have to construct (at least) one carbon–carbon bond. You also have to decide what starting materials to use, and what reactions to do with them. That’s quite a lot!

How to start (1): You need to make a ketone. Do you know any reactions that generate ketones?

Information (1): So far, only one—oxidation of a secondary alcohol with a chromium(VI) reagent (Section 8-6).

Proceed (1): Retrosynthetically, we say that the ketone derives from a secondary alcohol (below, left). An actual reaction that provides the ketone is shown below on the right. It must be the final step in your answer:

Retrosynthetic Analysis

\[ \text{O} \]

This arrow means “derives from”

Final Synthesis Step (Forward Direction)

\[ \text{OH} \]

Make sure you include actual reagents above the reaction arrow

What does the problem ask next? You are now faced with a new synthesis problem: making the starting material for this reaction (3-hexanol). It is a secondary alcohol.

How to start (2): Ask yourself, do you know any ways to make secondary alcohols?

Information (2): You know two ways, reduction of a ketone with a hydride reagent (Section 8-6) and addition of a Grignard reagent to an aldehyde (Section 8-8).

Proceed (2): Check these two options for feasibility. Reduction of a ketone is not a useful method here, because the ketone we would need to reduce to make 3-hexanol is the one we are trying to make: 3-hexanone. We would just be going around in circles. Turning to the second route, consider combinations of Grignard reagents and aldehydes that will give us 3-hexanol. Thinking retrosynthetically, we find that there are two combinations, because we can make either the carbon–carbon bond to the left of the alcohol carbon (bond \( \text{a} \)), or the one to the right (bond \( \text{b} \)):

Retrosynthetic Analysis of 3-Hexanol: Two Options

\[ \text{OH} \]

\[ \text{CH}_3\text{CH}_2\text{MgX} + \text{HCCCH}_2\text{CH}_3 \leftarrow \text{Aldehyde has four carbons} \]

\[ \text{CH}_3\text{CH}_2\text{CH} + \text{XMgCH}_2\text{CH}_2\text{CH}_3 \leftarrow \text{Both are 3-carbon compounds} \]

We can make bond \( \text{a} \), but one of the starting materials is a four-carbon aldehyde. Because we are allowed to use only starting materials with three carbons or less, we would have to build that aldehyde from smaller molecules. On the other hand, we can construct bond \( \text{b} \) from two three-carbon components of the Grignard reaction. The required Grignard reagent is generated from a haloalkane, such as 1-bromopropane, and magnesium (Section 8-7). The final synthetic scheme can be presented now as follows:

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \xrightarrow{1. \text{Mg}, (\text{CH}_3\text{CH}_2)_2\text{O}} \text{OH} \xrightarrow{2. \text{CH}_3\text{CH}_2\text{CHO}} \text{OH} \xrightarrow{3. \text{H}^+, \text{H}_2\text{O}} \text{Na}_2\text{Cr}_2\text{O}_7, \text{H}_2\text{SO}_4 \rightarrow \text{O} \]
Take a look around your room. Can you imagine how different it would appear if every polymer-derived material (including everything made of plastic) were to be removed? Polymers have had an enormous effect indeed on modern society. The chemistry of alkenes underlies our ability to produce polymeric materials of diverse structure, strength, elasticity, and function. In the later sections of this chapter, we shall investigate the processes that give rise to such substances. They are, however, only a subset of the varied types of reactions that alkenes undergo.

Additions constitute the largest group of alkene reactions and lead to saturated products. Through addition, we can take advantage of the fact that the alkene functional group bridges two carbons, and we can elaborate on the molecular structure at both carbons. Fortunately for us, most additions to the $\pi$ bond are exothermic: They are almost certain to take place if a mechanistic pathway is available.

Beyond our simple ability to add to the double bond, other features further enhance the usefulness and versatility of addition reactions. Many alkenes possess defined stereochemistry ($E$ and $Z$) and, as we shall see in our discussions, many of their addition reactions proceed in a stereochemically defined manner. By combining these facts with the realization that additions to unsymmetric alkenes may also take place regioselectively, we shall find that we have the ability to exert a large measure of control over the course of these reactions and, consequently, the structures of the products that are formed. This control has been exquisitely refined in applications toward the synthesis of enantiomerically pure pharmaceuticals (see Chemical Highlights 5-4 and 12-2, and Section 12-2).

We begin with a discussion of hydrogenation, focusing on the details of catalytic activation. Then we turn to the largest class of addition processes, those in which electrophiles such as protons, halogens, and metal ions are added to the alkene. Other additions that will contribute further to our synthetic repertoire include hydroboration, several oxidations (which can lead to complete rupture of the double bond if desired), and radical reactions. Each of these transformations takes us in a different direction; the Reaction Summary Road Map at the end of the chapter provides an overview of the interconversions leading to and from this versatile compound class.

**12-1 Why Addition Reactions Proceed: Thermodynamic Feasibility**

The carbon–carbon $\pi$ bond is relatively weak, and the chemistry of the alkenes is governed largely by its reactions. The most common transformation is addition of a reagent A–B to give a saturated compound. In the process, the A–B bond is broken, and A and B form...
single bonds to carbon. Thus, the *thermodynamic feasibility* of this process depends on the strength of the $\pi$ bond, the dissociation energy $DH_{A-B}^\circ$, and the strengths of the newly formed bonds of A and B.

\[
\text{Addition to the Alkene Double Bond}
\]

Recall that we can *estimate* the $\Delta H^\circ$ of such reactions by subtracting the combined strength of the bonds made from that of the bonds broken (Section 3-4):

\[
\Delta H^\circ = (DH_{\pi \text{ bond}}^\circ + DH_{A-B}^\circ) - (DH_{C-A}^\circ + DH_{C-B}^\circ)
\]

in which C stands for carbon.

Table 12-1 gives the $DH^\circ$ values [obtained by using the data from Tables 3-1 and 3-4 and by equating the strength of the $\pi$ bond to 65 kcal mol$^{-1}$ (272 kJ mol$^{-1}$)] and the

| Table 12-1 Estimated $\Delta H^\circ$ (all values in kcal mol$^{-1}$) for Additions to Ethene$^a$ |
|---------------------------------|---|---|---|---|
| CH$_2$=CH$_2$ + A-B $\rightarrow$ H-C-C-H |
| $DH_{\pi \text{ bond}}^\circ$ | $DH_{A-B}^\circ$ | $DH_{A-C}^\circ$ | $DH_{B-C}^\circ$ | $\Delta H^\circ$ |
| CH$_2$=CH$_2$ + H-H $\rightarrow$ CH$_2$-CH$_2$ |
| 65 | 104 | 101 | 101 | -33 |
| CH$_2$=CH$_2$ + Br#Br $\rightarrow$ H-C-C-H |
| 65 | 46 | 70 | 70 | -29 |
| CH$_2$=CH$_2$ + H-Cl $\rightarrow$ H-C-C-H |
| 65 | 103 | 101 | 84 | -17 |
| CH$_2$=CH$_2$ + H-OH $\rightarrow$ H-C-C-H |
| 65 | 119 | 101 | 94 | -11 |

$^a$ These values are only estimates: They do not take into account the changes in C-C and C-H $\sigma$-bond strengths that accompany changes in hybridization.
Catalytic Hydrogenation

The simplest reaction of the double bond is its saturation with hydrogen. As discussed in Section 11-5, this reaction allows us to estimate the relative stability of substituted alkenes from their heats of hydrogenation. The process requires a catalyst, which may be either heterogeneous or homogeneous—that is, either insoluble or soluble in the reaction medium.

Hydrogenation takes place on the surface of a heterogeneous catalyst

The hydrogenation of an alkene to an alkane, although exothermic, does not take place even at elevated temperatures. Ethene and hydrogen can be heated in the gas phase to 200°C for prolonged periods without any measurable change. However, as soon as a catalyst is added, hydrogenation proceeds at a steady rate even at room temperature. The catalysts frequently are insoluble materials such as palladium (e.g., dispersed on carbon, Pd–C), platinum (Adams’s* catalyst, PtO₂, which is converted into colloidal platinum metal in the presence of hydrogen), and nickel (finely dispersed, as in a preparation called Raney† nickel, Ra–Ni).

Exercise 12-1

Calculate the \( \Delta H^\circ \) for the addition of \( \text{H}_2\text{O}_2 \) to ethene to give 1,2-ethanediol (ethylene glycol) \([\Delta H^\circ_{\text{HO-OH}} = 49 \text{ kcal mol}^{-1} (205 \text{ kJ mol}^{-1})]\).

12-2 Catalytic Hydrogenation

The simplest reaction of the double bond is its saturation with hydrogen. As discussed in Section 11-5, this reaction allows us to estimate the relative stability of substituted alkenes from their heats of hydrogenation. The process requires a catalyst, which may be either heterogeneous or homogeneous—that is, either insoluble or soluble in the reaction medium.

Hydrogenation takes place on the surface of a heterogeneous catalyst

The hydrogenation of an alkene to an alkane, although exothermic, does not take place even at elevated temperatures. Ethene and hydrogen can be heated in the gas phase to 200°C for prolonged periods without any measurable change. However, as soon as a catalyst is added, hydrogenation proceeds at a steady rate even at room temperature. The catalysts frequently are insoluble materials such as palladium (e.g., dispersed on carbon, Pd–C), platinum (Adams’s* catalyst, PtO₂, which is converted into colloidal platinum metal in the presence of hydrogen), and nickel (finely dispersed, as in a preparation called Raney† nickel, Ra–Ni).

*Professor Roger Adams (1889–1971), University of Illinois at Urbana–Champaign.
†Dr. Murray Raney (1885–1966), Raney Catalyst Company, South Pittsburg, Tennessee.
The major function of the catalyst is the activation of hydrogen to generate metal-bound hydrogen on the catalyst surface (Figure 12-1). Without the metal, thermal cleavage of the strong H–H bond is energetically prohibitive. Solvents commonly used in such hydrogenations include methanol, ethanol, acetic acid, and ethyl acetate.

![Catalyst surface](image)

First hydrogen transfers to carbon of surface-bound alkene

Hydrogen atoms bound to metal atoms on catalyst surface

Alkane product released from surface

Second hydrogen transfers, completing hydrogenation

**Figure 12-1** Mechanism of catalytic hydrogenation of ethene to produce ethane. The hydrogens bind to the catalyst surface and are delivered to the carbons of the surface-adsorbed alkene.

The major function of the catalyst is the activation of hydrogen to generate metal-bound hydrogen on the catalyst surface (Figure 12-1). Without the metal, thermal cleavage of the strong H–H bond is energetically prohibitive. Solvents commonly used in such hydrogenations include methanol, ethanol, acetic acid, and ethyl acetate.

**Exercise 12-2**

**Working with the Concepts: Cis-trans Isomerization Under Alkene Hydrogenation Conditions**

During the catalytic hydrogenation of the cis double bond in oleic acid, a naturally occurring fatty acid, the formation of some of the trans isomer is observed. Explain.

![Oleic acid](image)

\[
\text{Oleic acid} \\
\text{COOH}
\]

\[
\text{R} \\
\text{(CH}_2\text{)}_7\text{COOH}
\]

\[
\text{R} = \text{C}_6\text{H}_{17}
\]

**Strategy**

Examine the mechanism in Figure 12-1. Look for a pathway that could (1) allow rotation about the bond between the originally double-bonded carbons followed by (2) regeneration of a double bond with a trans configuration.

**Solution**

- The mechanism possesses two key features that are applicable to this problem. First, each of the first three steps is reversible. Second, the two hydrogen atoms add to the carbons of the original double bond one at a time. Let us see how we can make use of these characteristics to define an isomerization pathway.
Hydrogenation is stereospecific

An important feature of catalytic hydrogenation is **stereospecificity**. The two hydrogen atoms are added to the same face of the double bond (**syn addition**). For example, 1-ethyl-2-methylcyclohexene is hydrogenated over platinum to give specifically **cis**-1-ethyl-2-methylcyclohexane. Addition of hydrogen can be from above or from below the molecular plane with equal probability. Therefore, each stereocenter is generated as both image and mirror image, and the product is racemic.

\[
\text{1-Ethyl-2-methylcyclohexene} \quad \xrightarrow{H_2, \text{PtO}_2, \text{CH}_3\text{CH}_2\text{OH}, 25^\circ\text{C}} \quad \text{cis-1-Ethyl-2-methylcyclohexane} \quad \text{(Racemic)}
\]

Exercise 12-3

Try It Yourself

During the course of the catalytic hydrogenation of 3-methyl-1-butene, some 2-methyl-2-butene is observed. Explain.
Chiral catalysts permit enantioselective hydrogenation

When steric hindrance inhibits hydrogenation on one face of a double bond, addition will take place exclusively to the less hindered face. This principle has been used to develop enantioselective or so-called asymmetric hydrogenation. The process employs homogeneous (soluble) catalysts, consisting of a metal, such as rhodium, and an enantiopure chiral phosphine ligand, which binds to the metal. A typical example is the Rh complex of the diphosphine \((R,R)\)-DIPAMP (margin). After coordination of the alkene double bond and a molecule of \(\text{H}_2\) to rhodium, hydrogenation occurs via syn addition, just as in the case of insoluble metal catalysts. However, the asymmetrically arranged bulky groups in the chiral ligand prevent addition of hydrogen to one of the faces of the double bond, resulting in the formation of only one of the two possible enantiomers of the hydrogenation product (see also Chemical Highlight 5-4).

This approach has proven to be a powerful method for synthesis of enantiomerically pure compounds of pharmaceutical significance. The industrial synthesis of \(L\)-DOPA (margin), the anti-Parkinson's disease agent, employs in its key step the asymmetric hydrogenation of the alkene shown to give exclusively the necessary \(S\) stereoisomer of the reduction product.

**Exercise 12-4**

Catalytic hydrogenation of \((S)\)-2,3-dimethyl-1-pentene gives only one optically active product. Show the product and explain the result. [**Hint:** Does addition of \(\text{H}_2\) either (1) create a new stereocenter or (2) affect any of the bonds around the stereocenter already present?]

**In Summary** Hydrogenation of the double bond in alkenes requires a catalyst. This transformation occurs stereospecifically by syn addition and, when there is a choice, from the least hindered side of the molecule. This principle underlies the development of enantioselective hydrogenation using chiral catalysts.

**12-3 Nucleophilic Character of the Pi Bond: Electrophilic Addition of Hydrogen Halides**

As noted earlier, the \(\pi\) electrons of a double bond are not as strongly bound as those of a \(\sigma\) bond. This \(\pi\)-electron cloud, located above and below the molecular plane of the alkene, is polarizable and capable of acting in a nucleophilic manner, just like the lone electron pairs of typical Lewis bases. The relatively high electron density of the double bond in 2,3-dimethylbutene is indicated (red) in its electrostatic potential map in the margin. In the
upcoming sections, we shall discuss reactions between the nucleophilic alkene \( \pi \) bond and a variety of electrophiles. As in hydrogenation, the final outcome of such reactions is addition. However, there are several different mechanisms for these transformations, collectively called \textit{electrophilic additions}, and they can be regioselective and stereospecific. We begin with the simplest electrophile, the proton.

**Electrophilic attack by protons gives carbocations**

The proton of a strong acid may add to a double bond to yield a carbocation. This process is the reverse of the deprotonation step in the E1 reaction and has the same transition state (Figure 7-7). When a good nucleophile is present, particularly at low temperatures, the carbocation is intercepted to give the \textit{electrophilic addition} product. For example, treatment of alkenes with hydrogen halides leads to the corresponding haloalkanes. The electrostatic potential map version of the general scheme shows the flow of electron density that occurs during this process.

![Mechanism of Electrophilic Addition of HX to Alkenes](image)

In the first step, an electron pair moves from the \( \pi \) bond (orange-red in the image at the left) toward the electrophilic (purple) proton to form a new \( \sigma \) bond. The map of the carbocation product of this step (center) shows that electron deficiency is now centered on the cationic carbon. Next, addition of the negative (and, therefore, red) halide ion is shown. In the resulting haloalkane product at the right, the polarity of the new C–X bond is reflected by the orange-red color for the strongly \( \delta^- \) halogen atom, and the range of colors from greenish-blue to purple for the rest of the structure, indicating the distribution of \( \delta^+ \) character among the remaining atoms.

In a typical experiment, the gaseous hydrogen halide, which may be HCl, HBr, or HI, is bubbled through pure or dissolved alkene. Alternatively, HX can be added in a solvent, such as acetic acid. Aqueous work-up furnishes the haloalkane in high yield.

![Iodocyclohexane](image)

**Exercise 12-5**

Write out two step-by-step mechanisms for the addition of HI to cyclohexene shown above. In the first, use a free proton as the electrophile. In the second, use undissociated HI in the electrophilic addition step. Make sure to include all necessary curved arrows to depict electron-pair movement.
The Markovnikov rule predicts regioselectivity in electrophilic additions

Are additions of HX to unsymmetric alkenes regioselective? To answer this question, let us consider the reaction of propene with hydrogen chloride. Two products are possible: 2-chloropropane and 1-chloropropane. However, the only product observed is 2-chloropropane.

\[
\text{CH}_3\text{CH} = \text{CH}_2 + \text{HCl} \rightarrow \text{CH}_3\text{CHCH}_2\text{Cl} \\
\text{CH}_3\text{CH} = \text{CH}_2 + \text{HCl} \rightarrow \text{CH}_3\text{CHCH}_2\text{Cl}
\]

Similarly, reaction of 2-methylpropene with hydrogen bromide gives only 2-bromo-2-methylpropane, and 1-methylcyclohexene combines with HI to furnish only 1-iodo-1-methylcyclohexane.

Two Further Examples of Regioselective Additions

We can see from these examples that, if the carbon atoms participating in the double bond are not equally substituted, the proton from the hydrogen halide attaches itself to the less substituted carbon. As a consequence, the halogen ends up at the more substituted carbon. This phenomenon, referred to as the Markovnikov* rule, can be explained by what we know about the mechanism of electrophile additions of protons to alkenes. The key is the relative stability of the resulting carbocation intermediates.

Consider the addition of HCl to propene. The regiochemistry of the reaction is determined in the first step, in which the proton attacks the \( \pi \) system to give an intermediate carbocation. Carbocation generation is rate determining; once it occurs, reaction with chloride proceeds quickly. Let us look at the crucial first step in more detail. The proton may attack either of the two carbon atoms of the double bond. Addition to the internal carbon leads to the primary propyl cation.

Protonation of Propene at C2—More Substituted Carbon (Does Not Occur)

In contrast, protonation at the terminal carbon results in the formation of the secondary 1-methylethyl (isopropyl) cation.

*Professor Vladimir V. Markovnikov (1838–1904), University of Moscow, formulated his rule in 1869.
Chapter 12

Protonation of Propene at C1—Less Substituted Carbon

As we know, a primary carbocation is too unstable to be a reasonable reaction intermediate in solution. In contrast, secondary cations form relatively readily. In addition, notice that the transition states for the two possible modes of addition show positive charge building up on primary and secondary carbons, respectively. Thus, the energies, and stabilities, of the transition states will reflect the relative energies of the cations to which they lead. The energy of the transition state (and, therefore, the activation energy) leading to the secondary cation is lower, meaning that this cation forms much faster. Figure 12-2 is a potential-energy diagram showing the two competing pathways. We see that these are late transition states, whose energies closely resemble those of the product cations.

On the basis of this analysis, we can rephrase the empirical Markovnikov rule: HX adds to unsymmetric alkenes in such a way that the initial protonation gives the more stable carbocation. For alkenes that are similarly substituted at both sp² carbons, product mixtures are to be expected, because carbocations of comparable stability are formed. By analogy with other carbocation reactions (e.g., SN1, Section 7-3), when addition to an achiral alkene generates a chiral product, this product is obtained as a racemic mixture.

Exercise 12-6

Predict the outcome of the addition of HBr to (a) 1-hexene; (b) trans-2-pentene; (c) 2-methyl-2-butene; (d) 4-methylcyclohexene. How many isomers can be formed in each case?

Exercise 12-7

Draw a potential-energy diagram for the reaction in (c) of Exercise 12-6.
Carbocation rearrangements may follow electrophilic addition

In the absence of a good nucleophile, carbocation rearrangements may occur following addition of an electrophile to the alkene double bond (Section 9-3). Rearrangements are favored in electrophilic additions of acids whose conjugate bases are poor nucleophiles. An example is trifluoroacetic acid, CF$_3$CO$_2$H. Its trifluoroacetate counterion is much less nucleophilic than are halide ions. Thus, addition of trifluoroacetic acid to 3-methyl-1-butene gives only about 43% of the normal product of Markovnikov addition. The major product results from a hydride shift that converts the initial secondary cation into a more stable tertiary cation before the trifluoroacetate can attach.

Rearrangement Accompanying Addition of Trifluoroacetic Acid to 3-Methyl-1-butene

![Chemical structure](image)

Exercise 12-8

Write a detailed step-by-step mechanism for the reaction depicted above. Refer to Section 9-3 if necessary.

The extent of carbocation rearrangement is difficult to predict: It depends on the alkene structure, the solvent, the strength and concentration of the nucleophile, and the temperature. In general, rearrangements are favored under strongly acidic, nucleophile-deficient conditions.

In Summary Additions of hydrogen halides to alkenes are electrophilic reactions that begin with protonation of the double bond to give a carbocation. Trapping of the carbocation by halide ion gives the final product. The Markovnikov rule predicts the regioselectivity of hydrohalogenation to haloalkanes. As in any carbocation reaction, rearrangements may occur if good nucleophiles are absent.

12-4 Alcohol Synthesis by Electrophilic Hydration: Thermodynamic Control

So far, we have seen attack on the double bond by a proton, followed by nucleophilic attachment of its counterion to the intermediate carbocation. Can other nucleophiles participate? Upon exposure of an alkene to an aqueous solution of sulfuric acid, which has a poorly nucleophilic counterion, water acts as the nucleophile to trap the carbocation formed by initial protonation. Overall, the elements of water add to the double bond, an electrophilic hydration. The addition follows the Markovnikov rule in that H$^+$ adds to the less substituted carbon and the OH group ends up at the more substituted one. Because water is a poor nucleophile, carbocation rearrangements can intervene in the hydration process.

This addition process is the reverse of the acid-induced elimination of water from alcohols (dehydration, Section 11-7). Its mechanism is the same in reverse, as illustrated in the hydration of 2-methylpropene, a reaction of industrial importance leading to 2-methyl-2-propanol (tert-butyl alcohol).
Electrophilic Hydration

\[
\text{H}_3\text{C} \chemistry{\begin{array}{c} \text{C=CH}_2 \end{array}} \overset{50\% \text{HOH}, \text{H}_2\text{SO}_4}{\text{H}_3\text{C} \chemistry{\begin{array}{c} \text{C-CH}_2-\text{H} \end{array}}} \quad 2\text{-Methylpropene} \quad 2\text{-Methyl-2-propanol}
\]

92%

Mechanism of the Hydration of 2-Methylpropene

Alkene hydration and alcohol dehydrogenation are equilibrium processes

In the mechanism of alkene hydration, all the steps are reversible. The proton acts only as a catalyst and is not consumed in the overall reaction. Indeed, without the acid, hydration would not occur; alkenes are stable in neutral water. The presence of acid, however, establishes an equilibrium between alkene and alcohol. This equilibrium can be driven toward the alcohol by using low reaction temperatures and a large excess of water. Conversely, we have seen (Section 11-7) that treating the alcohol with concentrated acid favors dehydration, especially at elevated temperatures.

Alcohol  \overset{\text{Conc. } \text{H}_2\text{SO}_4, \text{high temperature}}{\underset{\text{H}_2\text{SO}_4, \text{excess } \text{H}_2\text{O, low temperature}}{\longrightarrow}} \text{alkene} + \text{H}_2\text{O}

Exercise 12-9

Treatment of 2-methylpropene with catalytic deuterated sulfuric acid (D₂SO₄) in D₂O gives (CD₃)₃COD. Explain by a mechanism.

The reversibility of alkene protonation leads to alkene equilibration

In Section 11-17 we explained that the acid-catalyzed dehydrogenation of alcohols gives mixtures of alkenes in which the more stable isomers predominate. Equilibrating carbocation rearrangements, followed by E1, are partly responsible for these results. However, more important for the attainment of thermodynamic equilibration is that the E1 process is reversible: As we discussed above, alkenes can be protonated by acid to form carbocations.

Let us illustrate this feature of reversible protonation by envisaging what can happen when 2-butanol is dehydrated under acidic conditions. To avoid complications arising from S₈1, we will employ sulfuric acid bearing a nonnucleophilic counterion. The first thing to happen is protonation of the hydroxy group. Then, loss of water from the protonated alcohol gives the corresponding secondary carbocation. This species can undergo E1 in three different ways, to give the three observed products: 1-butene, cis-2-butene, and trans-2-butene. The initial ratio of these isomers is controlled by the relative energies of the transition states leading to them: It is under kinetic control (Section 2-1). However, under the strongly acidic conditions, a proton can re-add to the double bond of any of the isomers. In the case of the two 2-butenes, this process engenders the corresponding secondary carbocations. In the case of 1-butene, and as noted earlier, regioselective Markovnikov
addition leads to the same ion. Because this cation may again lose a proton to give any of the same three alkene isomers, the net effect is \textit{interconversion} of the isomers to an \textit{equilibrium mixture}, in which the thermodynamically most stable isomer is the major component. This system is therefore an example of a reaction that is under \textit{thermodynamic control} (Section 2-1).

**Thermodynamic Control in the Acid-Catalyzed Dehydration of 2-Butanol**

\[
\begin{align*}
\text{Cis-2-Butene} & \quad \text{Trans-2-Butene} \\
\end{align*}
\]

By this procedure, less stable alkenes may be catalytically converted into their more stable isomers (see below and margin).

**Acid-Catalyzed Equilibration of Alkenes**

\[
\begin{align*}
\text{(CH}_3\text{)}_3\text{C} & \quad \text{C}(\text{CH}_3)_3 \\
\text{Cis} & \quad \text{Trans} \\
\end{align*}
\]

**Exercise 12-10**

Write a mechanism for this rearrangement. What is the driving force for the reaction?

**In Summary** The carbocation formed by addition of a proton to an alkene may be trapped by water to give an alcohol, the reverse of alkene synthesis by alcohol dehydration. Reversible protonation equilibrates alkenes in the presence of acid, thereby forming a thermodynamically controlled mixture of isomers.

**12-5 Electrophilic Addition of Halogens to Alkenes**

Halogens, although they do not appear to contain electrophilic atoms, add to the double bond of alkenes, giving vicinal dihalides. These compounds have uses as solvents for dry cleaning and degreasing and as antiknock additives for gasoline.

Halogen addition works best for chlorine and bromine. The reaction of fluorine is too violent to be generally employed, and iodine addition is not normally favorable thermodynamically.
Chapter 12

519

Halogenation of Alkenes

\[ \text{X} = \text{Cl, Br} \]

Vicinal dihalide

Exercise 12-11

Calculate (as in Table 12-1) the \( \Delta H^\circ \) values for the addition of \( \text{F}_2 \) and \( \text{I}_2 \) to ethene. (For \( \Delta H^\circ \), see Section 3-5.)

Bromine addition is particularly easy to observe because bromine solutions immediately change from red to colorless when exposed to an alkene. This phenomenon is sometimes used as a color test for unsaturation.

Halogenations are best carried out at or below room temperature in inert halogenated solvents such as tetrachloromethane (carbon tetrachloride).

Electrophilic Halogen Addition of \( \text{Br}_2 \) to 1-Hexene

\[
\begin{align*}
\text{CH}_3(\text{CH}_2)_2\text{CH} &= \text{CH}_2 & \text{Br} \quad \text{CCl}_4 \\
\rightarrow & \quad \text{CH}_3(\text{CH}_2)_2\text{CHCH}_2\text{Br} : \\
& \quad \text{Br} : \\
& \quad 90\% \\
\end{align*}
\]

1-Hexene 1,2-Dibromohexane

Halogen additions to double bonds may seem to be similar to hydrogenations. However, their mechanism is quite different, as revealed by the stereochemistry of bromination; similar arguments hold for the other halogens.

**Bromination takes place through anti addition**

What is the stereochemistry of bromination? Do the two bromine atoms add from the same side of the double bond (syn, as in catalytic hydrogenation) or from opposite sides (see margin)? Let us examine the bromination of cyclohexene. Addition on the same side should give cis-1,2-dibromocyclohexane; the alternative would result in trans-1,2-dibromocyclohexane. The second pathway is borne out by experiment—only anti addition is observed. Because anti addition to the two reacting carbon atoms can take place with equal probability in two possible ways—in either case, from both above and below the \( \pi \) bond—the product is racemic.

**Anti Bromination of Cyclohexene**

\[
\begin{align*}
\text{Br}_2, \text{CCl}_4 & \quad \text{Br} : \quad \text{Br} : \\
\rightarrow & \quad \text{Br} : \quad \text{Br} : \\
& \quad \text{83}\% \\
\end{align*}
\]

Racemic trans-1,2-dibromocyclohexane

With acyclic alkenes, the reaction is also cleanly stereospecific. For example, cis-2-butene is brominated to furnish a racemic mixture of \( (2R,3R) \) and \( (2S,3S) \)-2,3-dibromobutane; trans-2-butene results in the meso diastereomer.
Cyclic bromonium ions explain the stereochemistry

How does bromine attack the electron-rich double bond even though it does not appear to contain an electrophilic center? The answer lies in the polarizability of the Br–Br bond, which is prone to heterolytic cleavage upon reaction with a nucleophile. The π-electron cloud of the alkene is nucleophilic and attacks one end of the bromine molecule, with simultaneous displacement of the second bromine atom as bromide ion in an $S_N2$-like process.

What is the product of this process? We might expect a carbocation, in analogy with the proton additions discussed in Sections 12-3 and 12-4. However, if the first step of addition of bromine to cyclohexene were to give a carbocation, the bromide ion released in this process could attack the positively charged carbon atom from either the same or the opposite side of the ring, resulting in a mixture of cis- and trans-1,2-dibromocyclohexanes. However, as shown previously, only the trans product is obtained. How can we explain this result?

The stereochemistry of bromination is explained if we propose that initial attack of bromine on the double bond gives a cyclic bromonium ion, in which the bromine bridges both carbon atoms of the original double bond to form a three-membered ring (Figure 12-3). The structure of this ion is rigid, and it may be attacked by bromide ion only on the side opposite the bridging bromine atom. The three-membered ring is thus opened stereospecifically (compare nucleophilic ring opening of oxacyclopropanes in Section 9-9). The leaving group is the bridging bromine. In symmetric bromonium ions, attack is equally probable at either carbon atom, thereby giving the racemic (or meso) products observed.
Formation and Nucleophilic Opening of a Cyclic Bromonium Ion

Exercise 12-12

Draw the intermediate in the bromination of cyclohexene, using the following conformational picture. Show why the product is racemic. What can you say about the initial conformation of the product?

The halogenation of alkenes should not be confused with halogenation of alkanes (Sections 3-4 through 3-8). The addition to alkenes follows a mechanism in which a nucleophile (the alkene π bond) interacts with an electrophilic species (such as molecular Cl₂ or Br₂) via movement of electron pairs. Alkane halogenation is a radical process that requires an initiation step to generate halogen atoms. This step typically needs heat, light, or a radical initiator (such as a peroxide) and proceeds via a mechanism involving movement of single electrons.

**In Summary** Halogens add as electrophiles to alkenes, producing vicinal dihalides. The reaction begins with the formation of a bridged halonium ion. This intermediate is opened stereospecifically by the halide ion displaced in the initial step to give overall anti addition to the double bond. In subsequent sections, we shall see that other stereochemical outcomes are possible, depending on the electrophile.

12-6 The Generality of Electrophilic Addition

Halogens are just one of many electrophile–nucleophile combinations that add to alkene double bonds. In this section we begin a survey of some of the most important of these processes, beginning with addition of halogens (the electrophile source) in the presence of water (the nucleophile). The products, 2-haloalcohols, commonly known as halohydrins, are widely used in a number of industrial and synthetic applications. In particular, they are important intermediates for the synthesis of oxacyclopropanes (epoxides, Section 9-9).

The bromonium ion can be trapped by other nucleophiles

The creation of a bromonium ion in alkene brominations suggests that, in the presence of other nucleophiles, competition might be observed in the trapping of the intermediate. For example, bromination of cyclopentene in water as solvent gives the vicinal bromoalcohol (common name, bromohydrin). In this case, the bromonium ion is attacked by water, which is
present in large excess. The net transformation is the *anti* addition of Br and OH to the double bond. The other product formed is HBr. The corresponding chloroalcohols (chlorohydrins) can be made from chlorine in water through a chloronium ion intermediate.

**Bromoalcohol (Bromohydrin) Synthesis**

\[
\begin{align*}
\text{Cyclopentene} & \xrightarrow{\text{Br}_2, \text{H}_2\text{O}, 0^\circ\text{C}} \text{Bromoalcohol (Bromohydrin)} \\
\text{Cyclopentene} & \xrightarrow{\text{Cl}_2, \text{H}_2\text{O}, 25^\circ\text{C}} \text{Vicinal Haloether}
\end{align*}
\]

**Exercise 12-13**

Write the expected product from the reaction of (a) *trans*-2-butene and (b) *cis*-2-pentene with aqueous chlorine. Show the stereochemistry clearly.

Vicinal haloalcohols undergo intramolecular ring closure in the presence of base to give oxacyclopropanes (Section 9-9) and are therefore useful intermediates in organic synthesis.

**Oxacyclopropane Formation from an Alkene Through the Haloalcohol**

If alcohol is used as a solvent instead of water in these halogenations, the corresponding vicinal haloethers are produced, as shown in the margin.

**Halonium ion opening can be regioselective**

In contrast with addition of two identical halogens, mixed additions to double bonds can pose regiochemical problems. Is the addition of Br and OH (or OR) to an unsymmetric double bond selective? The answer is yes. For example, 2-methylpropene is converted by aqueous bromine into only 1-bromo-2-methyl-2-propanol; none of the alternative regioisomer, 2-bromo-2-methyl-1-propanol, is formed.
The electrophilic halogen in the product always becomes linked to the less substituted carbon of the original double bond. The subsequently added nucleophile attaches to the more highly substituted center.

How can this be explained? The situation is very similar to the acid-catalyzed nucleophilic ring opening of oxacyclopropanes (Section 9-9), in which the intermediate contains a protonated oxygen in the three-membered ring. In both reactions, the nucleophile attacks the more highly substituted carbon of the ring, because this carbon is more positively polarized than the other.

A simple rule of thumb is that electrophilic additions of unsymmetric reagents of this type add in a Markovnikov-like fashion, with the electrophilic unit emerging at the less substituted carbon of the double bond. Mixtures are formed only when the two carbons are not sufficiently differentiated [see Exercise 12-14(b)].

**Exercise 12-14**

What are the product(s) of the following reactions?

(a) \( \text{CH}_3\text{CH} = \text{CH}_2 \xrightarrow{\text{Cl}_2, \text{CH}_3\text{OH}} \)

(b) \( \text{CH}_3\text{C} \rightarrow \text{H}_2\text{O} \)

**Exercise 12-15**

**Working with the Concepts: Mechanism of Electrophilic Addition to Alkenes**

Write a mechanism for the reaction shown in Exercise 12-14(a).

**Strategy**

This problem is quite similar to the transformation shown on the preceding page. We have simply replaced bromine with chlorine.

**Solution**

- Initial attack of the alkene \( \pi \) bond on a molecule of \( \text{Cl}_2 \) gives rise to a cyclic *chloronium* ion:

  \[
  \text{CH}_3\text{CH} = \text{CH}_2 \quad \xrightarrow{...} \quad \text{CH}_3\text{CH} - \text{CH}_2 + \text{Cl}_2^-
  \]

- This species is not symmetric: In particular, of the two carbons bonded to the positive chlorine, the internal (secondary) carbon is more positively polarized. Attack of the nucleophilic solvent
methanol occurs preferentially at this center. Loss of a proton from the resulting oxonium ion completes the reaction:

\[
\text{CH}_3\text{CH} = \text{CH}_2 + \text{CH}_3\text{O} - \text{H} \rightarrow \text{CH}_3\text{CH} = \text{CH}_2 \rightarrow \text{CH}_3\text{CH} = \text{CHCH}_2
\]

**Exercise 12-16**

**Try It Yourself**

Write a mechanism for the reaction shown in Exercise 12-14(b). [**Caution:** The presence of the methyl group on the cyclohexane ring has a significant stereochemical effect (compared with the other examples in the section)! **Hint:** The initial addition of halogen to the alkene $\pi$ bond can occur either from the same face of the ring that contains the methyl group or from the opposite face. How many isomers do you expect to result from this addition?]

**Exercise 12-17**

What would be a good alkene precursor for a racemic mixture of $(2R,3R)$- and $(2S,3S)$-2-bromo-3-methoxypentane? What other isomeric products might you expect to find from the reactions that you propose?

In general, alkenes can undergo stereo- and regiospecific addition reactions with reagents of the type A–B, in which the A–B bond is polarized such that A acts as the electrophile $A^+$ and B as the nucleophile $B^-$. Table 12-2 shows how such reagents add to 2-methylpropene.

**Table 12-2  Reagents A–B That Add to Alkenes by Electrophilic Attack**

*X here denotes acetate.*
In Summary  Halonium ions are subject to stereospecific and regioselective ring opening in a manner that is mechanistically very similar to the nucleophilic opening of protonated oxacyclopropanes. Halonium ions can be trapped by halide ions, water, or alcohols to give vicinal dihaloalkanes, haloalcohols, or haloethers, respectively. The principle of electrophilic additions can be applied to any reagent A–B containing a polarized or polarizable bond.

12-7 Oxymercuration–Demercuration: A Special Electrophilic Addition

The last example in Table 12-2 is an electrophilic addition of a mercuric salt to an alkene. The reaction is called *mercuration*, and the resulting compound is an alkylmercury derivative, from which the mercury can be removed in a subsequent step. One particularly useful reaction sequence is *oxymercuration–demercuration*, in which mercuric acetate acts as the reagent. In the first step (oxymercuration), treatment of an alkene with this species in the presence of water leads to the corresponding addition product.

![Oxymercuration reaction](image)

In the subsequent demercuration, the mercury-containing substituent is replaced by hydrogen through treatment with sodium borohydride in base. The net result is hydration of the double bond to give an alcohol.

![Demercuration reaction](image)

Oxymercuration is *anti* stereospecific and regioselective. This outcome implies a mechanism similar to that for the electrophilic addition reactions discussed so far. The mercury reagent initially dissociates to give an acetate ion and a cationic mercury species. This mercury cation then attacks an alkene double bond, furnishing a mercurinium ion, with a structure similar to that of a cyclic bromonium ion. The water that is present attacks the more substituted carbon (Markovnikov rule regioselectivity) to give an alkylmercuric acetate intermediate. Replacement of mercury by hydrogen (demercuration) is achieved by sodium borohydride reduction through a complex and only incompletely understood mechanism. It is not stereospecific.

The alcohol obtained after demercuration is the same as the product of Markovnikov hydration (Section 12-4) of the starting material. However, oxymercuration–demercuration is a valuable alternative to acid-catalyzed hydration, because no carbocation is involved; therefore *oxymercuration–demercuration is not susceptible to the rearrangements that commonly occur under acidic conditions* (Section 12-3). Its use is limited by the expense of the mercury reagent and its toxicity, which requires careful removal of mercury from the product and safe disposal.
Juvenile Hormone Analogs in the Battle against Insect-Borne Diseases

Juvenile hormone (JH) is a substance that controls metamorphosis in insects. It is produced by the male wild silk moth, *Hyalophora cecropia* L., and its presence delays the maturation of insect larvae until the appropriate developmental stage is reached. Exposure to JH causes insect metamorphosis to stall at the pupa stage: Mosquitoes exposed to JH fail to develop into biting, egg-laying adults. JH therefore has the potential for use in controlling mosquito-borne diseases such as malaria, yellow fever, and West Nile virus. This potential is limited by the instability of JH and the difficulty with which it can be isolated naturally or prepared synthetically. As a result, analogs have been sought that are more stable, suitably bioactive, and easy to prepare.

The synthetic compound methoprene possesses all of these desirable features. Its synthesis utilizes several reactions we have studied, including oxymercuration–demercuration to give the tertiary methyl ether, ester hydrolysis (Section 8-5), and PCC oxidation of a primary alcohol to produce an aldehyde (Section 8-6).

Whereas earlier attempts to prepare JH analogs gave compounds with very poor activity, methoprene is up to 1000 times more bioactive than JH toward a variety of pests. It is effective against fleas, mosquitoes, and fire ants and is now marketed under a number of trade names. Methoprene may be used indoors to eliminate flea infestations, greatly reducing the need for conventional insecticides. Although the product does not kill insects that have already reached adulthood, the eggs they lay after exposure do not develop into adults. Spreading methoprene as granules in areas where mosquitoes may breed prevents their survival past the pupal stage. Methoprene possesses relatively low toxicity toward vertebrates and, unlike chlorinated insecticides such as DDT (Chemical Highlight 3-2), it does not persist in the environment. Although it is stable enough to be effective for weeks to months after application, it is degraded over time by sunlight into innocuous smaller molecules. Methoprene and several other JH analogs have therefore become important new tools for pest management.
Mechanism of Oxymercuration–Demercuration

Step 1. Dissociation

\[
\text{CH}_3\text{COHgOCCH}_3 \rightleftharpoons \text{CH}_3\text{CO}^- + \text{HgOCCH}_3^+
\]

Step 2. Electrophilic attack

\[
\text{C} = \text{C} + \text{HgOCCH}_3 \rightarrow \text{C} = \text{C} \quad \text{Mercurinium ion}
\]

Step 3. Nucleophilic opening (Markovnikov regioselectivity)

\[
\text{C} = \text{C} + \text{H}^-\text{OH} \rightarrow \text{C} = \text{C} \quad \text{Alkylmercuric acetate}
\]

Step 4. Reduction

\[
\text{CH}_3\text{COHg} \rightarrow \text{CH}_3\text{CO}^- + \text{Hg} + \text{H}_2\text{O}
\]

When the oxymercuration of an alkene is executed in an alcohol solvent, demercuration gives an ether, as shown in the margin.

Exercise 12-18

Working with the Concepts: Addressing a Difficult Mechanism Problem

Explain the result shown below.

Strategy
Start by addressing the apparent dissimilarity between the structure of the substrate and that of the product. You can clarify the pathway to a solution by numbering the carbon atoms in the substrate and then identifying the corresponding atoms in the product. Then you can begin the process of **thinking mechanistically**—following the steps of the process as we understand them to see where they lead.

Solution
- Begin with mercuration of the double bond:
In all previous examples, the next step involved a molecule of solvent—either water or alcohol—which provided a nucleophilic oxygen atom to add to one carbon of the mercurinium ion and open the ring. In this case, however, we can see that an oxygen atom already present in the substrate (at C7) becomes attached to one of the original double-bond carbons (C2) in the product. This process is one of intramolecular bond formation. After removal of the mercury by NaBH₄, we arrive at the final product:

![Reaction Diagram]

**Exercise 12-19**

Try It Yourself

The reaction below proceeds to a cyclic product that is an isomer of the starting material. Suggest a structure for it. (Hint: Think mechanistically. Begin with the appropriate electrophilic attack. Then utilize a nucleophilic atom already present in the substrate in order to complete the addition process. Caution: There is a regioselectivity issue to address. Use the examples presented in the chapter section to guide you.)

2. NaBH₄, NaOH, H₂O

1. Hg(O₂CCH₃)₂

In Summary Oxymercuration–demercuration is a synthetically useful method for converting alkenes regioselectively (following the Markovnikov rule) into alcohols or ethers. Carbocations are not involved; therefore, rearrangements do not occur.

**12-8 Hydroboration–Oxidation: A Stereospecific Anti-Markovnikov Hydration**

So far in this chapter, we have seen two ways to add the elements of water to alkenes to give alcohols. This section presents a third method, which complements the other two synthetically by giving in a different regiochemical outcome. The process involves a reaction that lies mechanistically between hydrogenation and electrophilic addition: hydroboration of double bonds. The alkylboranes that result can be oxidized to alcohols.

**The boron–hydrogen bond adds across double bonds**

Borane, BH₃, adds to double bonds without catalytic activation, a reaction called hydroboration by its discoverer, H. C. Brown.*

*Professor Herbert C. Brown (1912–2004), Purdue University, West Lafayette, Indiana, Nobel Prize 1979 (chemistry).
Borane (which by itself exists as a dimer, B₂H₆) is commercially available in ether and tetrahydrofuran (THF). In these solutions, borane exists as a Lewis acid-base complex with the ether oxygen (see Sections 2-2 and 9-5), an aggregate that allows the boron to have an electron octet (for the molecular-orbital picture of BH₃, see Figure 1-17).

How does the B–H unit add to the π bond? The π bond is electron rich and borane is electron poor. Therefore, it is reasonable to formulate an initial Lewis acid-base complex similar to that of a bromonium ion (Figure 12-3), requiring the participation of the empty p orbital on BH₃. This shifts electron density from the alkene to boron. Subsequently, one of the hydrogens is transferred by means of a four-center transition state to one of the alkene carbons, while the boron shifts to the other. The stereochemistry of the addition is syn. All three B–H bonds are reactive in this way. The boron in the product alkylborane is again electron deficient. The electrostatic potential maps of the general scheme shown below (on a scale that maximizes the desired color changes) show how the boron in borane starts out as an electron-deficient species (blue), becomes more electron rich (red) in the complex, and then loses the electron density gained as it proceeds to product (blue).

**Mechanism of Hydroboration**

Hydroboration is not only stereospecific (syn addition), it is also regioselective. Unlike the electrophilic additions described previously, steric more than electronic factors primarily control the regioselectivity: The boron binds to the less hindered (less substituted) carbon. The reactions of the trialkylboranes resulting from these hydroborations are of special interest to us, as the next section will explain.

**The oxidation of alkylboranes gives alcohols**

Trialkylboranes can be oxidized with basic aqueous hydrogen peroxide to furnish alcohols in which the hydroxy function has replaced the boron atom. The net result of the two-step sequence, hydroboration–oxidation, is the addition of the elements of water to a double bond. In contrast with the hydrations described in Sections 12-4 and 12-7, however, those using borane proceed with the opposite regioselectivity: In this sequence, the OH group ends up at the less substituted carbon, an example of anti-Markovnikov addition.
Chapter 12
Reactions of Alkenes

Hydroboration–Oxidation Sequence

\[
3 \text{RCH} = \text{CHR} \xrightarrow{\text{BH}_3, \text{THF}} (\text{RCH}_2\text{CHR})_3\text{B} \xrightarrow{\text{H}_2\text{O}_2, \text{NaOH, H}_2\text{O}} \text{R} \xrightarrow{\text{3 RCH}_2\text{CHOH}}
\]

4-Methyl-1-pentene 4-Methyl-1-pentanol

In the mechanism of alkylborane oxidation, the nucleophilic hydroperoxide ion attacks the electron-poor boron atom. The resulting species undergoes a rearrangement in which an alkyl group migrates with its electron pair—and with retention of configuration—to the neighboring oxygen atom, thus expelling a hydroxide ion in the process.

Mechanism of Alkylborane Oxidation

\[
\begin{align*}
\text{B} + \text{O} = \text{OH} & \quad \rightarrow \quad \text{B} = \text{O} = \text{OH} \\
& \quad \rightarrow \quad \text{B} \quad \text{O} = \text{OH} \quad \rightarrow \quad \text{B} \quad \text{O} = \text{O} \\
\end{align*}
\]

This process is repeated until all three alkyl groups have migrated to oxygen atoms, finally forming a triakyl borate \((\text{RO})_3\text{B}\). This inorganic ester is then hydrolyzed by base to the alcohol and sodium borate.

\[
(\text{RO})_3\text{B} + 3 \text{NaOH} \xrightarrow{\text{H}_2\text{O}} \text{Na}_3\text{BO}_3 + 3 \text{ROH}
\]

Because borane additions to double bonds and subsequent oxidation are so selective, this sequence allows the stereospecific and regioselective synthesis of alcohols from alkenes. The anti-Markovnikov regioselectivity of the hydroboration–oxidation sequence complements that of acid-catalyzed hydration and oxymercuration–demercuration. In addition, hydroboration, like oxymercuration, occurs without the participation of carbocations; therefore, rearrangements are not observed.

A Stereospecific and Regioselective Alcohol Synthesis by Hydroboration–Oxidation

Exercise 12-20

Give the products of hydroboration–oxidation of (a) propene and (b) \((E)\)-3-methyl-2-pentene. Show the stereochemistry clearly.

In Summary Hydroboration–oxidation constitutes another method for hydrating alkenes. The initial addition is syn and regioselective, the boron shifting to the less hindered carbon. Oxidation of alkyl boranes with basic hydrogen peroxide gives anti-Markovnikov alcohols with retention of configuration of the alkyl group.
12-9 Diazomethane, Carbenes, and Cyclopropane Synthesis

Cyclopropanes make interesting synthetic targets. Their highly strained structures (Section 4-2) are fascinating to study, as are the functional contributions they make to a variety of naturally occurring biological compounds (Section 4-7). Cyclopropanes may be quite readily prepared by the addition of reactive species called carbenes to the double bond of alkenes. Carbenes have the general structure $R_2C\equiv N$, in which the central carbon atom possesses an electron sextet. Although neutral, carbenes are electron deficient and act as electrophiles toward alkenes.

Diazomethane forms methylene, which converts alkenes into cyclopropanes

The unusual substance diazomethane, CH$_2$N$_2$, is a yellow, highly toxic, and explosive gas. It decomposes on exposure to light, heat, or copper metal by loss of N$_2$. The result is the highly reactive species methylene, H$_2$C\equiv N, the simplest carbene.

When methylene is generated in the presence of compounds containing double bonds, addition takes place to furnish cyclopropanes. The process is usually stereospecific, with retention of the original configuration of the double bond.

Exercise 12-21

Diazomethane is the simplest member of the class of compounds called diazoalkanes or diazo compounds, $R_2C\equiv N_2$. When diazo compound A is irradiated in heptane solution at $-78^\circ$C, it gives a hydrocarbon, C$_4$H$_6$, exhibiting three signals in $^1$H NMR and two signals in $^{13}$C NMR spectroscopy, all in the aliphatic region. Suggest a structure for this molecule.

Halogenated carbenes and carbenoids also give cyclopropanes

Cyclopropanes may also be synthesized from halogenated carbenes, which are prepared from halomethanes. For example, treatment of trichloromethane (chloroform) with a strong base causes an unusual elimination reaction in which both the proton and the leaving group are removed from the same carbon. The product is dichlorocarbene, which gives cyclopropanes when generated in the presence of alkenes.
Dichlorocarbene from Chloroform and Its Trapping by Cyclohexene

\[
\text{(CH}_3\text{)}_3\text{CO}^+ + \text{HCCl}_3 \xrightarrow{\text{(CH}_3\text{)}_3\text{COH}} \text{::CCl}_2 \xrightarrow{\text{::Cl/CH}_3\text{CO}} 
\]

In another route to cyclopropanes, diiodomethane is treated with zinc powder (usually activated with copper) to generate \( \text{ICl}_2\text{ZnI} \), called the Simmons-Smith* reagent. This species is an example of a carbenoid, or carbenelike substance, because, like carbenes, it also converts alkenes into cyclopropanes stereospecifically. Use of the Simmons-Smith reagent in cyclopropane synthesis avoids the hazards associated with diazomethane preparation.

**Simmons-Smith Reagent in Cyclopropane Synthesis**

An impressive example of the use of the Simmons-Smith reagent in the construction of natural products is the highly unusual, potent antifungal agent FR-900848, obtained in 1990 from a fermentation broth of *Streptoverticillium fervens* and first synthesized in 1996. Its most noteworthy feature is the fatty acid residue, which contains five cyclopropanes, four of which are contiguous and all of which were made by Simmons-Smith cyclopropanations.

**FR-900848**

**In Summary** Diazomethane is a useful synthetic intermediate as a methylene source for forming cyclopropanes from alkenes. Halogenated carbenes, which are formed by dehalogenation of halomethanes, and the Simmons-Smith reagent, a carbenoid arising from the reaction of diiodomethane with zinc, also convert alkenes into cyclopropanes. Additions of carbenes to alkenes differ from other addition processes because a single carbon atom becomes bonded to both alkene carbons.

**12-10 Oxacyclopropane (Epoxide) Synthesis: Epoxidation by Peroxycarboxylic Acids**

This section describes how an electrophilic oxidizing agent is capable of introducing a single oxygen atom to connect to both carbons of a double bond. This produces oxacyclopropanes, which may, in turn, be converted into vicinal anti diols. Sections 12-11 and 12-12

*Dr. Howard E. Simmons (1929–1997) and Dr. Ronald D. Smith (b. 1930), both with E. I. du Pont de Nemours and Company, Wilmington, Delaware.*
will show methods for the attachment of oxygen atoms to each alkene carbon to give vicinal syn diols by partial double-bond cleavage or carbonyl compounds by complete double-bond cleavage.

**Peroxycarboxylic acids deliver oxygen atoms to double bonds**

The OH group in peroxycarboxylic acids, RCOOH, contains an electrophilic oxygen. These compounds react with alkenes by adding this oxygen to the double bond to form oxacyclopropanes. The other product of the reaction is a carboxylic acid. The transformation is of value because, as we know, oxacyclopropanes are versatile synthetic intermediates (Section 9-9). It proceeds at room temperature in an inert solvent, such as chloroform, dichloromethane, or benzene. This reaction is commonly referred to as epoxidation, a term derived from epoxide, one of the older common names for oxacyclopropanes. A popular peroxycarboxylic acid for use in the research laboratory is meta-chloroperoxybenzoic acid (MCPBA). For large-scale and industrial purposes, however, the somewhat shock-sensitive (explosive) MCPBA has been replaced by magnesium monoperoxyphthalate (MMPP).

**Oxacyclopropane Formation: Epoxidation of a Double Bond**

The transfer of oxygen is stereospecifically syn, the stereochemistry of the starting alkene being retained in the product. For example, trans-2-butene gives trans-2,3-dimethyloxacyclopropane; conversely, the cis-2-butene yields cis-2,3-dimethoxacyclopropane.

**Mechanism of Oxacyclopropane Formation**

What is the mechanism of this oxidation? It is related but not quite identical to electrophilic halogenation (Section 12-5). In epoxidation, we can write a cyclic transition state in which the electrophilic oxygen is added to the π bond at the same time as the peroxycarboxylic acid proton is transferred to its own carbonyl group, releasing a molecule of carboxylic acid, which is a good leaving group. The two new C–O bonds in the oxacyclopropane product are formally derived from the electron pairs of the alkene π bond and of the cleaved O–H linkage.
In accord with the electrophilic mechanism, the reactivity of alkenes toward peroxycarboxylic acids increases with alkyl substitution, allowing for selective oxidations. For example,

\[
\text{CH}_3\text{COOH (1 equivalent), CHCl}_3, 10^\circ\text{C} \rightarrow \text{Epoxidation only at more electron-rich double bond}
\]

\[
\text{Disubstituted Monosubstituted}
\]

**Hydrolysis of oxacyclopropanes furnishes the products of anti dihydroxylation of an alkene**

Treatment of oxacyclopropanes with water in the presence of catalytic acid or base leads to ring opening to the corresponding vicinal diols. These reactions follow the mechanisms described in Section 9-9: The nucleophile (water or hydroxide) attacks the side opposite the oxygen in the three-membered ring, so the net result of the oxidation–hydrolysis sequence constitutes an *anti dihydroxylation* of an alkene. In this way, *trans*-2-butene gives *meso*-2,3-butanediol, whereas *cis*-2-butene furnishes the racemic mixture of the *2R,3R* and *2S,3S* enantiomers.

**Vicinal Anti Dihydroxylation of Alkenes**

\[
\text{H}_2\text{C} = \text{C} \xrightarrow{1. \text{MCPBA, CH}_2\text{Cl}_2} \text{HO:} \quad \text{H}_2\text{C} \xleftarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{OH}
\]

**Synthesis of Isomers of 2,3-Butanediol**

\[
\text{H}_3\text{C} \xrightarrow{1. \text{MCPBA, CH}_2\text{Cl}_2} \text{HO:} \quad \text{H}_3\text{C} \xleftarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{OH}
\]

\[
\text{H}_3\text{C} \xrightarrow{1. \text{MCPBA, CH}_2\text{Cl}_2} \text{HO:} \quad \text{H}_3\text{C} \xleftarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{OH}
\]

**Exercise 12-23**

Give the products obtained by treating the following alkenes with MCPBA and then aqueous acid:
(a) 1-hexene; (b) cyclohexene; (c) *cis*-2-pentene; (d) *trans*-2-pentene.

**In Summary** Peroxycarboxylic acids supply oxygen atoms to convert alkenes into oxacyclopropanes (epoxidation). Oxidation–hydrolysis reactions with peroxycarboxylic acids furnish vicinal diols in a stereospecifically *anti* manner.
12-11 Vicinal Syn Dihydroxylation with Osmium Tetroxide

Osmium tetroxide reacts with alkenes in a two-step process to give the corresponding vicinal diols in a stereospecifically syn manner. The process therefore complements the epoxidation–hydrolysis sequence described in the previous section, which proceeds with anti selectivity.

Vicinal Syn Dihydroxylation with Osmium Tetroxide

The process leads initially to an isolable cyclic ester, which is reductively hydrolyzed with H₂S or bisulfite, NaHSO₃. For example,

What is the mechanism of this transformation? The initial reaction of the π bond with osmium tetroxide constitutes a concerted (Section 6-4) addition in which three electron pairs move simultaneously to give a cyclic ester containing Os(VI). This process can be viewed as an electrophilic attack on the alkene: Two electrons flow from the alkene onto the metal, which is reduced [Os(VIII) → Os(VI)]. For steric reasons, the product can form only in a way that introduces the two oxygen atoms on the same face of the double bond—syn. This intermediate is usually not isolated but converted upon reductive work-up into the free diol.

Mechanism of the Osmium Tetroxide Oxidation of Alkenes

Because OsO₄ is expensive and highly toxic, a commonly used modification calls for the use of only catalytic quantities of the osmium reagent and stoichiometric amounts of another oxidizing agent such as H₂O₂, which serves to reoxidize reduced osmium.

An older reagent for vicinal syn dihydroxylation of alkenes is potassium permanganate, KMnO₄. Although this reagent functions in a manner that is mechanistically similar to OsO₄, it is less useful for synthesizing diols because of a tendency to give poorer yields owing to overoxidation. Potassium permanganate solutions, which are deep purple, are useful as a color test for alkenes, however: Upon reaction, the purple reagent is immediately converted into the brown precipitate of its reduction product, MnO₂.

Potassium Permanganate Test for Alkene Double Bonds

Because OsO₄ is expensive and highly toxic, a commonly used modification calls for the use of only catalytic quantities of the osmium reagent and stoichiometric amounts of another oxidizing agent such as H₂O₂, which serves to reoxidize reduced osmium.

An older reagent for vicinal syn dihydroxylation of alkenes is potassium permanganate, KMnO₄. Although this reagent functions in a manner that is mechanistically similar to OsO₄, it is less useful for synthesizing diols because of a tendency to give poorer yields owing to overoxidation. Potassium permanganate solutions, which are deep purple, are useful as a color test for alkenes, however: Upon reaction, the purple reagent is immediately converted into the brown precipitate of its reduction product, MnO₂.
In the decade of the 1990s, a significant shift occurred in the way in which new pharmaceuticals were synthesized. Before this time, most of the available methods for the preparation of chiral molecules in enantiomerically pure form were impractical on an industrial scale. Thus, typically, racemic mixtures were generated, although in many cases only one of the enantiomers in such mixtures possessed the desired activity (see Chemical Highlight 5-4). When it was medically and financially advantageous, such mixtures were resolved by classical methods (Section 5-8). However, fundamental conceptual advances in catalysis changed this situation. Some of the most useful examples are a series of highly enantioselective oxidation reactions of double bonds developed by K. B. Sharpless (see Chemical Highlight 5-4). The first such process is a variant of the oxacyclopropanation reaction discussed in Section 12-10, as applied specifically to 2-propenyl (allylic) alcohols. However, instead of a peroxycarboxylic acid, the reagent is tert-butyl hydroperoxide in the presence of titanium (IV) isopropoxide (“Sharpless epoxidation”), the function of the chiral auxiliary being assumed by tartaric acid diethyl ester (Chemical Highlight 5-3). The naturally occurring (+)-(2R,3R)-diethyl tartrate and its unnatural (−)-(2S,3S) mirror image are both commercial products. One delivers oxygen to one face of the double bond, the other to the opposite face, as shown below, giving either enantiomer of the oxacyclopropane product with high enantiomer excess (Section 5-2). The reaction works so well because the Ti tetraisopropoxide exchanges all four alkoxides for the four hydroxides derived from the other components of the mixture: two from the tartrate, one from the hydroperoxide, and one from the allylic alcohol. Once all assembled around the central metal, the transition state experiences maximally the stereocontrolling influence of the chiral auxiliary.

The role of the chiral coordinated ligand is to provide a pocket into which the substrate can enter in only one spatial orientation. In this respect, it bears the characteristics of many enzymes, biological catalysts that function in essentially the same way (see Chemical Highlight 5-5 and Chapter 26). In the absence of the chiral ligand, a racemic mixture forms.

The Sharpless enantioselective oxacyclopropanation has been exploited in the synthesis of many chiral, enantiomerically pure building blocks for the construction of important drugs. An example is the key step of a route to the powerful antitumor agent aclacinomycin A (see also Chemical Highlight 7-1), depicted on top of the next page.

Sharpless applied the same principle of using a central metal that can hold a chiral directing group proximal to an alkene substrate in an enantioselective version of the OsO4-catalyzed alkene dihydroxylation (Section 12-11). Here, the essence of the chiral auxiliary is an amine derived from the family of natural alkaloids called the *cinchona* (Section 25-8). One of these amines is dihydroquinine, which is added in the linked dimeric form shown on p. 537. Instead of H2O2 as the stoichiometric oxidant (Section 12-11), Fe3+ [as K3Fe(CN)6] is employed. This method has been applied by E. J. Corey (Section 8-9) to the enantioselective synthesis of ovalicin, a member of a class of fungal-derived natural products called antiangiogenesis agents: They inhibit the growth...
A recently identified synthetic derivative of ovalicin, called TNP-470, possesses powerful antiangiogenesis activity, is chemically stable, nontoxic, noninflammatory, and potentially amenable to oral administration. Several preliminary studies revealed the effectiveness of TNP-470 against tumors in animals. By early 2004, TNP-470 had been entered in numerous human clinical trials to determine its applicability toward the treatment of cancers of the breast, brain, cervix, liver, and prostate, as well as AIDS-related Kaposi sarcoma, lymphoma, and leukemia. Unfortunately, as is often the case in drug testing, clinical trials were suspended, in this case because of neurological side effects. These problems were solved by attaching polymeric side chains at the chloride end of the molecule and, as of early 2009, it was hoped that this drug would eventually make it to market.
Ozone is a blue gas that condenses to a dark blue, highly unstable liquid. Ozone is a powerful bactericide. As a result, ozonators are used for disinfecting water in pools and spas.

**Exercise 12-24**

The stereochemical consequences of the vicinal *syn* dihydroxylation of alkenes are complementary to those of vicinal *anti* dihydroxylation. Show the products (indicate stereochemistry) of the vicinal *syn* dihydroxylation of cis- and trans-2-butene.

**In Summary** Osmium tetroxide, either stoichiometrically or catalytically together with a second oxidizing agent, converts alkenes into *syn*-1,2-diols. A similar reaction of purple potassium permanganate is accompanied by decolorization, a result that makes it a useful test for the presence of double bonds.

**12-12 Oxidative Cleavage: Ozonolysis**

Although oxidation of alkenes with osmium tetroxide breaks only the π bond, other reagents may rupture the σ bond as well. The most general and mildest method of oxidatively cleaving alkenes is through the reaction with ozone, ozonolysis. The products are carbonyl compounds.

Ozone, O₃, is produced in the laboratory in an instrument called an ozonator, in which an arc discharge generates 3–4% ozone in a dry oxygen stream. The gas mixture is passed through a solution of the alkene in methanol or dichloromethane. The first isolable intermediate is a species called an ozonide, which is reduced directly in a subsequent step by exposure to zinc in acetic acid or by reaction with dimethyl sulfide. The net result of the ozonolysis-reduction sequence is the cleavage of the molecule at the carbon–carbon double bond; oxygen becomes attached to each of the carbons that had originally been doubly bonded.

**Mechanism of Ozonolysis**

**Step 1.** Molozonide formation and cleavage
Exercise 12-25
An unknown hydrocarbon of the molecular formula C_{12}H_{20} exhibited an \(^1\)H NMR spectrum with a complex multiplet of signals between 1.0 and 2.2 ppm. Ozonolysis of this compound gave two equivalents of cyclohexanone, whose structure is shown in the margin. What is the structure of the unknown?

Exercise 12-26
Give the products of the following reactions.

(a) \[\text{H}_2\text{C} = \text{CH} \quad \xrightarrow{\text{1. O}_3, \text{CH}_2\text{Cl}_2} \quad \text{CH}_2 = \text{CH} \quad \xrightarrow{\text{2. (CH}_3)_2\text{S}}\]

(b) \[\text{CH}_2 = \text{CH} \quad \xrightarrow{\text{1. O}_3, \text{CH}_2\text{Cl}_2} \quad \xrightarrow{\text{2. Zn, CH}_3\text{COH}}\]

(c) \[\text{CH}_3 \quad \xrightarrow{\text{1. O}_3, \text{CH}_2\text{Cl}_2} \quad \xrightarrow{\text{2. (CH}_3)_2\text{S}}\]

Exercise 12-27
Working with the Concepts: Deducing the Structure of an Ozonolysis Substrate

What is the structure of the following starting material?

\[\text{C}_{10}\text{H}_{16} \quad \xrightarrow{\text{1. O}_3} \quad \text{O}\]

Strategy
Begin by counting atoms: How does the molecular formula of the product compare to that of the starting material? Then consider the reaction: What kind of reaction is it and what transformation does it achieve? Putting this information together should enable you to reconstruct the starting material.

Solution
• The molecular formula of the product is C_{10}H_{16}O_2, which is identical to the starting material plus two oxygen atoms. This information simplifies the problem: How were these oxygens introduced? Can we imagine undoing that process in order to identify the original structure?
• The reaction is ozonolysis, which achieves the overall transformation

that is, the addition of two oxygen atoms to the original starting species, which is exactly the change observed in the problem.
In Summary

Ozonolysis followed by reduction yields aldehydes and ketones. Mechanistically, the reactions presented in Sections 12-10 through 12-12 can be related in that initial attack by an electrophilic oxidizing agent on the $\pi$ bond leads to its rupture. Unlike the reaction sequences studied in Sections 12-10 and 12-11, however, ozonolysis causes cleavage of both the $\pi$ and the $\sigma$ bonds.

12-13 Radical Additions: Anti-Markovnikov Product Formation

Radicals, lacking a closed outer shell of electrons, are capable of reacting with double bonds. However, a radical requires only one electron for bond formation, unlike the electrophiles presented in this chapter so far, which consume both electrons of the $\pi$ bond upon addition. The product of radical addition to an alkene is an alkyl radical, and the final products exhibit anti-Markovnikov regiochemistry, similar to the products of hydroboration–oxidation (Section 12-8).

Exercise 12-28

Try It Yourself

Suggest a structure for a substance that, upon ozonolysis followed by treatment with (CH$_3$)$_2$S, gives as the sole product CH$_3$C=OCH$_2$CH$_2$CH$_2$CHO. (Hint: Begin by writing out a bond-line formula of this product so that you can clearly see its structure and number its carbon atoms.)
Chapter 12

12-13 Anti-Markovnikov Regiochemistry of Radical Additions

The mechanism of the addition reaction under these conditions is not an ionic sequence; rather, it is a much faster radical chain sequence. The reason is that the activation energies of the component steps of radical reactions are very small, as we observed earlier during the discussion of the radical halogenation of alkanes (Section 3-4). Consequently, in the presence of radicals, anti-Markovnikov hydrobromination simply outpaces the regular addition pathway. The initiation steps are

1. the homolytic cleavage of the weak RO–OR bond \([DH^o \approx 39 \text{ kcal mol}^{-1} (163 \text{ kJ mol}^{-1})]\), and
2. reaction of the resulting alkoxy radical with hydrogen bromide.

The driving force for the second (exothermic) step is the formation of the strong O–H bond. The bromine atom generated in this step initiates chain propagation by attacking the double bond. One of the \(\pi\) electrons combines with the unpaired electron on the bromine atom to form the carbon–bromine bond. The other \(\pi\) electron remains on carbon, giving rise to a radical.

The halogen atom’s attack is regioselective, creating the relatively more stable secondary radical rather than the primary one. This result is reminiscent of the ionic additions of hydrogen bromide (Section 12-3), except that the roles of the proton and bromine are reversed. In the ionic mechanism, a proton attacks first to generate the more stable carbocation, which is then trapped by bromide ion. In the radical mechanism, a bromine atom is the attacking species, creating the more stable radical center. The alkyl radical subsequently reacts with HBr by abstracting a hydrogen and regenerating the chain-carrying bromine atom. Both propagation steps are exothermic, and the reaction proceeds rapidly. As usual, termination is by radical combination or by some other removal of the chain carriers (Section 3-4).

Mechanism of Radical Hydrobromination

Initiation steps

\[
\text{RO} \quad \overset{\Delta}{\longrightarrow} \quad 2 \text{RO}^\cdot \quad \Delta H^o = +39 \text{ kcal mol}^{-1} \quad (+163 \text{ kJ mol}^{-1})
\]

\[
\text{RO}^\cdot + \text{H}^\cdot \text{Br} \quad \overset{\Delta}{\longrightarrow} \quad \text{RO}^\cdot + \text{Br}^\cdot \quad \Delta H^o = -17 \text{ kcal mol}^{-1} \quad (-71 \text{ kJ mol}^{-1})
\]

Propagation steps

\[
\text{CH}_3\text{CH}_2 + \overset{\cdot}{\text{Br}} \quad \longrightarrow \quad \text{CH}_3\text{CH}_2\text{CH}^\cdot \text{CH}_2\text{Br}^\cdot \quad \Delta H^o = -5 \text{ kcal mol}^{-1} \quad (-21 \text{ kJ mol}^{-1})
\]

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{Br} + \overset{\cdot}{\text{Br}} \quad \longrightarrow \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{Br}^\cdot + \text{Br}^\cdot \quad \Delta H^o = -11.5 \text{ kcal mol}^{-1} \quad (-48 \text{ kJ mol}^{-1})
\]

Are radical additions general?

Hydrogen chloride and hydrogen iodide do not give anti-Markovnikov addition products with alkenes; in both cases, one of the propagating steps is endothermic and consequently so slow that the chain reaction terminates. As a result, HBr is the only hydrogen halide that adds to an alkene under radical conditions to give anti-Markovnikov products. Additions of HCl and HI proceed only by ionic mechanisms to give normal Markovnikov products regardless of the presence or absence of radicals. Other reagents such as thiols, however, do undergo radical additions to alkenes.

Radical Addition of a Thiol to an Alkene

\[
\text{CH}_3\text{CH} = \text{CH}_2 + \overset{\cdot}{\text{CH}_3\text{CH}_2\text{SH}} \quad \overset{\text{ROOR}}{\longrightarrow} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{SCH}_3
\]

Ethanethiol Ethyl propyl sulfide
In this example, the initiating alkoxy radical abstracts a hydrogen from sulfur to yield \( \text{CH}_3\text{CH}_2\text{S}^\cdot \), which then attacks the double bond. Bis(1,1-dimethylethyl) peroxide (di-tert-butyl peroxide) and dibenzoyl peroxide are commercially available initiators for such radical addition reactions.

**Exercise 12-29**

Ultraviolet irradiation of a mixture of 1-octene and diphenylphosphine, \((\text{C}_6\text{H}_5)\text{PH}\), furnishes 1-(diphenylphosphino)octane by radical addition. Write a plausible mechanism for this reaction.

\[
(\text{C}_6\text{H}_5)\text{PH} + \text{CH}==\text{CH(\text{CH}_3)}\text{CH}_3 \xrightarrow{\text{hv}} (\text{C}_6\text{H}_5)\text{P}==\text{CH}_2==\text{CH}_2(\text{CH}_3)_2\text{CH}_3
\]

As we saw in the case of hydroboration (Section 12-8), anti-Markovnikov additions are synthetically useful because their products complement those obtained from ionic additions. The ability to control regiochemistry is an important feature in the development of new synthetic methods.

**In Summary** Radical initiators alter the mechanism of the addition of HBr to alkenes from ionic to radical chain. The consequence of this change is anti-Markovnikov regioselectivity. Other species, most notably thiols, but not HCl or HI, are capable of undergoing similar reactions.

**12-14 Dimerization, Oligomerization, and Polymerization of Alkenes**

Is it possible for alkenes to react with one another? Indeed it is, but only in the presence of an appropriate catalyst—for example, an acid, a radical, a base, or a transition metal. In this reaction the unsaturated centers of the alkene monomer (*monos*, Greek, single; *meros*, Greek, part) are linked to form dimers, trimers, *oligomers* (*oligos*, Greek, few, small), and ultimately *polymers* (*polymeres*, Greek, of many parts), substances of great industrial importance.

**Carbocations attack pi bonds**

Treatment of 2-methylpropene with hot aqueous sulfuric acid gives two dimers: 2,4,4-trimethyl-1-pentene and 2,4,4-trimethyl-2-pentene. This transformation is possible because 2-methylpropene can be protonated under the reaction conditions to furnish the 1,1-dimethylethyl (tert-butyl) cation. This species can attack the electron-rich double bond of 2-methylpropene with formation of a new carbon–carbon bond. Electrophilic addition proceeds according to the Markovnikov rule to generate the more stable carbocation. Subsequent deprotonation from either of two adjacent carbons furnishes a mixture of the two observed products.
Repeated attack can lead to oligomerization and polymerization

The two dimers of 2-methylpropene tend to react further with the starting alkene. For example, when 2-methylpropene is treated with strong acid under more stringent conditions, trimers, tetramers, pentamers, and so forth, are formed by repeated electrophilic attack of intermediate carbocations on the double bond. This process, which leads to alkane chains of intermediate length, is called **oligomerization**.

**Oligomerization of the 2-Methylpropene Dimers**

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\ 
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\
\end{align*}
\]

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\ 
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\
\end{align*}
\]

At higher temperatures, the oligomerization of alkenes continues to give polymers containing many subunits.

**Polymerization of 2-Methylpropene**

\[
n \text{CH}_2=\text{C(CH}_3)_2 \quad \overset{\text{H}^+, 200^\circ \text{C}}{\longrightarrow} \quad \text{H}-(\text{CH}_2-\text{C})_{n=1-2} \quad \text{CH}_2\text{C}=\text{CH}_2
\]

**Poly(2-methylpropene)**

(Polyisobutylene)

**In Summary** Catalytic acid causes alkene–alkene additions to occur, a process that forms dimers, trimers, oligomers containing several components, and finally polymers, which are composed of a great many alkene subunits.

**12-15 Synthesis of Polymers**

Many alkenes are suitable monomers for polymerization. Polymerization is exceedingly important in the chemical industry, because many polymers have desirable properties, such as durability, inertness to many chemicals, elasticity, transparency, and electrical and thermal resistance.

Although the production of polymers has contributed to pollution—many of them are not biodegradable—they have varied uses as synthetic fibers, films, pipes, coatings, and...
Reactions of Alkenes

Polymers are also being used increasingly as coatings for medical implants. Names such as polyethylene, poly(vinyl chloride) (PVC), Teflon, polystyrene, Orlon, and Plexiglas (Table 12-3) have become household words.

Acid-catalyzed polymerizations, such as that described for poly(2-methylpropene), are carried out with H₂SO₄, HF, and BF₃ as the initiators. Because they proceed through carbocation intermediates, they are also called cationic polymerizations. Other mechanisms of polymerizations are radical, anionic, and metal catalyzed.

### Radical polymerizations lead to commercially useful materials

An example of radical polymerization is that of ethene in the presence of an organic peroxide at high pressures and temperatures. The reaction proceeds by a mechanism that, in its initial stages, resembles that of the radical addition to alkenes (Section 12-13). The peroxide initiators cleave into alkoxy radicals, which begin polymerization by addition to the double bond of ethene. The alkyl radical thus created attacks the double bond of another ethene molecule, furnishing another radical center, and so on. Termination of the polymerization can be by dimerization, disproportionation of the radical, or other radical-trapping reactions (Section 3-4).

#### Mechanism of Radical Polymerization of Ethene

**Initiation steps**

- \( \text{RO} \cdot + \text{CH}_2=\text{CH}_2 \rightarrow \text{ROCH}_2\text{CH}_2\cdot \)
Chapter 12

Synthesis of Polymers

Propagation steps

\[ \text{ROCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\cdot + \text{CH}_2=\text{CH}_2 \rightarrow \text{ROCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\cdot \]

Polyethene (polyethylene) produced in this way does not have the expected linear structure. Branching occurs by abstraction of a hydrogen along the growing chain by another radical center followed by chain growth originating from the new radical. The average molecular weight of polyethene is almost 1 million.

Polychloroethene [poly(vinyl chloride), PVC] is made by similar radical polymerization. Interestingly, the reaction is regioselective. The peroxide initiator and the intermediate chain radicals add only to the unsubstituted end of the monomer, because the radical center formed next to chlorine is relatively stable. Thus, PVC has a very regular head-to-tail structure of molecular weight in excess of 1.5 million. Although PVC itself is fairly hard and brittle, it can be softened by addition of carboxylic acid esters (Section 20-4), called plasticizers (plastikos, Greek, to form). The resulting elastic material is used in “vinyl leather,” plastic covers, and garden hoses.

Exposure to chloroethene (vinyl chloride) has been linked to the incidence of a rare form of liver cancer (angiocarcinoma). The Occupational Safety and Health Administration (OSHA) has set limits to human exposure of less than an average of 1 ppm per 8-h working day per worker.

CHEMICAL HIGHLIGHT 12-3

Polymers in the Clean-Up of Oil Spills

Poly-2-methylpropene (polyisobutylene) is the principal ingredient in a product called Elastol, which over two decades of use has demonstrated to be an effective agent in the clean-up of oil spills. When Elastol is sprayed on an oil slick, its polymer chains, which normally wrap tightly around each other, unravel and mix with the oil. The oil is bound by the polymer into a viscous mat, which may be skimmed off the surface of a body of water. Elastol can absorb 100 times its volume of medium- to heavy-weight petroleum oil. A valuable feature of this method is that the oil may be recovered from the polymer by processing through a special pump. Elastol is also effective for removing contaminants from groundwater, such as aromatic hydrocarbons and MTBE (methyl tert-butyl ether, which replaced lead as an octane enhancer for gasoline but whose seepage into groundwater supplies created environmental concerns). Elastol has been used to remediate petroleum spills in New Haven Harbor in Connecticut, on the Potomac and Neches (Texas) rivers, and around the oil pipelines in the Russian Arctic. Elastol has also proven to be useful in safely cleaning birds and other animals affected by oil spills. In particular, it selectively binds and removes the oil-based contaminants without affecting the natural skin oils of the animal.
An iron compound, FeSO₄, in the presence of hydrogen peroxide promotes the radical polymerization of propenenitrile (acrylonitrile). Polypropenenitrile (polyacrylonitrile), \(-(\text{CH}_2\text{CHCN})_n\)-, also known as Orlon, is used to make fibers. Similar polymerizations of other monomers furnish Teflon and Plexiglas.

Exercise 12-30

Prior to 2005, Saran Wrap was made by radical polymerization of 1,1-dichloroethene and chloroethene together. Propose a structure. Note: This is a “copolymerization,” in which the two monomers alternate in the final polymer.

Anionic polymerizations require initiation by bases

Anionic polymerizations are initiated by strong bases such as alkyllithiums, amides, alkoxides, and hydroxide. For example, methyl 2-cyanopropanoate (methyl \(\alpha\)-cyanoacrylate) polymerizes rapidly in the presence of even small traces of hydroxide. When spread between two surfaces, it forms a tough, solid film that cements the surfaces together. For this reason, commercial preparations of this monomer are marketed as Super Glue.

What accounts for this ease of polymerization? When the base attacks the methylene group of \(\alpha\)-cyanoacrylate, it generates a carbanion whose negative charge is located next to the nitrile and ester groups, both of which are strongly electron withdrawing. The anion is stabilized because the nitrogen and oxygen atoms polarize their multiple bonds in the sense \(\delta^+\text{C} \equiv \text{N} ^\delta^-\) and \(\delta^+\text{C} \equiv \text{O} ^\delta^-\) and because the charge can be delocalized by resonance.

Metal-catalyzed polymerizations produce highly regular chains

An important metal-catalyzed polymerization is that initiated by Ziegler-Natta\(^*\) catalysts. They are typically made from titanium tetrachloride and a trialkylaluminum, such as triethylaluminum, \(\text{Al(\text{CH}_2\text{CH}_3)}_3\). The system polymerizes alkenes, particularly ethene, at relatively low pressures with remarkable ease and efficiency.

Although we shall not consider the mechanism here, two features of Ziegler-Natta polymerization are the regularity with which substituted alkane chains are constructed from substituted alkenes, such as propene, and the high linearity of the chains. The polymers that result possess higher density and much greater strength than those obtained from radical polymerization. An example of this contrast is found in the properties of polyethene (polyethylene) prepared by the two methods. The chain branching that occurs during radical polymerization of ethene results in a flexible, transparent material (low-density polyethylene) used for food storage bags, whereas the Ziegler-Natta method produces a tough, chemically resistant plastic (high-density polyethylene) that may be molded into containers.

\(^*\)Professor Karl Ziegler (1898–1973), Max Planck Institute for Coal Research, Mülheim, Germany, Nobel Prize 1963 (chemistry); Professor Giulio Natta (1903–1979), Polytechnic Institute of Milan, Nobel Prize 1963 (chemistry).
In Summary  Alkenes are subject to attack by carbocations, radicals, anions, and transition metals to give polymers. In principle, any alkene can function as a monomer. The intermediates are usually formed according to the rules that govern the stability of charges and radical centers.

12-16 Ethene: An Important Industrial Feedstock

Ethene (ethylene) can serve as a case study for the significance of alkenes in industrial chemistry. This monomer is the basis for the production of polyethylene, millions of tons of which are manufactured in the United States annually. The major source of ethene is the pyrolysis of petroleum, or hydrocarbons derived from natural gas, such as ethane, propane, other alkanes, and cycloalkanes (Section 3-3).

Apart from its direct use as a monomer, ethene is the starting material for many other industrial chemicals. For example, acetaldehyde is obtained in the reaction of ethene with water in the presence of a palladium(II) catalyst, air, and CuCl₂. The product formed initially, ethenol (vinyl alcohol), is unstable and spontaneously rearranges to the aldehyde (see Chapters 13 and 18). The catalytic conversion of ethene into acetaldehyde is also known as the Wacker* process.

**The Wacker Process**

\[
\begin{align*}
\text{CH}_2=\text{CH}_2 + \text{H}_2\text{O}, \text{O}_2, \text{catalytic PdCl}_2, \text{CuCl}_2 & \rightarrow \text{CH}_2=\text{CHOH} \quad \text{Ethenol (Vinyl alcohol) (Unstable)} \\
\text{CH}_2=\text{CHOH} & \rightarrow \text{CH}_3\text{CH} \quad \text{Acetaldehyde}
\end{align*}
\]

Chloroethene (vinyl chloride) is made from ethene by a chlorination–dehydrochlorination sequence in which addition of Cl₂ produces 1,2-dichloroethane. This compound is converted into the desired product by elimination of HCl.

**Chloroethene (Vinyl Chloride) Synthesis**

\[
\begin{align*}
\text{CH}_2=\text{CH}_2 + \text{Cl}_2 & \rightarrow \text{CH}_2\text{CHCl} \quad \text{1,2-Dichloroethane} \\
\text{CH}_2\text{CHCl} & \rightarrow \text{CH}_2=\text{CHCl} \quad \text{Chloroethene (Vinyl chloride)}
\end{align*}
\]

Oxidation of ethene with oxygen in the presence of silver furnishes oxacyclopropane (ethylene oxide), the hydrolysis of which gives 1,2-ethanediol (ethylene glycol) (Section 9-11). Hydration of ethene gives ethanol (Section 9-11).

**In Summary**  Ethene is a valuable source of various industrial raw materials, including ethanol, 1,2-ethanediol (ethylene glycol), and several important monomers for the polymer industry.

**CHEMICAL HIGHLIGHT 12-4**

**Metal-Catalyzed Alkene Metathesis for Constructing Medium and Large Rings**

One of the most startling examples of metal-catalyzed chemistry is alkene metathesis, a reaction in which two alkenes exchange their double-bonded carbon atoms, as shown in general form here.

$$W_2C\equiv CX_2 + Y_2C\equiv CZ_2 \rightleftharpoons CW_2Y_2 + CX_2Z_2$$

The equilibrium in this reversible process may be driven by removal of one of the four components (Le Chatelier’s principle). This idea has been employed to form medium- and large-sized rings that are otherwise very difficult to construct, because of unfavorable strain and entropy factors. The example below illustrates ring closure of an acyclic starting compound with terminal double bonds. The products are a cyclic alkene and ethene, which, being a gas, evolves rapidly out of the reaction mixture, driving the equilibrium toward product.

![Catalyst](image)

A recent, extraordinary application of methathesis is the synthesis of ciguatoxin by Hirama.* Ciguatoxin is 100 times more poisonous than brevetoxin, the “red tide” toxin (Section 9-5), and is responsible for more human poisoning from seafood consumption than any other substance: More than 20,000 people become sick in this way each year, developing gastrointestinal, cardiovascular, and neurological abnormalities that can lead to paralysis, coma, and death.

The tiny amounts of ciguatoxin in fish are far too small to have any effect on the flavor or odor of the food. Thus, a supply of this material is needed to develop sensitive detection methods. Ciguatoxin contains 13 ether rings and 30 stereocenters, making it a formidable synthetic target. Its synthesis was an amazing 12-year effort, culminating in the linkage of two polycyclic molecules containing five and seven rings, respectively, and closure of the final nine-membered “F” ring using alkene metathesis. The catalyst, developed by

![Coral grouper](image)

The coral grouper can turn lethal when ciguatoxin accumulates in its tissue.
Pheromones are chemical substances used for communication within a living species. There are sex, trail, alarm, and defense pheromones, to mention a few. Many insect pheromones are simple alkenes; they are isolated by extraction of certain parts of the insect and separation of the resulting product mixture by chromatographic techniques. Often only minute quantities of the bioactive compound can be obtained, in which case the synthetic organic

Grubbs,* contains a ruthenium atom linked by a double bond to carbon, an example of a so-called metal carbene complex. Metal carbenes were proposed (by Chauvin)† and confirmed as intermediates in alkene metathesis decades ago. Subsequently, Grubbs and Schrock‡ prepared stable carbenes of Ru and Mo, respectively, that catalyze the process in a well-controlled manner. Alkene metathesis is now one of the most reliable and widely used methods for medium- and large-ring construction.

†Professor Yves Chauvin (b. 1930), Institut Français du Pétrole, Rueil-Malmaison, France, Nobel Prize 2005 (chemistry).
‡Professor Richard R. Schrock (b. 1945), Massachusetts Institute of Technology, Nobel Prize 2005 (chemistry).
A chemist can play a very important role in the design and execution of total syntheses. Interestingly, the specific activity of a pheromone frequently depends on the configuration around the double bond (e.g., E or Z), as well as on the absolute configuration of any chiral centers present ($R$, $S$) and the composition of isomer mixtures. For example, the sex attractant for the male silkworm moth, 10-trans-12-cis-hexadecadien-1-ol (known as bombykol, margin), is 10 billion times more active in eliciting a response than the 10-cis-12-trans isomer, and 10 trillion times more active than the trans, trans compound.

As is the case for the juvenile hormones (Chemical Highlight 12-1), pheromone research affords an important opportunity for achieving pest control. Minute quantities of sex pheromones can be used per acre of land to confuse male insects about the location of their female partners. These pheromones can thus serve as lures in traps to remove insects effectively without spraying crops with large amounts of other chemicals. It is clear that organic chemists in collaboration with insect biologists will make important contributions in this area in the years to come.

**THE BIG PICTURE**

We saw in Chapter 11 that in the double bonds of alkenes the $\pi$ bond is weaker than the $\sigma$ bond. Thus, the general process of addition, in which $\pi$ bonds are replaced by $\sigma$ bonds, is generally energetically favorable. We also found that although the C=C bond is nonpolar, it has a higher concentration of electrons than does a single bond. These two features are the basis of the reactivity of the alkene function. Thus, the alkene double bond acts as a nucleophile, and many of its reactions begin with attack by an electrophile on the $\pi$ electrons.

In this chapter, we found that alkene chemistry subdivides into several categories, including reactions with simple electrophiles, such as the proton, to give carbocations, followed by attachment of a nucleophile to give the final addition product. These processes are very much like the familiar acid-base reactivity we discussed in Chapter 2. Alkenes also undergo reactions that proceed through more complex pathways, often involving ring formation. Issues of regio- and stereochemistry apply, depending on the specific mechanism, but the underlying theme of nucleophile–electrophile interaction is almost always present.

Many of the same ideas in alkene chemistry also apply to the carbon–carbon triple bond. In Chapter 13, we shall examine the behavior of alkynes and see that much of their chemistry is a direct extension of alkene reactivity to a system with two $\pi$ bonds.

**CHAPTER INTEGRATION PROBLEMS**

**12-31.** Compare and contrast the addition reactions of each of the following reagents with (E)-3-methyl-3-hexene: $H_2$ (catalyzed by $PtO_2$), HBr, dilute aqueous $H_2SO_4$, Br$_2$ in CCL$_4$, mercuric acetate in $H_2O$, and $B_2H_6$ in THF. Consider regiochemistry and stereochemistry. Which of these reactions can be used to synthesize alcohols? In what respects do the resulting alcohols differ?

**SOLUTION**

First, we need to identify the starting material’s structure. Recall (Section 11-1) that the designation “E” describes the stereoisomer in which the two highest-priority groups (according to Cahn-Ingold-Prelog guidelines, Section 5-3) are on opposite sides of the double bond (i.e., trans to each other). In 3-methyl-3-hexene, the two ethyl groups are of highest priority. We therefore are starting with the compound shown in the margin.

Now let us consider the behavior of this alkene toward our list of reagents. In each case, it may be necessary to choose between two different regiochemical and two different stereochemical modes of addition. We recognize this situation because the starting alkene is substituted differently at each carbon, a regiochemical characteristic, and it has a defined (E) stereochemistry. To answer such questions completely correctly, it is essential to consider the mechanism of each reaction—that is, to think mechanistically.

Thus, the addition of $H_2$ with $PtO_2$ as a catalyst is an example of catalytic hydrogenation. Because the same kind of atom (hydrogen) adds to each of the alkene carbons, regiochemistry is not a consideration. Stereochemistry may be one, however. Catalytic hydrogenation is a syn addition, in which both hydrogen atoms attach to the same face of the alkene $\pi$ bond (Section 12-2). If we view the
alkene in a plane perpendicular to the plane of the page (Figure 12-1), addition will be on the top face 50% of the time and on the bottom face 50% of the time:

\[
\begin{align*}
\text{H}_2C & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_2
\end{align*}
\]

Racemic mixture

The addition generates one stereocenter (marked in each of the two products in the center of the scheme by an asterisk); therefore each product molecule is chiral (Section 5-1). Because the products form in equal amounts, the consequence is a racemic mixture of \((R)\)- and \((S)\)-3-methylhexane.

The next two reactions, with HBr and with aqueous H\(_2\)SO\(_4\), begin with addition of the electrophile H\(^+\) (Sections 12-3 and 12-4). These processes generate carbocations and follow the regiochemical guideline known as Markovnikov’s rule: Addition is by attachment of H\(^+\) to the less substituted alkenyl carbon to give the more stable carbocation. The carbocation is trapped by any available nucleophile — Br\(_2\) in the case of HBr, and H\(_2\)O in the case of aqueous H\(_2\)SO\(_4\). Both steps proceed without stereoselectivity and, because the carbocation formed is already tertiary, rearrangement to a more stable carbocation is not possible. So we have the following result:

\[
\begin{align*}
\text{H}_2C & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_2
\end{align*}
\]

Racemic mixture

The next two are examples of additions of electrophiles that form bridged cationic intermediates: a cyclic bromonium ion in the first case (Section 12-5) and a cyclic mercurinium ion in the second (Section 12-7). Additions therefore proceed stereospecifically \(\text{anti}\), because the cyclic ion can be attacked only from the direction opposite the location of the bridging electrophile (Figure 12-3). With Br\(_2\), identical atoms add to both alkene carbons, so regiochemistry is not a consideration. In oxymercuration, the nucleophile is water, and it will add to the most substituted alkene carbon, because the latter is tertiary and possesses the greatest partial positive charge. Stereochemistry must be considered because addition of the electrophile occurs with equal probability from the top and from the bottom and stereocenters are created. So we have

\[
\begin{align*}
\text{H}_2C & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_2
\end{align*}
\]

Racemic mixture

Equal amounts—a racemic mixture—of the two chiral, enantiomERICally related products are formed.

Finally, we come to hydroboration. Again, both regio- and stereoselectivity must be considered. As in hydrogenation, the stereochemistry is \(\text{syn}\); unlike the preceding electrophilic additions, the regiochemistry is \(\text{anti-Markovnikov}\): Boron attaches to the less substituted alkene carbon:

\[
\begin{align*}
\text{H}_2C & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_2
\end{align*}
\]

Racemic mixture
For simplicity, addition of only one of the B–H bonds is shown. The picture strongly resembles that of hydrogenation, but, because of the unsymmetric nature of the reagent, both alkene carbons are now transformed into stereocenters.

Three of the six reactions are well suited for the synthesis of alcohols: acid-catalyzed hydration, oxymercuration (after reduction of the C–Hg bond by NaBH₄), and hydroboration (by oxidation of the C–B bond by H₂O₂). Compare the alcohol from hydration (shown earlier) with that from demercuration of the oxymercuration product:

They are the same. Had a rearrangement taken place during hydration, this outcome might not have been the case (Section 9-3).

Oxidation of the hydroboration product gives a different, regioisomeric alcohol having two stereocenters, also as a racemic mixture (the boron atoms are shown without the additional alkyl groups):

12-32. Thujene, which occurs in numerous plant oils, possesses the molecular formula C₁₀H₁₆ and is a monoterpen (Section 4-7). Several chemical and spectroscopic characteristics of thujene follow. What does each of these pieces of information tell you about the structure of thujene? (i) Thujene reacts instantly with one equivalent of KMnO₄ in aqueous solution to discharge the purple color of permanganate and form a brown precipitate. Additional KMnO₄ is not decolorized. (ii) Hydroboration–oxidation of thujene forms a compound C₁₀H₁₈O, called thujyl alcohol, whose ¹H NMR spectrum shows a ¹H signal at δ = 3.40 ppm. (iii) Oxymercuration–demercuration of thujene forms a different alcohol C₁₀H₁₈O, whose ¹H NMR spectrum shows no signals downfield of δ = 3 ppm. (iv) Ozonolysis of thujene gives

SOLUTION
Beginning with the molecular formula, we may ascertain that thujene possesses three degrees of unsaturation (Section 11-11): [(2 × 10 + 2) – 16]/2 = 6/2 = 3. (i) The fact that thujene reacts with only one equivalent of KMnO₄ implies that only one of these unsaturations is a π bond (Section 12-11); the other two must be rings. (ii) The NMR spectrum of thujyl alcohol is consistent only with a secondary alcohol: , because the signal in the region between δ = 3 and 4 integrates for only one hydrogen. (iii) In contrast, the oxymercuration product lacks an NMR signal in this region, meaning that this product cannot have a hydrogen on the HO-bearing carbon: In other words, it must be a tertiary alcohol. Taken together, these three pieces of information tell us that thujene has two rings and a trisubstituted double bond, . The result of ozonolysis completes the picture, because it gives a product with 10 carbons. Therefore, this product is simply thujene with its alkene function cleaved into two separate C=O units, one being an aldehyde and the other a ketone. Reversing this process, we have
New Reactions

1. General Addition to Alkenes (Section 12-1)

\[ \text{C} = \text{C} + \text{AB} \rightarrow \text{C} - \text{C} \]

2. Hydrogenation (Section 12-2)

\[ \text{C} = \text{C} \xrightarrow{\text{H}_2 \text{ catalyst}} \text{C} - \text{C} \]

Syn addition

Typical catalysts: PtO₂, Pd–C, Ra–Ni

Electrophilic Additions

3. Hydrohalogenation (Section 12-3)

\[ \text{RCH} = \text{CH}_2 + \text{HX} \rightarrow \text{RCH} - \text{CH}_3 \]

Regiospecific (Markovnikov rule)

Through more stable carbocation

4. Hydration (Section 12-4)

\[ \text{C} = \text{C} + \text{H}_2\text{O} \rightarrow \text{C} - \text{OH} \]

Through more stable carbocation

5. Halogenation (Section 12-5)

\[ \text{C} = \text{C} + \text{X}_2 \rightarrow \text{C} - \text{X} \]

Stereospecific (anti)

\[ X \_ = \text{Cl} \_ \text{ or Br} \_ \text{, but not I} \_ \]

6. Vicinal Haloalcohol Synthesis (Section 12-6)

\[ \text{C} = \text{C} + \text{X}_2 \cdot \text{H}_2\text{O} \rightarrow \text{C} - \text{OH} \]

OH attaches to more substituted carbon

7. Vicinal Haloether Synthesis (Section 12-6)

\[ \text{C} = \text{C} + \text{X}_2 \cdot \text{ROH} \rightarrow \text{C} - \text{OR} \]

OR attaches to more substituted carbon

8. General Electrophilic Additions (Section 12-6, Table 12-2)

\[ \text{AB} \rightarrow \text{C} - \text{C} \rightarrow \text{C} - \text{B} \]

A = electropositive, B = electronegative

B attaches to more substituted carbon
9. Oxymercuration–Demercuration (Section 12-7)

\[ \text{C} = \text{C} + \text{Hg(OCCCH}_3\text{)_2, H}_2\text{O} \overset{1.}{\rightarrow} \text{H} + \text{OH} \]
\[ \text{C} = \text{C} + \text{NaBH}_4, \text{NaOH, H}_2\text{O} \overset{2.}{\rightarrow} \text{C} = \text{C} + \text{OR} \]

Initial addition is anti, through mercurinium ion. OH or OR attaches to more substituted carbon.

10. Hydroboration (Section 12-8)

\[ \text{R} = \text{CH}_2 + \text{BH}_3 \underset{\text{THF}}{\overset{\text{BH}_3}{\longrightarrow}} (\text{RCH}_2\text{CH}_2)_3\text{B} \]

Regiospecific. 

B attaches to less substituted carbon.

11. Hydroboration–Oxidation (Section 12-8)

\[ \text{C} = \text{C} + \text{BH}_3, \text{THF} \overset{\text{1. BH}_3, \text{THF}}{\rightarrow} \text{C} = \text{C} + \text{HO} \]

Stereospecific (syn) and anti-Markovnikov. OH attaches to less substituted carbon.

12. Carbene Addition for Cyclopropane Synthesis (Section 12-9)

Using diazomethane:

\[ \text{R} = \text{CH}_2 + \text{CH}_2\text{N}_2 \overset{\text{hv} \text{ or } \Delta \text{ or Cu}}{\longrightarrow} \text{R} = \text{C} \]

Stereospecific.

Other sources of carbenes or carbenoids:

\[ \text{CHCl}_3 \overset{\text{Base}}{\longrightarrow} \cdot \text{CCl}_2 \]
\[ \text{CH}_2\text{I}_2 \overset{\text{Zn-Cu}}{\longrightarrow} \text{ICH}_2\text{ZnI} \]

Oxidation

13. Oxacyclopropane Formation (Section 12-10)

\[ \text{C} = \text{C} + \text{RCOOH, CH}_2\text{Cl}_2 \overset{\text{RCOOH, CH}_2\text{Cl}_2}{\longrightarrow} \text{C} = \text{C} + \text{RCOH} \]

Stereospecific (syn).

14. Vicinal Anti Dihydroxylation (Section 12-10)

\[ \text{C} = \text{C} + \text{RCOOH, CH}_2\text{Cl}_2 \overset{\text{1. RCOOH, CH}_2\text{Cl}_2}{\longrightarrow} \text{C} = \text{C} + \text{RCOH} \]

15. Vicinal Syn Dihydroxylation (Section 12-11)

\[ \text{C} = \text{C} + \text{1. OsO}_4, 2. \text{H}_2\text{S; or catalytic OsO}_4, \text{H}_2\text{O} \]
16. Ozonolysis (Section 12-12)

\[
\text{C} = \text{C} \xrightarrow{1. \text{O}_3, \text{CH}_3\text{OH}} \text{C} \xrightarrow{2. (\text{CH}_3)_2\text{S} \text{ or Zn, CH}_3\text{COH}} \text{C} = \text{O} + \text{O} = \text{C}
\]

Through molozonide and ozonide intermediates

**Radical Additions**

17. Radical Hydrobromination (Section 12-13)

\[
\text{C} = \text{CH}_2 \xrightarrow{\text{HBr, ROOR}} \text{C} - \text{C} - \text{H} - \text{H}
\]

Anti-Markovnikov

Does not occur with HCl or HI

18. Other Radical Additions (Section 12-13)

\[
\text{C} = \text{C} \xrightarrow{\text{RSH, ROOR}} \text{C} - \text{C} - \text{H} - \text{H}
\]

Anti-Markovnikov

**Monomers and Polymers**

19. Dimerization, Oligomerization, and Polymerization (Sections 12-14 and 12-15)

\[
\text{C} = \text{C} \xrightarrow{\text{H}^+ \text{ or RO}^+ \text{ or B}^-} (\text{C} - \text{C})_n
\]

**Important Concepts**

1. The reactivity of the double bond manifests itself in exothermic addition reactions leading to saturated products.

2. The hydrogenation of alkenes is immeasurably slow unless a catalyst capable of splitting the strong H–H bond is used. Possible catalysts are palladium on carbon, platinum (as PtO₂), and Raney nickel. Addition of hydrogen is subject to steric control, the least hindered face of the least substituted double bond frequently being attacked preferentially.

3. As a Lewis base, the \(\pi\) bond is subject to attack by acid and electrophiles, such as \(\text{H}^+\), \(\text{X}_2\), and \(\text{Hg}^{2+}\). If the initial intermediate is a free carbocation, the more highly substituted carbocation is formed. Alternately, a cyclic onium ion is generated subject to nucleophilic ring opening at the more substituted carbon. Carbocation formation leads to control of regiochemistry (Markovnikov rule); onium ion formation leads to control of both regio- and stereochemistry.

4. Mechanistically, hydroboration lies between hydrogenation and electrophilic addition. The first step is \(\pi\) complexation to the electron-deficient boron, whereas the second is a concerted transfer of the hydrogen to carbon. Hydroboration–oxidation results in the anti-Markovnikov hydration of alkenes.

5. Carbenes and carbenoids are useful for the synthesis of cyclopropanes from alkenes.

6. Peroxycarboxylic acids may be thought of as containing an electrophilic oxygen atom, transferable to alkenes to give oxacyclopropanes. The process is often called epoxidation.

7. Osmium tetroxide acts as an electrophilic oxidant of alkenes; in the course of the reaction, the oxidation state of the metal is reduced by two units. Addition takes place in a concerted manner through cyclic six-electron transition states to give vicinal diols.

8. Ozonolysis followed by reduction yields carbonyl compounds derived by cleavage of the double bond.

9. In radical chain additions to alkenes, the chain carrier adds to the \(\pi\) bond to create the more highly substituted radical. This method allows for the anti-Markovnikov hydrobromination of alkenes, as well as the addition of thiols and some halomethanes.

10. Alkenes react with themselves through initiation by charged species, radicals, or some transition metals to give polymers. The initial attack at the double bond yields a reactive intermediate that perpetuates carbon–carbon bond formation.
Problems

33. With the help of the $DH^\circ$ values given in Tables 3-1 and 3-4, calculate the $\Delta H^\circ$ values for addition of each of the following molecules to ethene, using 65 kcal mol$^{-1}$ for the carbon–carbon $\pi$ bond strength.

(a) Cl$_2$  
(b) IF ($DH^\circ = 67$ kcal mol$^{-1}$)
(c) IBr ($DH^\circ = 43$ kcal mol$^{-1}$)  
(d) HF
(e) HI  
(f) HO–Cl ($DH^\circ = 60$ kcal mol$^{-1}$)
(g) Br–CN ($DH^\circ = 83$ kcal mol$^{-1}$; $DH^\circ$ for C$_{sp^3}$–CN = 124 kcal mol$^{-1}$)  
(h) CH$_3$S–H ($DH^\circ = 88$ kcal mol$^{-1}$; $DH^\circ$ for C$_{sp^3}$–S = 60 kcal mol$^{-1}$)

34. The bicyclic alkene car-3-ene, a constituent of turpentine, undergoes catalytic hydrogenation to give only one of the two possible stereoisomeric products. The product has the common name
cis-carane, indicating that the methyl group and the cyclopropane ring are on the same face of the cyclohexane ring. Suggest an explanation for this stereochemical outcome.
35. Give the expected major product of catalytic hydrogenation of each of the following alkenes. Clearly show and explain the stereochemistry of the resulting molecules.

(a) \[\text{CH}_3\text{(CH}_2\text{)}_2\text{CH}_2\text{H} \]

(b) \[\text{CH}_3\text{CCH} = \text{CHCO}_2\text{CH}_3 \]

(c) \[\text{H}_2\text{CCH} = \text{CH}_2 \]

36. Would you expect the catalytic hydrogenation of a small-ring cyclic alkene such as cyclobutene to be more or less exothermic than that of cyclohexene? (Hint: Which has more bond-angle strain, cyclobutene or cyclobutane?)

37. Give the expected major product from the reaction of each alkene with (i) peroxide-free HBr and (ii) HBr in the presence of peroxides.

(a) 1-Hexene; (b) 2-methyl-1-pentene; (c) 2-methyl-2-pentene; (d) (Z)-3-hexene; (e) cyclohexene.

38. Give the product of addition to Br\(_2\) to each alkene in Problem 37. Pay attention to stereochemistry.

39. What alcohol would be obtained from treatment of each alkene in Problem 37 with aqueous sulfuric acid? Would any of these alkenes give a different product upon oxymercuration-demercuration? Upon hydroboration-oxidation?

40. Give the reagents and conditions necessary for each of the following transformations and comment on the thermodynamics of each (a) cyclohexanol \(\rightarrow\) cyclohexene; (b) cyclohexene \(\rightarrow\) cyclohexanol; (c) chlorocyclopentane \(\rightarrow\) cyclopentene; (d) cyclopentene \(\rightarrow\) chlorocyclopentane.

41. Problem 51 of Chapter 6 presented a strategy for the synthesis of the amino acid (2S,3S)-3-hydroxyleucine, requiring as the starting material a specific stereoisomer of 2-bromo-3-hydroxy-4-methylpentanoic acid. Addition of bromine and water to the methyl ester of 4-methyl-2-pentenoic acid (margin) gives the corresponding ester of 2-bromo-3-hydroxy-4-methylpentanoic acid. (a) Which stereoisomer of the unsaturated ester, cis or trans, is needed for this addition to give the necessary stereoisomer of the product? (b) Can this strategy give the bromoalcohol as a single enantiomer or not? Explain, mechanistically.

42. Formulate the product(s) that you would expect from each of the following reactions. Show stereochemistry clearly.

(a) \[\text{CH}_2\text{CH}_3\text{CH} = \text{CH}_2 \xrightarrow{\text{HCl}} \text{CH}_2\text{CH}_3\text{CH}_2\text{CH}_3\]

(b) \[\text{trans-3-Heptene} \xrightarrow{\text{Cl}_2} \text{1-Ethylcyclohexene} \xrightarrow{\text{Br}_2, \text{H}_2\text{O}} \]

(c) \[\text{CH}_3\text{Cl} \xrightarrow{\text{1. } \text{Hg(OCCH}_3)_2, \text{CH}_3\text{OH} \text{2. } \text{NaBH}_4, \text{CH}_3\text{OH}} \text{cis-2-Butene} \xrightarrow{\text{Br}_2, \text{excess } \text{Na}^+\text{N}_3^-} \]

(d) \[\text{Product of (c)} \xrightarrow{\text{NaOH, H}_2\text{O}} \text{1. BH}_3, \text{THF} \text{2. } \text{H}_2\text{O}_2, \text{NaOH, H}_2\text{O} \]

43. Show how you would synthesize each of the following molecules from an alkene of appropriate structure (your choice).

(a) \[\text{OH} \]

(b) \[\text{Cl} \]

(c) \[\text{(meso-4R,5S-isomer)} \]

(d) \[\text{(Racemate of 4R,5R and 4S,5S isomers)} \]
44. Propose efficient methods for accomplishing each of the following transformations. Most will require more than one step.

(a) \[ \text{Br} \rightarrow \text{I} \]  
(b) \[ \text{HO} \rightarrow \text{HO} \quad (\text{meso-2R,3S-isomer}) \]  
(c) \[ \text{HO} \rightarrow \text{HO} + \text{HO} \]  
(d) \[ \text{O} \rightarrow \text{O} \]

45. **Reaction review.** Without consulting the Reaction Road Map on pp. 556–557, suggest a reagent to convert a general alkene, \( \text{C} = \text{C} \), into each of the following types of compounds.

(a) \[ \text{Br} \quad \text{Br} \]  
(b) \[ \text{OH} \quad \text{H} \quad (\text{Markovnikov product}) \]  
(c) \[ \text{Br} \quad \text{C} \quad \text{H} \]  
(d) \[ \text{C} \quad \text{C} \quad \text{H} \]  
(e) \[ \text{O} \quad \text{H} \quad \text{H} \quad (\text{anti-Markovnikov product}) \]  
(f) \[ \text{H} \quad \text{H} \]  
(g) \[ \text{OH} \quad \text{OH} \]  
(h) \[ \text{H} \quad \text{Br} \quad (\text{anti-Markovnikov product}) \]  
(i) \[ \text{H} \quad \text{CH}_2 \]  
(j) \[ \text{CH}_3 \quad \text{O} \quad \text{H} \]  
(k) \[ \text{Br} \quad \text{H} \quad (\text{Markovnikov product}) \]  
(l) \[ \text{OH} \quad \text{Br} \]  
(m) \[ \text{Cl} \quad \text{H} \]  
(n) \[ \text{H} \quad \text{C} \quad \text{C} \quad \text{polymer} \]  
(o) \[ \text{CH}_3 \quad \text{O} \quad \text{Br} \]  
(p) \[ \text{C} = \text{O} + \text{O} = \text{C} \quad \text{H} \]  
(q) \[ \text{C} \quad \text{C} \quad \text{H} \quad (\text{anti-Markovnikov product}) \]
46. Give the expected product of reaction of 2-methyl-1-pentene with each of the following reagents.

- (a) H₂, PtO₂, CH₃CH₂OH
- (b) D₂, Pd-C, CH₃CH₂OH
- (c) BH₃, THF then NaOH + H₂O₂
- (d) HCl
- (e) HBr
- (f) HBr + peroxides
- (g) HI + peroxides
- (h) H₂SO₄ + H₂O
- (i) Cl₂
- (j) ICl
- (k) Br₂ + CH₃CH₂OH
- (l) CH₃SH + peroxides
- (m) MCPBA, CH₂Cl₂
- (n) OsO₄, then H₂S
- (o) O₃, then Zn + CH₃COH
- (p) Hg(OCCH₃)₂ + H₂O, then NaBH₄
- (q) Catalytic H₂SO₄ + heat

47. What are the products of reaction of (E)-3-methyl-3-hexene with each of the reagents in Problem 46?

48. Write the expected products of reaction of 1-ethylcyclopentene with each of the reagents in Problem 46.

49. Write out detailed step-by-step mechanisms for the reactions in parts (c), (e), (f), (h), (j), (k), (m), (n), (o), and (p) of Problem 46.

50. What alkene monomer gives the following polymer?

\[
\begin{array}{c}
\text{CH₃H} \\
\text{C} \quad \text{C} \\
\text{H} \quad \text{H} \\
\end{array}
\]

51. Give the expected major product from reaction of 3-methyl-1-butene with each of the following reagents. Explain any differences in the products mechanistically.

- (a) 50% aqueous H₂SO₄
- (b) Hg(OCCH₃)₂ in H₂O, followed by NaBH₄
- (c) BH₃ in THF, followed by NaOH and H₂O₂

52. Answer the question posed in Problem 51 for cyclohexylethene.

53. Give the expected major product of reaction of magnesium monoperoxyphthalate (MMPP) with each alkene. In each case, also give the structure of the material formed upon hydrolysis in aqueous acid of the initial product.

- (a) 1-Hexene
- (b) (Z)-3-ethyl-2-hexene
- (c) (E)-3-ethyl-2-hexene
- (d) (E)-3-hexene
- (e) 1,2-dimethylcyclohexene

54. Give the expected major product of reaction of OsO₄, followed by H₂S, with each alkene in Problem 53.

55. Give the expected major product of reaction of CH₃SH in the presence of peroxides with each alkene in Problem 53.

56. Propose a mechanism for the peroxide-initiated reaction of CH₃SH with 1-hexene.

57. Write the expected products of each of the following reactions.

- (a) (E)-2-Pentene + CHCl₃ \( \xrightarrow{\text{KOC(CH₃)₂, (CH₃)₃COH}} \) \( \text{Zn-Cu, (CH₃CH₂)₂O} \)
- (b) 1-Methylcyclohexene + CH₂I₂ \( \xrightarrow{\text{Cu, Δ}} \) \( \text{Zn-Cu, (CH₃CH₂)₂O} \)
- (c) Propene + CH₂N₂ \( \xrightarrow{\text{Cu, Δ}} \) \( \text{Zn-Cu, (CH₃CH₂)₂O} \)
- (d) (Z)-1,2-Diphenylethene + CHBr₃ \( \xrightarrow{\text{KOC(CH₃)₂, (CH₃)₃COH}} \) \( \text{Zn-Cu, (CH₃CH₂)₂O} \)
- (e) (E)-1,3-Pentadiene + 2 CH₂I₂ \( \xrightarrow{\text{Cu, Δ}} \) \( \text{Zn-Cu, (CH₃CH₂)₂O} \)
- (f) CH₂=CHCH₂CH₂CH₂CH₂NH \( \xrightarrow{\text{hv}} \)
58. $^1H$ NMR spectrum A corresponds to a molecule with the formula C$_3$H$_5$Cl. The compound shows significant IR bands at 730 (see Problem 53 of Chapter 11), 930, 980, 1630, and 3090 cm$^{-1}$. (a) Deduce the structure of the molecule. (b) Assign each NMR signal to a hydrogen or group of hydrogens. (c) The “doublet” at $\delta = 4.05$ ppm has $J = 6$ Hz. Is this in accord with your assignment in (b)? (d) This “doublet,” upon fivefold expansion, becomes a doublet of triplets (inset, spectrum A), with $J \approx 1$ Hz for the triplet splittings. What is the origin of this triplet splitting? Is it reasonable in light of your assignment in (b)?

59. Reaction of C$_3$H$_5$Cl (Problem 58, spectrum A) with Cl$_2$ in H$_2$O gives rise to two products, both C$_3$H$_6$Cl$_2$O, whose spectra are shown in B and C. Reaction of either of these products with KOH yields the same molecule C$_3$H$_5$ClO (spectrum D, next page). The insets show expansions of some of the multiplets. The IR spectrum reveals bands at 720 and 1260 cm$^{-1}$ and the absence of signals between 1600 and 1800 cm$^{-1}$ and between 3200 and 3700 cm$^{-1}$. (a) Deduce the structures of the compounds giving rise to spectra B, C, and D. (b) Why does reaction of the starting chloride compound with Cl$_2$ in H$_2$O give two isomeric products? (c) Write mechanisms for the formation of the product C$_3$H$_5$ClO from both isomers of C$_3$H$_6$Cl$_2$O.
60. \(^1\)H NMR spectrum E corresponds to a molecule with the formula \(\text{C}_4\text{H}_8\text{O}\). Its IR spectrum has important bands at 945, 1015, 1665, 3095, and 3360 \text{cm}^{-1}. (a) Determine the structure of the unknown. (b) Assign each NMR and IR signal. (c) Explain the splitting patterns for the signals at \(\delta = 1.3, 4.3\), and 5.9 ppm (see inset for 10-fold expansion).

61. Reaction of the compound corresponding to spectrum E with \(\text{SOCl}_2\) produces a chloroalkane, \(\text{C}_4\text{H}_7\text{Cl}\), whose NMR spectrum is almost identical with spectrum E, except that the broad signal at \(\delta = 1.5\) ppm is absent. Its IR spectrum shows bands at 700 (Problem 53, Chapter 11), 925, 985, 1640, and 3090 \text{cm}^{-1}. Treatment with \(\text{H}_2\) over \(\text{PtO}_2\) results in \(\text{C}_4\text{H}_9\text{Cl}\) (spectrum F, next page). Its IR spectrum reveals the absence of all the bands quoted for its precursor, except for the signal at 700 \text{cm}^{-1}. Identify these two molecules.
62. The mass spectra of both of the compounds described in Problem 61 show two molecular ion peaks, two mass units apart, in an intensity ratio of about 3:1. Explain.

63. Give the structure of an alkene that will give the following carbonyl compounds upon ozonolysis followed by reduction with (CH₃)$_2$S.

(a) CH₃CHO only  
(b) CH₃CHO and CH₃CH₂CHO  
(c) (CH₃)$_2$C=O and H₂C=O  
(d) CH₃CH₂CCH₃ and CH₃CHO  
(e) Cyclopentanone and CH₃CH₂CHO

64. **CHALLENGE** Plan syntheses of each of the following compounds, utilizing retrosynthetic-analysis techniques. Starting compounds are given in parentheses. However, other simple alkanes or alkenes also may be used, as long as you include at least one carbon–carbon bond-forming step in each synthesis.

(a) CH₃CHO and CH₃CH₂CHO  
(b) CH₃CH₂CH₂CHCH₂CH₃ (propene, again)  
(c) (CH₃)$_2$C=O and H₂C=O  
(d) CH₃CH₂CCH₃ and CH₃CHO  
(e) Cyclopentanone and CH₃CH₂CHO

65. Show how you would convert cyclopentane into each of the following molecules.

(a) cis-1,2-Dideuteriocyclopentane  
(b) trans-1,2-Dideuteriocyclopentane  
(c) 1,2-Dimethylcyclopentene  
(d) trans-1,2-Dimethyl-1,2-cyclopentanediol
66. Give the expected major product(s) of each of the following reactions.

(a) \( \text{CH}_3\text{OCH}_2\text{CH}_2\text{CH} = \text{CH}_2 \) → \( \text{CH}_3\text{CH} = \text{CH}_2 \)

(b) \( \text{H}_2\text{C} \equiv \text{C} \) → \( \text{CH}_2\text{OH} \)

(c) \( \text{CH} = \text{CH}_2 \) → \( \text{H}_2\text{C} \equiv \text{CHNO}_2 \)

(d) \( \text{H}_2\text{C} \equiv \text{C} \) → \( \text{H}_2\text{C} \equiv \text{C} \)

(e) \( \text{H}_2\text{C} \equiv \text{C} \) → \( \text{H}_2\text{C} \equiv \text{C} \)

(f) \( \text{H}_2\text{C} \equiv \text{C} \) → \( \text{H}_2\text{C} \equiv \text{C} \)

(g) \( \text{CH}_3\text{CH} = \text{CH}_2 \) → \( \text{H}_2\text{C} \equiv \text{CH}_2 \) (Hint: Draw Lewis structures for the NO\(_2\) group.)

67. (E)-5-Hepten-1-ol reacts with the following reagents to give products with the indicated formulas. Determine their structures and explain their formation by detailed mechanisms. (a) HCl, C\(_7\)H\(_{14}\)O (no Cl); (b) Cl\(_2\), C\(_7\)H\(_{16}\)ClO (IR: 740 cm\(^{-1}\); nothing between 1600 and 1800 cm\(^{-1}\) and between 3200 and 3700 cm\(^{-1}\)).

68. When a cis alkene is mixed with a small amount of I\(_2\) in the presence of heat or light, it isomerizes to some trans alkene. Propose a detailed mechanism to account for this observation.

69. Treatment of \( \alpha \)-terpineol (Chapter 10, Problem 60) with aqueous mercuric acetate followed by sodium borohydride reduction leads predominantly to an isomer of the starting compound (C\(_{10}\)H\(_{18}\)O) instead of a hydration product. This isomer is the chief component in oil of eucalyptus and, appropriately enough, is called eucalyptol. It is popularly used as a flavoring for otherwise foul-tasting medicines because of its pleasant spicy taste and aroma. Deduce a structure for eucalyptol on the basis of sensible mechanistic chemistry and the following proton-decoupled \(^{13}\)C NMR data. (Hint: The IR spectrum shows nothing between 1600 and 1800 cm\(^{-1}\) or between 3200 and 3700 cm\(^{-1}\))

60. Both borane and MCPBA react highly selectively with molecules, such as limonene, that contain double bonds in very different environments. Predict the products of reaction of limonene with (a) one equivalent of BH\(_3\) in THF, followed by basic aqueous H\(_2\)O\(_2\), and (b) one equivalent of MCPBA in CH\(_2\)Cl\(_2\). Explain your answers.

71. Oil of marjoram contains a pleasant, lemon-scented substance, C\(_{10}\)H\(_{16}\) (compound G). Upon ozonolysis, G forms two products. One of them, H, has the formula C\(_8\)H\(_{14}\)O\(_2\) and can be independently synthesized in the following way.

From this information, propose reasonable structures for compounds G through J.

72. Humulene and \( \alpha \)-caryophyllene alcohol are terpene constituents of carnation extracts. The former is converted into the latter by acid-catalyzed hydration in one step. Write a mechanism. (Hint: Follow the labeled carbon atoms retrosynthetically. The mechanism includes carbocation-induced cyclizations and hydrogen and alkyl-group migrations.)
73. Predict the product(s) of ozonation of humulene (Problem 72), followed by reduction with zinc in acetic acid. If you had not known the structure of humulene ahead of time, would the identities of these ozonolysis products have enabled you to determine it unambiguously?

74. Challenge. Caryophyllene (C₁₅H₂₄) is an unusual sesquiterpene familiar to you as a major cause of the odor of cloves. Determine its structure from the following information. (Caution: The structure is totally different from that of α-caryophyllene alcohol in Problem 72.)

Reaction 1

\[ \text{Caryophyllene} \xrightarrow{\text{H₂ , Pd - C}} \text{C}_{15}\text{H}_{28} \]

Reaction 2

\[ \text{Caryophyllene} \xrightarrow{1. \text{O₃, CH₂Cl₂} \quad 2. \text{Zn, CH₃COH}} \]

\[ \text{H₃C} \quad \text{CH₃} \quad \text{CH₃} \quad \text{O} \quad \text{H} \quad \text{O} \]

\[ \text{CH₃} \quad + \text{CH₃} = \text{O} \]

Reaction 3

\[ \text{Caryophyllene} \xrightarrow{1. \text{One equivalent of BH₃, THF} \quad 2. \text{H₂O₂, NaOH, H₂O} \quad 1. \text{O₃, CH₂Cl₂} \quad 2. \text{Zn, CH₃COH}} \]

\[ \text{H₃C} \quad \text{O} \quad \text{H} \quad \text{CH₃} \quad \text{CH₃} \quad \text{H} \quad \text{O} \quad \text{O} \quad \text{O} \]

\[ \text{CH₃} \quad \text{CH₂OH} \quad \text{H} \quad \text{CH₂OH} \]

An isomer, isocaryophyllene, gives the same products as caryophyllene upon hydrogenation and ozonolysis. Hydroboration-oxidation of isocaryophyllene gives a C₁₅H₂₆O product isomeric to the one shown in reaction 3; however, ozonolysis converts this compound into the same final product shown. In what way do caryophyllene and its isomer differ?

75. Juvenile hormone (JH, Chemical Highlight 12-1) has been synthesized in several ways. Two intermediates are shown in (a) and (b). Propose completions for syntheses of JH that start with each of them. Your synthesis for (a) should be stereospecific. Also for (a), note that the double bond between C10 and C11 is the most reactive toward electrophilic reagents.

Team Problem

76. The selectivity of hydroboration increases with increasing bulkiness of the borane reagent.

(a) For example, 1-pentene is selectively hydroborated in the presence of cis- and trans-2-pentene when treated with bis(1,2-dimethylpropyl)borane (disiamylborane) or with 9-borabicyclo[3.3.1]nonane, 9-BBN. Divide the task of formulating the structure of the starting alkene used in preparing
both of these bulky borane reagents among yourselves. Make models to visualize the features of these reagents that direct the structural selectivity.

(b) In an enantioselective approach to making secondary alcohols, two equivalents of one enantiomer of α-pinene are treated with BH₃. The resulting borane reagent is treated with cis-2-butene followed by basic hydrogen peroxide to yield optically active 2-butanol.

Share your model kits to make a model of α-pinene and the resulting borane reagent. Discuss what is directing the enantioselectivity of this hydroboration–oxidation reaction. What products besides 2-butanol result from the oxidation step?

Preprofessional Problems

77. A chiral compound, C₅H₈, upon simple catalytic hydrogenation, yields an achiral compound, C₅H₁₀. What is the best name for the former? (a) 1-Methylocyclobutene; (b) 3-methylocyclobutene; (c) 1,2-dimethylocyclopene; (d) cyclopentene.

78. A chemist reacted 300 g of 1-butene with excess Br₂ (in CCl₄) at 25°C. He isolated 418 g of 1,2-dibromobutane. What is the percent yield? (Atomic weights: C = 12.0, H = 1.00, Br = 80.0.) (a) 26; (b) 36; (c) 46; (d) 56; (e) 66.

79. trans-3-Hexene and cis-3-hexene differ in one of the following ways. Which one? (a) Products of hydrogenation; (b) products of ozonolysis; (c) products of Br₂ addition in CCl₄; (d) products of hydroboration–oxidation; (e) products of combustion.

80. Which reaction intermediate is believed to be part of the following reaction?

\[ RCH\equiv CHCH₂Br + HBr, ROOR \rightarrow RCH₂CH₂Br \]

(a) Radical; (b) carbocation; (c) oxacyclopropane; (d) bromonium ion.

81. When 1-pentene is treated with mercuric acetate, followed by sodium borohydride, which of the following compounds is the resulting product? (a) 1-Pentyne; (b) pentane; (c) 1-pentanol; (d) 2-pentanol.
Alkynes

The Carbon–Carbon Triple Bond

Alkynes are hydrocarbons that contain carbon–carbon triple bonds. It should not come as a surprise that their characteristics resemble the properties and behavior of alkenes, their double-bonded cousins. In this chapter we shall see that, like alkenes, alkynes find numerous uses in a variety of modern settings. For example, the polymer derived from the parent compound, ethyne (HC≡CH), can be fashioned into electrically conductive sheets usable in lightweight, all-polymer batteries. Ethyne is also a substance with a relatively high energy content, a property that is exploited in oxyacetylene torches. A variety of alkynes, both naturally occurring and synthetic, have found use in medicine for their antibacterial, antiparasitic, and antifungal activities.

\[ \text{Alkene triple bond} \]

Because the \( \text{C≡C} \) functional group contains two \( \pi \) linkages (which are mutually perpendicular; recall Figure 1-21), its reactivity is much like that of the double bond. For example, like alkenes, alkynes are electron rich and subject to attack by electrophiles. Many of the alkenes that serve as monomers for the production of polymeric fabrics, elastics, and plastics are prepared by electrophilic addition reactions to ethyne and other alkynes. Alkynes can be prepared by elimination reactions similar to those used to generate alkenes, and they are likewise most stable when the multiple bond is internal rather than terminal. A further, and useful, feature is that the alkynyl hydrogen is much more acidic than its alkenyl or alkyl counterpart, a property that permits easy deprotonation by strong bases. The resulting alkynyl anions are valuable nucleophilic reagents in synthesis.

We begin with discussions of the naming, structural characteristics, and spectroscopy of the alkynes. Subsequent sections introduce methods for the synthesis of compounds in this class and the typical reactions they undergo. We end with an overview of the extensive industrial uses and physiological characteristics of alkynes.
13-1 Naming the Alkynes

A carbon–carbon triple bond is the functional group characteristic of the alkynes. The general formula for the alkynes is \( C_nH_{2n−2} \), the same as that for the cycloalkenes. The common names for many alkynes are still in use, including acetylene, the common name of the smallest alkyne, \( C_2H_2 \). Other alkynes are treated as its derivatives—for example, the alkylacetylenes.

The IUPAC rules for naming alkenes (Section 11-1) also apply to alkynes, the ending -yne replacing -ene. A number indicates the position of the triple bond in the main chain.

\[
\begin{align*}
& \text{HC}≡\text{CH} & & \text{Br} & & \text{CH}_3 \\
& \text{CH}_3\text{C}≡\text{CH}_3 & & \text{CH}_3\text{C}≡\text{CCH}_2\text{CH}_3 & & \text{CH}_3\text{C}≡\text{CH} \\
& \text{Ethyne} & & \text{2-Butyne} & & \text{4-Bromo-2-hexyne} \\
& & & (\text{An internal alkyne}) & & (\text{A terminal alkyne}) \\
\end{align*}
\]

Alkynes having the general structure \( RC≡CR' \) are terminal, whereas those with the structure of \( RC≡CR' \) are internal.

Substituents bearing a triple bond are alkyne \( \text{yl} \) groups. Thus, the substituent \(-C≡CH\) is named ethynyl; its homolog \(-CH_2C≡CH\) is 2-propynyl (propargyl). Like alkanes and alkenes, alkynes can be depicted in straight-line notation.

In IUPAC nomenclature, a hydrocarbon containing both double and triple bonds is called an alkenyne. The chain is numbered starting from the end closest to either of the functional groups. When a double bond and a triple bond are at equidistant positions from either terminus, the double bond is given the lower number. Alkynes incorporating the hydroxy function are named alkyne \( \text{ols} \). Note the omission of the final e of -ene in -enyne and of -yne in -ynol. The OH group takes precedence over both double and triple bonds in the numbering of a chain.

\[
\begin{align*}
& \text{trans-1,2-Diethynycyclohexane} & & \text{2-Propynyleclobutan} \\
& & & \text{(Propargyleclobutane)} & & \text{2-Propyn-1-ol} \\
& & & \text{(Propargyl alcohol)} & & \\
\end{align*}
\]

Exercise 13-1

Give the IUPAC names for (a) all the alkynes of composition \( C_6H_{10} \);

(b) \( \text{HC}≡\text{C}−\text{CH} \);

(c) all butynols. Remember to include and designate stereoisomers.

13-2 Properties and Bonding in the Alkynes

The nature of the triple bond helps explain the physical and chemical properties of the alkynes. In molecular-orbital terms, we shall see that the carbons are \( sp \) hybridized, and the four singly filled \( p \) orbitals form two perpendicular \( \pi \) bonds.
Alkynes are relatively nonpolar

Alkynes have boiling points very similar to those of the corresponding alkenes and alkanes. Ethyne is unusual in that it has no boiling point at atmospheric pressure; rather, it sublimes at −84°C. Propyne (b.p. −23.2°C) and 1-butyne (b.p. 8.1°C) are gases, whereas 2-butyne is barely a liquid (b.p. 27°C) at room temperature. The medium-sized alkynes are distillable liquids. Care must be taken in the handling of alkynes: They polymerize very easily—frequently with violence. Ethyne explodes under pressure but can be shipped in pressurized gas cylinders that contain acetone and a porous filler such as pumice as stabilizers.

**Ethyne is linear and has strong, short bonds**

In ethyne, the two carbons are $sp$ hybridized (Figure 13-1A). One of the hybrid orbitals on each carbon overlaps with hydrogen, and a $\sigma$ bond between the two carbon atoms results from mutual overlap of the remaining $sp$ hybrids. The two perpendicular $p$ orbitals on each carbon contain one electron each. These two sets overlap to form two perpendicular $\pi$ bonds (Figure 13-1B). Because $\pi$ bonds are diffuse, the distribution of electrons in the triple bond resembles a cylindrical cloud (Figure 13-1C). As a consequence of hybridization and the two $\pi$ interactions, the strength of the triple bond is about 229 kcal mol$^{-1}$, considerably stronger than either the carbon–carbon double or single bonds (margin). As with alkenes, however, the alkyne $\pi$ bonds are much weaker than the $\sigma$ component of the triple bond, a feature that gives rise to much of its chemical reactivity. The C–H bond-dissociation energy of terminal alkynes is also substantial: 131 kcal mol$^{-1}$ (548 kJ mol$^{-1}$).

**Figure 13-1** (A) Orbital picture of $sp$-hybridized carbon, showing the two perpendicular $p$ orbitals. (B) The triple bond in ethyne: The orbitals of two $sp$-hybridized CH fragments overlap to create a $\sigma$ bond and two $\pi$ bonds. (C) The two $\pi$ bonds produce a cylindrical electron cloud around the molecular axis of ethyne. (D) The electrostatic potential map reveals the (red) belt of high electron density around the central part of the molecular axis.

Because both carbon atoms in ethyne are $sp$ hybridized, its structure is linear (Figure 13-2). The carbon–carbon bond length is 1.20 Å, shorter than that of a double bond (1.33 Å, Figure 11-1). The carbon–hydrogen bond also is short, again because of the relatively large degree of $s$ character in the $sp$ hybrids used for bonding to hydrogen. The electrons in these orbitals (and in the bonds that they form by overlapping with other orbitals) reside relatively close to the nucleus and produce shorter (and stronger) bonds.

**Alkynes are high-energy compounds**

The alkyne triple bond is characterized by a concentration of four $\pi$ electrons in a relatively small volume of space. The resulting electron–electron repulsion contributes to the relative weakness of the two $\pi$ bonds and to a very high energy content of the alkyne molecule itself. Because of this property, alkynes often react with the release of considerable amounts of energy. In addition to being prone to explosive decomposition, ethyne has a heat of combustion of 311 kcal mol$^{-1}$. As shown in the equation for ethyne combustion on the next page, this energy is distributed among only three product molecules, one of water and two...
of CO₂, causing each to be heated to extremely high temperatures (>2500°C), sufficient for use in welding torches.

**Combustion of Ethyne**

\[
\text{HC} ≡ \text{CH} + 2.5 \text{O}_2 \rightarrow 2 \text{CO}_2 + \text{H}_2\text{O} \quad \Delta H^o = -311 \text{ kcal mol}^{-1} \quad (-1301 \text{ kJ mol}^{-1})
\]

As we found in our discussion of alkene stabilities (Section 11-5), heats of hydrogenation also provide convenient measures of the relative stabilities of alkyne isomers. In the presence of catalytic amounts of platinum or palladium on charcoal, the two isomers of butyne hydrogenate by addition of two molar equivalents of H₂ to produce butane. Just as we discovered in the case of alkenes, hydrogenation of the internal alkyne isomer releases less energy, allowing us to conclude that 2-butyne is the more stable of the two. Hyperconjugation is the reason for the greater relative stability of internal compared with terminal alkynes.

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{C} ≡ \text{CH} + 2 \text{H}_2 \xrightarrow{\text{Catalyst}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \quad \Delta H^o &= -69.9 \text{ kcal mol}^{-1} \quad (-292.5 \text{ kJ mol}^{-1}) \\
\text{CH}_3\text{C} ≡ \text{CCH}_3 + 2 \text{H}_2 \xrightarrow{\text{Catalyst}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \quad \Delta H^o &= -65.1 \text{ kcal mol}^{-1} \quad (-272.4 \text{ kJ mol}^{-1})
\end{align*}
\]

**Exercise 13-2**

Are the heats of hydrogenation of the butynes consistent with the notion that alkynes are high-energy compounds? Explain. (Hint: Compare these values with the heats of hydrogenation of alkene double bonds.)

**Terminal alkynes are remarkably acidic**

In Section 2-2 you learned that the strength of an acid, H – A, increases with increasing electronegativity, or electron-attracting capability, of atom A. Is the electronegativity of an atom the same in all structural environments? The answer is no: Electronegativity varies with hybridization. Electrons in s orbitals are more strongly attracted to an atomic nucleus than are electrons in p orbitals. As a consequence, an atom with hybrid orbitals high in s character (e.g., sp, with 50% s and 50% p character) will be slightly more electronegative than the same atom with hybrid orbitals with less s character (sp², 25% s and 75% p character). This effect is indicated below in the electrostatic potential maps of ethane, ethene, and ethyne. The increasingly positive polarization of the hydrogen atoms is reflected in their increasingly blue shadings, whereas the carbon atoms become more electron rich (red) along the series. The relatively high s character in the carbon hybrid orbitals of terminal alkynes makes them more acidic than alkanes and alkenes. The pKₐ of ethyne, for example, is 25, remarkably low compared with that of ethene and ethane.
Exercise 13-3

Working with the Concepts: Deprotonation of Alkynes

What is the equilibrium constant, $K_{eq}$, for the acid-base reaction shown above? Does its value explain why the reaction is written with only a forward arrow, suggesting that it is “irreversible”?

Strategy
Recall how $pK_a$ values relate to acid dissociation constants. Use this information to determine the value for $K_{eq}$.

Solution
• The $pK_a$ is the negative logarithm of the acid dissociation constant. Dissociation of the alkyne therefore has a $K_a < 10^{-2.5}$, very unfavorable, at least in comparison with the more familiar acids. However, butyllithium is the conjugate base of butane, which has a $K_a < 10^{-5.5}$. As an acid, butane is 25 orders of magnitude weaker than is the terminal alkyne. Thus, butyllithium is that much stronger a base compared with the alkynyl anion.
• The $K_{eq}$ for the reaction is found by dividing the $K_a$ for the acid on the left by the $K_a$ for the acid on the right: $10^{-2.5}/10^{-5.5} = 10^{2.5}$. The reaction is very favorable in the forward direction, so much so that for all practical purposes it may be considered to be irreversible. (Caution: Use common sense to avoid major errors in solving acid-base problems, such as deciding that the equilibrium lies the wrong direction. Use this hint: The favored direction for an acid-base reaction converts the stronger acid/stronger base pair into the weaker acid/weaker base pair.)

Exercise 13-4

Try It Yourself

Strong bases other than those mentioned here for the deprotonation of alkynes were introduced earlier. Two examples are potassium tert-butoxide and lithium diisopropylamide (LDA). Would either (or both) of these compounds be suitable for making ethynyl anion from ethyne? Explain, in terms of their $pK_a$ values.

In Summary
The characteristic hybridization scheme for the triple bond of an alkyne controls its physical and electronic features. It is responsible for strong bonds, the linear structure, and the relatively acidic alkynyl hydrogen. In addition, alkynes are highly energetic compounds. Internal isomers are more stable than terminal ones, as shown by the relative heats of hydrogenation.

13-3 Spectroscopy of the Alkynes

Alkenyl hydrogens (and carbons) are deshielded and give rise to relatively low-field NMR signals compared with those in saturated alkanes (Section 11-4). In contrast, alkynyl hydrogens have chemical shifts at relatively high field, much closer to those in alkanes. Similarly, the $sp$-hybridized carbons absorb in a range between that recorded for alkenes and alkanes. Alkynes, especially terminal ones, are also readily identified by IR spectroscopy. Finally, mass spectrometry can be a useful tool for identification and structure elucidation of alkynes.
The NMR absorptions of alkyne hydrogens show a characteristic shielding

Unlike alkenyl hydrogens, which are deshielded and give $^1$H NMR signals at $\delta = 4.6-5.7$ ppm, protons bound to $sp$-hybridized carbon atoms are found at $\delta = 1.7-3.1$ ppm (Table 10-2). For example, in the NMR spectrum of 3,3-dimethyl-1-butyne, the alkynyl hydrogen resonates at $\delta = 2.06$ ppm (Figure 13-3).

Why is the terminal alkyne hydrogen so shielded? Like the $\pi$ electrons of an alkene, those in the triple bond enter into a circular motion when an alkyne is subjected to an external magnetic field (Figure 13-4). However, the cylindrical distribution of these electrons (Figure 13-1C) now allows the major direction of this motion to be perpendicular to...
that in alkenes and to generate a local magnetic field that opposes $H_0$ in the vicinity of the alkyne hydrogen. The result is a strong *shielding* effect that cancels the deshielding tendency of the electron-withdrawing $sp$-hybridized carbon and gives rise to a relatively high-field chemical shift.

**The triple bond transmits spin–spin coupling**

The alkyne functional group transmits coupling so well that the terminal hydrogen is split by the hydrogens across the triple bond, even though it is separated from them by three carbons. This result is an example of long-range coupling. The coupling constants are small and range from about 2 to 4 Hz. Figure 13-5 shows the NMR spectrum of 1-pentyne. The alkynyl hydrogen signal at $\delta = 1.94$ ppm is a triplet ($J = 2.5$ Hz) because of coupling to the two equivalent hydrogens at C3, which appear at $\delta = 2.16$ ppm. The latter, in turn, give rise to a doublet of triplets, representing coupling to the two hydrogens at C4 ($J = 6$ Hz) as well as that at C1 ($J = 2.5$ Hz).

**Exercise 13-5**

**Working with the Concepts: Predicting an NMR Spectrum**

Predict the first-order splitting pattern in the $^1H$ NMR spectrum of 3-methyl-1-butyne.

**Strategy**

First, write out the structure. Then identify groups of hydrogens within coupling distance of each other, both neighboring and long range. Finally, use information regarding approximate values of coupling constants (and the $N + 1$ rule) to generate expected splitting patterns.

**Solution**

- The structure of the molecule is

$$\begin{align*}
\text{CH}_3 & \\
\text{CH}_3\text{CH}_2\text{CH}_2\text{C} & \equiv \text{CH} \\
\text{CH}_3 & \\
\end{align*}$$

- The two methyl groups are equivalent and give one signal that is split into a doublet by the single hydrogen atom at C3 ($N + 1 = 2$ lines). The coupling constant ($J$ value) for this splitting is the typical 6–8 Hz found in saturated systems (Section 10-7).
Chapter 13
Alkynes

The $^{13}$C NMR chemical shifts of alkyne carbons are distinct from those of the alkanes and alkenes. Carbon-$^{13}$ NMR spectroscopy also is useful in deducing the structure of alkynes. For example, the triple-bonded carbons in alkyl-substituted alkynes resonate in the range of $\delta = 65–95$ ppm, quite separate from the chemical shifts of analogous alkane ($\delta = 5–45$ ppm) and alkene ($\delta = 100–150$ ppm) carbon atoms (Table 10-6).

* The alkyne $\text{C} \equiv \text{CH}$ hydrogen at C1 experiences long-range coupling to the same H at C3, appearing also as a doublet, but $J$ is smaller, about 3 Hz.
* Finally, the signal for the hydrogen at C3 displays a more complex pattern. The 6–8-Hz splitting by the six hydrogens of the methyl groups gives a septet ($N + 1 = 7$ lines). Each line of this septet is further split by the additional 3-Hz coupling to the alkyne H. As the actual spectrum below shows, the outermost lines of this signal, a doublet of septets, are so small that they are barely visible (see Tables 10-4 and 10-5). (Caution: When interpreting $^1$H NMR spectra, be aware of the very low intensity of the outer lines in highly split signals. In fact, it is prudent to assume that such signals may consist of more lines than are readily visible.)

Exercise 13-6
Try It Yourself

Predict the first-order splitting pattern in the $^1$H NMR spectrum of 2-pentyne.

The $^{13}$C NMR chemical shifts of alkyne carbons are distinct from those of the alkanes and alkenes

Carbon-$^{13}$ NMR spectroscopy also is useful in deducing the structure of alkynes. For example, the triple-bonded carbons in alkyl-substituted alkynes resonate in the range of $\delta = 65–95$ ppm, quite separate from the chemical shifts of analogous alkane ($\delta = 5–45$ ppm) and alkene ($\delta = 100–150$ ppm) carbon atoms (Table 10-6).

**Typical Alkyne $^{13}$C NMR Chemical Shifts**

Terminal alkynes give rise to two characteristic infrared absorptions

Infrarred spectroscopy is helpful in identifying terminal alkynes. Characteristic stretching bands appear for the alkynyl hydrogen at 3260–3330 cm$^{-1}$ and for the C$\equiv$C triple bond at 2100–2260 cm$^{-1}$. There is also a diagnostic $\nu_C$–$\nu_H$ bending absorption at 640 cm$^{-1}$.
(Figure 13-6). Such data are especially useful when $^1$H NMR spectra are complex and difficult to interpret. However, the band for the $\text{C}═\text{C}$ stretching vibration in internal alkynes is often weak, like that for internal alkenes (Section 11-8), thus reducing the value of IR spectroscopy for characterizing these systems.

**Mass spectral fragmentation of alkynes gives resonance-stabilized cations**

The mass spectra of alkynes, like those of alkenes, frequently show prominent molecular ions. Thus high-resolution measurements can reveal the molecular formula and therefore the presence of two degrees of unsaturation derived from the presence of the triple bond.

In addition, fragmentation at the carbon once removed from the triple bond is observed, giving resonance-stabilized cations. For example, the mass spectrum of 3-heptyne (Figure 13-7) shows an intense molecular ion peak at $m/z = 96$ and loss of both methyl...
(cleavage $a$) and ethyl (cleavage $b$) fragments to give two different stabilized cations, with $m/z = 81$ and 67 (base peak), respectively:

**Fragmentation of an Alkyne in the Mass Spectrometer**

\[
\begin{align*}
\text{[CH}_3\text{CH}2 - &C\equiv C - CH_2 + CH_2CH_3] \\
&\text{[CH}_2\text{C} - C\equiv C - CH_2CH_3] \\
&\text{m/z = 81}
\end{align*}
\]

Unfortunately, under the high energy conditions of the mass spectrometry experiment, migration of the triple bond can occur. Thus this fragmentation is not typically very useful for identifying the location of the triple bond in a longer-chain alkyne.

**In Summary** The cylindrical $\pi$ cloud around the carbon–carbon triple bond induces local magnetic fields that lead to NMR chemical shifts for alkynyl hydrogens at higher fields than those of alkenyl protons. Long-range coupling is observed through the $C\equiv C$ linkage. Infra-red spectroscopy provides a useful complement to NMR data, displaying characteristic bands for the $C\equiv C$ and $C\equiv C$ – $H$ bonds of terminal alkynes. In the mass spectrometer, alkynes fragment to give resonance-stabilized cations.

## 13-4 Preparation of Alkynes by Double Elimination

The two basic methods used to prepare alkynes are double elimination from 1,2-dihaloalkanes and alkylation of alkynyl anions. This section deals with the first method, which provides a synthetic route to alkynes from alkenes; Section 13-5 addresses the second, which converts terminal alkynes into more complex, internal ones.

**Alkynes are prepared from dihaloalkanes by elimination**

As discussed in Section 11-6, alkenes can be prepared by E2 reactions of haloalkanes. Application of this principle to alkyne synthesis suggests that treatment of vicinal dihaloalkanes with two equivalents of strong base should result in double elimination to furnish a triple bond.

![Double Elimination from Dihaloalkanes to Give Alkynes](image)

Indeed, addition of 1,2-dibromohexane (prepared by bromination of 1-hexene, Section 12-5) to sodium amide in liquid ammonia followed by evaporation of solvent and aqueous work-up gives 1-hexyne.
Example of Double Dehydrohalogenation to Give an Alkyne

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH} \quad \text{CH}_2\text{Br} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH} \quad \text{CH} \\
\text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br}
\]

1. 3 NaNH\text{2}, liquid NH\text{3}  
2. H\text{2}O  
3. H\text{2}O  

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH} \quad \text{CH}_2\text{Br} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH} \quad \text{CH} \\
\text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br} \quad \text{Br}
\]

Three equivalents of NaNH\text{2} are necessary in the preparation of a terminal alkyne because, as this alkyne forms, its acidic terminal hydrogen (Section 13-2) immediately protonates an equivalent amount of base. Eliminations in liquid ammonia are usually carried out at its boiling point, \(-33^\circ\text{C}\).

Because vicinal dihaloalkanes are readily available from alkenes by halogenation, this sequence, called halogenation–double dehydrohalogenation, is a ready means of converting alkenes into the corresponding alkynes.

### A Halogenation–Double Dehydrohalogenation Used in Alkyne Synthesis

**Exercise 13-7**

Illustrate the use of halogenation–double dehydrohalogenation in the synthesis of the alkynes (a) 2-pentyne; (b) 1-octyne; (c) 2-methyl-3-hexyne.

**Haloalkenes are intermediates in alkyne synthesis by elimination**

Dehydrohalogenation of dihaloalkanes proceeds through the intermediacy of haloalkenes, also called alkenyl halides. Although mixtures of \(E\)- and \(Z\)-haloalkenes are in principle possible, with diastereomerically pure vicinal dihaloalkanes only one product is formed because elimination proceeds stereospecifically \textit{anti} (Section 11-6).

**Exercise 13-8**

Give the structure of the bromoalkene intermediate in the bromination–dehydrobromination of \textit{cis}-2-butene to 2-butyne. Do the same for the trans isomer. (\textbf{Caution:} There is stereochemistry involved in both steps. \textbf{Hint:} Refer to Section 12-5 for useful information, and use models.)

The stereochemistry of the intermediate haloalkene is of no consequence when the sequence is used for alkyne synthesis. Both \(E\)- and \(Z\)-haloalkenes eliminate with base to give the same alkyne.

**In Summary** Alkynes are made from vicinal dihaloalkanes by double elimination. Alkenyl halides are intermediates, being formed stereospecifically in the first elimination.

### 13-5 Preparation of Alkynes from Alkynyl Anions

Alkynes can also be prepared from other alkynes. The reaction of terminal alkynyl anions with alkylating agents, such as primary haloalkanes, oxacyclop propane, aldehyde, or ketones, results in carbon–carbon bond formation. As we know (Section 13-2), such anions are readily prepared from terminal alkynes by deprotonation with strong bases (mostly alkyllithium reagents, sodium amide in liquid ammonia, or Grignard reagents). Alkylation
with methyl or primary haloalkanes is typically done in liquid ammonia or in ether solvents. The process is unusual, because ordinary alkyl organometallic compounds are unreactive in the presence of haloalkanes. Alkynyl anions are an exception, however.

\[ \text{C≡CH} \xrightarrow{\text{CH}_3\text{CH}_2\text{CH}_2\text{Li, THF}} \text{C≡C}^-\text{Li} \xrightarrow{\text{CH}_3\text{CH}_2\text{CH}_2\text{Li}, 65^\circ\text{C}} \text{C≡CCH}_2\text{CH}_2\text{CH}_3 \]

\[ \text{Alkylation of an Alkynyl Anion} \]

85%

1-Pentynylcyclohexane

Attempted alkylation of alkynyl anions with secondary and tertiary halides leads to E2 products because of the strongly basic character of the nucleophile (recall Section 7-8). Ethyne itself may be alkylated in a series of steps through the selective formation of the monoanion to give mono- and dialkyl derivatives.

Alkynyl anions react with other carbon electrophiles such as oxacyclopropanes and carbonyl compounds in the same manner as do other organometallic reagents (Sections 8-8 and 9-9).

Reactions of Alkynyl Anions

(a) \[ \text{from} \]

(b) \[ \text{from ethyne} \]

Exercise 13-10

3-Butyn-2-ol is an important raw material in the pharmaceutical industry. It is the starting point for the synthesis of a variety of medicinally valuable alkaloids (Section 25-8), steroids (Section 4-7), and prostaglandins (Chemical Highlight 11-1 and Section 19-13), as well as vitamins E (Section 22-9) and K. Propose a short synthesis of 3-butyn-2-ol by using the techniques outlined in this section.
In Summary  Alkynes can be prepared from other alkynes by alkylation with primary haloalkanes, oxacyclopropanes, or carbonyl compounds. Ethyne itself can be alkylated in a series of steps.

13-6 Reduction of Alkynes: The Relative Reactivity of the Two Pi Bonds

Now we turn from the preparation of alkynes to the characteristic reactions of the triple bond. In many respects, alkynes are like alkenes, except for the availability of two \( \pi \) bonds. Thus, alkynes can undergo additions, such as hydrogenation and electrophilic attacks.

In this section we introduce two new hydrogen addition reactions: step-by-step hydrogenation and dissolving-metal reduction by sodium to give cis and trans alkenes, respectively.

Cis alkenes can be synthesized by catalytic hydrogenation

Alkynes can be hydrogenated under the same conditions used to hydrogenate alkenes. Typically, platinum or palladium on charcoal is suspended in a solution containing the alkyne and the mixture is exposed to a hydrogen atmosphere. Under these conditions, the triple bond is saturated completely.

Complete Hydrogenation of Alkynes

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{C} \equiv \text{CCH}_2\text{CH}_3 \xrightarrow{\text{H}_2, \text{Pt}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \]

3-Heptyne

Hydrogenation is a stepwise process that may be stopped at the intermediate alkene stage by the use of modified catalysts, such as the Lindlar* catalyst. This catalyst is palladium that has been precipitated on calcium carbonate and treated with lead acetate and quinoline. The surface of the metal rearranges to a less active configuration than that of palladium on carbon so that only the first \( \pi \) bond of the alkyne is hydrogenated. As with catalytic hydrogenation of alkenes (Section 12-2), the addition of \( \text{H}_2 \) is a syn process. As a result, this method affords a stereoselective synthesis of cis alkenes from alkynes.

Hydrogenation with Lindlar Catalyst

\[ \begin{array}{c}
\text{3-Heptyne} \\
\xrightarrow{\text{H}_2, \text{Lindlar catalyst}, 25^\circ \text{C}} \end{array} \]

100% cis-3-Heptene

*Dr. Herbert H. M. Lindlar (b. 1909), Hoffman–La Roche Ltd., Basel.
Chapter 13: Alkynes

With a method for the construction of cis alkenes at our disposal, we might ask: Can we modify the reduction of alkynes to give only trans alkenes? The answer is yes, with a different reducing agent and through a different mechanism.

Sequential one-electron reductions of alkynes produce trans alkenes

When we use sodium metal dissolved in liquid ammonia (dissolving-metal reduction) as the reagent for the reduction of alkynes, we obtain trans alkenes as the products. For example, 3-heptyne is reduced to trans-3-heptene in this way. Unlike sodium amide in liquid ammonia, which functions as a strong base, elemental sodium in liquid ammonia acts as a powerful electron donor (i.e., a reducing agent).

Dissolving-Metal Reduction of an Alkyne

In the first step of the mechanism of this reduction, the \( \pi \) framework of the triple bond accepts one electron to give a radical anion. This anion is protonated by the ammonia solvent (step 2) to give an alkenyl radical, which is further reduced (step 3) by accepting another electron to give an alkenyl anion. This species is again protonated (step 4) to give the product alkene, which is stable to further reduction. The trans stereochemistry of the final alkene is set in the first two steps of the mechanism, which give rise preferentially to the less sterically hindered trans alkenyl radical. Under the reaction conditions (liquid \( \text{NH}_3 \), \(-33^\circ\text{C}\)), the second one-electron transfer takes place faster than cis-trans equilibration of the radical. This type of reduction typically provides >98% stereochemically pure trans alkene.

Some perfumes have star quality (from left to right): Jean Paul Gaultier MaDame Perfume, Paris Hilton Fairy Dust, Armani Prive Oranger Alhambra, and Jeanne Lanvin.

Exercise 13-11

Write the structure of the product expected from the following reaction.

![Reaction](https://example.com/reaction.png)

Exercise 13-12

The perfume industry makes considerable use of naturally occurring substances such as those obtained from rose and jasmine extracts. In many cases, the quantities of fragrant oils available by natural product isolation are so small that it is necessary to synthesize them. Examples are the olfactory components of violets, which include trans-2-cis-6-nonadien-1-ol and the corresponding aldehyde. An intermediate in their large-scale synthesis is cis-3-hexen-1-ol, whose industrial preparation is described as “a closely guarded secret.” Using the methods in this and the preceding sections, propose a synthesis from 1-butyne.

With a method for the construction of cis alkenes at our disposal, we might ask: Can we modify the reduction of alkynes to give only trans alkenes? The answer is yes, with a different reducing agent and through a different mechanism.
Mechanism of the Reduction of Alkynes by Sodium in Liquid Ammonia

**Step 1.** One-electron transfer

A

**Step 2.** First protonation

B

**Step 3.** Second one-electron transfer

C

**Step 4.** Second protonation

The equation below illustrates the application of dissolving-metal reduction in the synthesis of the sex pheromone of the spruce budworm, which is the most destructive pest to the spruce and fir forests of North America. The pheromone “lure” is employed at hundreds of sites in the United States and Canada as part of an integrated pest-management strategy (Section 12-17). The key reaction is reduction of 11-tetradecyn-1-ol to the corresponding trans alkenol. Subsequent oxidation to the aldehyde completes the synthesis.
Alkynes are very similar in reactivity to alkenes, except that they have two π bonds, both of which may be saturated by addition reactions. Hydrogenation of the first π bond, which gives cis alkenes, is best achieved by using the Lindlar catalyst. Alkynes are converted into trans alkenes by treatment with sodium in liquid ammonia, a process that includes two successive one-electron reductions.

13-7 Electrophilic Addition Reactions of Alkynes

As a center of high electron density, the triple bond is readily attacked by electrophiles. This section describes the results of three such processes: addition of hydrogen halides, reaction with halogens, and hydration. The hydration is catalyzed by mercury(II) ions. As is the case in electrophilic additions to unsymmetrical alkenes (Section 12-3), the Markovnikov rule is followed in transformations of terminal alkynes: The electrophile adds to the terminal (less substituted) carbon atom.

Addition of hydrogen halides forms haloalkenes and geminal dihaloalkanes

The addition of hydrogen bromide to 2-butyne yields (Z)-2-bromobutene. The mechanism is analogous to that of hydrogen halide addition to an alkene (Section 12-3).
Addition of a Hydrogen Halide to an Internal Alkyne

\[
\text{CH}_3\text{C}≡\text{CCH}_3 + \text{HBr}, \text{Br}^- \rightarrow \text{CH}_3\text{C}≡\text{CBr} \quad 60\% \\
\text{(Z)-2-Bromobutene}
\]

The stereochemistry of this type of addition is typically anti, particularly when excess halide ion is used. A second molecule of hydrogen bromide may also add, with regioselectivity that follows Markovnikov's rule, giving the product with both bromine atoms bound to the same carbon, a geminal dihaloalkane.

\[
\text{CH}_3\text{C}≡\text{CBr} + \text{HBr} \rightarrow \text{CH}_3\text{C}≡\text{CBr} \quad 90\%
\]

\[
\text{2,2-Dibromobutane}
\]

The addition of hydrogen halides to terminal alkynes also proceeds in accord with the Markovnikov rule.

Addition to a Terminal Alkyne

\[
\text{CH}_3\text{C}≡\text{CH} + \text{HI, } -70 ^\circ\text{C} \rightarrow \text{CH}_3\text{C}≡\text{CI} \quad 35\% \\
\text{CH}_3\text{C}≡\text{CI} \quad 65\%
\]

It is usually difficult to limit such reactions to addition of a single molecule of HX.

**Exercise 13-15**

Write a step-by-step mechanism for the addition of HBr twice to 2-butyne to give 2,2-dibromobutane. Show clearly the structure of the intermediate formed in each step.

**Halogenation also takes place once or twice**

Electrophilic addition of halogen to alkynes proceeds through the intermediacy of isolable vicinal dihaloalkenes, the products of a single anti addition. Reaction with additional halogen gives tetrahaloalkanes. For example, halogenation of 3-hexyne gives the expected (E)-dihaloalkene and the tetrahaloalkane.

**Double Halogenation of an Alkyne**

\[
\text{CH}_3\text{CH}_2\text{C}≡\text{CCH}_2\text{CH}_3 + \text{Br}_2, \text{CH}_3\text{COOH}, \text{LiBr} \rightarrow \text{CH}_3\text{CH}_2\text{C}≡\text{CBrCH}_2\text{CH}_3 \quad 99\% \\
\text{(E)-3,4-Dibromo-3-hexene} \quad 3,3,4,4-\text{Tetrabromohexane}
\]

**Exercise 13-16**

Give the products of addition of one and two molecules of Cl₂ to 1-butyne.
Mercuric ion–catalyzed hydration of alkynes furnishes ketones

In a process analogous to the hydration of alkenes, water can be added to alkynes in a Markovnikov sense to give alcohols—in this case enols, in which the hydroxy group is attached to a double-bond carbon. As mentioned in Section 12-16, enols spontaneously rearrange to the isomeric carbonyl compounds. This process, called tautomerism, interconverts two isomers by simultaneous proton and double-bond shifts. The enol is said to tautomerize to the carbonyl compound, and the two species are called tautomers *(tauto,* Greek, the same; *meros,* Greek, part). We shall look at tautomerism more closely in Chapter 18 when we investigate the behavior of carbonyl compounds. Hydration followed by tautomerism converts alkynes into ketones. The reaction is catalyzed by Hg(II) ions.

Hydration follows Markovnikov’s rule: Terminal alkynes give methyl ketones.

**Hydration of a Terminal Alkyne**

\[
\text{RC≡CR} + \text{HOH, H}^+, \text{HgSO}_4 \rightarrow \text{RCH=CR} \xrightarrow{\text{Tautomerism}} \text{RC=CR} \]

Enol

Ketone

**Exercise 13-17**

Draw the structure of the enol intermediate in the reaction above.

Symmetric internal alkynes give a single carbonyl compound; unsymmetric systems lead to a mixture of ketones.

**Hydration of Internal Alkynes**

**Example of Hydration of an Internal Alkyne That Gives a Mixture of Two Ketones**

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{C≡CCH}_3 + \text{H}_2\text{SO}_4, \text{H}_2\text{O}, \text{HgSO}_4 \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CCH}_2\text{CH}_3 + \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CCH}_3
\]

**Exercise 13-18**

Give the products of mercuric ion–catalyzed hydration of (a) ethyne; (b) propyne; (c) 1-butyn; (d) 2-butyn; (e) 2-methyl-3-hexyne.
In Summary
Alkynes can react with electrophiles such as hydrogen halides and halogens either once or twice. Terminal alkynes transform in accord with the Markovnikov rule. Mercuric ion–catalyzed hydration furnishes enols, which convert into ketones by a process called tautomerism.

13-8 Anti-Markovnikov Additions to Triple Bonds
Just as methods exist to permit anti-Markovnikov additions to double bonds (Sections 12-8 and 12-13), similar techniques allow additions to terminal alkynes to be carried out in an anti-Markovnikov manner.

Radical addition of HBr gives 1-bromoalkenes
As with alkenes, hydrogen bromide can add to triple bonds by a radical mechanism in an anti-Markovnikov fashion if light or other radical initiators are present. Both syn and anti additions are observed.
Alkenes result from hydroboration–oxidation of terminal alkynes

Terminal alkynes are hydroborated in a regioselective, anti-Markovnikov fashion, the boron attacking the less hindered carbon. However, with borane itself, this reaction leads ultimately to sequential hydroboration of both π bonds. To stop at the alkenylborane stage, bulky borane reagents, such as dicyclohexylborane, are used.

**Exercise 13-21**

Dicyclohexylborane is made by a hydroboration reaction. What are the starting materials for its preparation?

Like alkylboranes (Section 12-8), alkenylboranes can be oxidized to the corresponding alcohols—in this case, to terminal enols that spontaneously rearrange to aldehydes.

**Exercise 13-22**

Give the products of hydroboration–oxidation of (a) ethyne; (b) 1-propyne; (c) 1-butyne.

**Exercise 13-23**

Outline a synthesis of the following molecule from 3,3-dimethyl-1-butyne.

In Summary HBr in the presence of peroxides undergoes anti-Markovnikov addition to terminal alkynes to give 1-bromoalkenes. Hydroboration–oxidation with bulky boranes furnishes intermediate enols that tautomerize to the final product aldehydes.
**13-9 Chemistry of Alkenyl Halides**

We have encountered haloalkenes—alkenyl halides—as intermediates in both the preparation of alkynes by dehydrohalogenation and also the addition to alkynes of hydrogen halides. Alkenyl halides have become increasingly important as synthetic intermediates in recent years as a result of developments in organometallic chemistry. These systems do not, however, follow the mechanisms familiar to us from our survey of the haloalkanes (Chapters 6 and 7). This section discusses their reactivity.

**Alkenyl halides do not undergo S_N2 or S_N1 reactions**

Unlike haloalkanes, alkenyl halides are relatively unreactive toward nucleophiles. Although we have seen that, with strong bases, alkenyl halides undergo elimination reactions to give alkynes, they do not react with weak bases and relatively nonbasic nucleophiles, such as iodide. Similarly, S_N1 reactions do not normally take place, because the intermediate alkenyl cations are species of high energy.

\[
\text{CH}_2\text{=C-Br} \xrightarrow{\text{base}} \text{CH}_2\text{=C-H} + \text{Br}^- \\
\text{Does not take place}
\]

\[
\text{CH}_2\text{=C-I} \xrightarrow{\text{base}} \text{CH}_2\text{=C-H} + \text{I}^- \\
\text{Does not take place}
\]

Alkenyl halides, however, can react through the intermediate formation of alkenyl organometallics (see Exercise 11-6). These species allow access to a variety of specifically substituted alkenes.

**Alkenyl Organometallics in Synthesis**

\[
\text{CH}_2\text{=C-Br} + \text{Mg} \rightarrow \text{CH}_2\text{=C-MgBr} \\
\text{90%}
\]

1-Bromoethylene (Vinyl bromide)

Grignard addition to ketone gives tertiary alcohol

\[
\text{CH}_2\text{=C-MgBr} \rightarrow \text{CH}_2\text{=C-OH} \\
\text{2-Methyl-3-buten-2-ol} \text{ (A vinyl Grignard reagent)}
\]

**Metal catalysts couple alkenyl halides to alkenes in the Heck reaction**

In the presence of soluble complexes of metals such as Ni and Pd, alkenyl halides undergo carbon–carbon bond formation with alkenes to produce dienes. In this process, called the **Heck* reaction**, a molecule of hydrogen halide is liberated.

**The Heck Reaction**

\[
\text{HCl is lost} \\
\text{Ni or Pd catalyst} \\
\text{A new C=C bond forms}
\]

---

*Professor Richard F. Heck (b. 1931), University of Delaware.*
In common with other transition metal–catalyzed cross-couplings (see Chemical Highlight 8-3), assembly of the fragments around the catalyst precedes carbon–carbon bond formation. A simplified mechanism for the Heck reaction begins with reaction between the metal and the alkenyl halide to give an alkenylmetal halide (1). The alkene then complexes with the metal (2), and inserts itself into the carbon–metal bond, forming the new carbon–carbon linkage (3). Finally, elimination of HX in an E2-like manner gives the diene product and frees the metal catalyst (4).

![Mechanism of the Heck Reaction](image-url)

The growing popularity of the Heck reaction arises from both its versatility and its efficiency. In particular, it requires only a very small amount of catalyst compared with the quantity of the substrates; typically, 1% of palladium acetate in the presence of a phosphine ligand (R₃P) is sufficient.

---

**CHEMICAL HIGHLIGHT 13-1**

**Metal-Catalyzed Stille, Suzuki, and Sonogashira Coupling Reactions**

Three additional processes, the Stille, Suzuki, and Sonogashira* reactions, further broaden the scope of transition metal–catalyzed bond-forming processes. All utilize catalytic palladium or nickel; the differences lie in the nature and functionality of the substrates commonly employed.

In the Stille coupling, Pd catalyzes the direct linkage between alkenyl halides and alkenyltin compounds:

**Stille Coupling Reaction**

\[
\text{(CH}_3\text{)}_3\text{SnI} + \text{Pd catalyst, Cul, R}_3\text{As} \rightarrow \text{Product, 93%}
\]

Copper(I) iodide and an arsenic-derived ligand, R₃As, facilitate this very efficient process. The product shown was converted into a close relative of a microbially derived natural product that inhibits a factor associated with immune and inflammation responses. This factor also affects HIV activation and cell-death processes that are disrupted in cancer.

The Suzuki reaction replaces tin with boron and provides a different spectrum of utility. In particular,

**Suzuki Coupling Reaction**

\[
\text{I} + \text{(HO)₂B} \rightarrow \text{Product, 63%}
\]

*Professor John K. Stille (1930–1990), Colorado State University; Professor Akira Suzuki (b. 1930), Kurashiki University, Japan; Professor Kenkichi Sonogashira (b. 1931), Osaka City University, Japan.
Exercise 13-24

Write out a detailed step-by-step mechanism for the first of the two examples of Heck reactions above.
In Summary  Alkenyl halides are unreactive in nucleophilic substitutions. However, they can participate in carbon–carbon bond-forming reactions after conversion to alkenyllithium or alkenyl Grignard reagents, or in the presence of transition-metal catalysts such as Ni and Pd.

13-10 Ethyne as an Industrial Starting Material

Ethyne was once one of the four or five major starting materials in the chemical industry for two reasons: Addition reactions to one of the π bonds produce useful alkene monomers (Section 12-15), and it has a high heat content. Its industrial use has declined because of the availability of cheap ethene, propene, butadiene, and other hydrocarbons through oil-based technology. However, in the 21st century, oil reserves are expected to dwindle to the point that other sources of energy will have to be developed. One such source is coal. There are currently no known processes for converting coal directly into the aforementioned alkenes; ethyne, however, can be produced from coal and hydrogen or from coke (a coal residue obtained after removal of volatiles) and limestone through the formation of calcium carbide. Consequently, it may once again become an important industrial raw material.

Production of ethyne from coal requires high temperatures

The high energy content of ethyne requires the use of production methods that are costly in energy. One process for making ethyne from coal uses hydrogen in an arc reactor at temperatures as high as several thousand degrees Celsius:

\[
\text{Coal} + \text{H}_2 \xrightarrow{\Delta} \text{HC}≡\text{CH} + \text{nonvolatile salts} \quad 33\% \text{ conversion}
\]

The oldest large-scale preparation of ethyne proceeds through calcium carbide. Lime- stone (calcium oxide) and coke are heated to about 2000°C, which results in the desired product and carbon monoxide.

\[
3 \text{Coke} + 2 \text{CaO} \xrightarrow{2000^\circ C} \text{CaC}_2 + \text{CO}
\]

The calcium carbide is then treated with water at ambient temperatures to give ethyne and calcium hydroxide.

\[
\text{CaC}_2 + 2 \text{H}_2\text{O} \rightarrow \text{HC}≡\text{CH} + \text{Ca(OH)}_2
\]

Ethyne is a source of valuable monomers for industry

Ethyne chemistry underwent important commercial development in the 1930s and 1940s in the laboratories of Badische Anilin and SodaFabriken (BASF) in Ludwigshafen, Germany. Ethyne under pressure was brought into reaction with carbon monoxide, carbonyl compounds, alcohols, and acids in the presence of catalysts to give a multitude of valuable raw materials to be used in further transformations. For example, nickel carbonyl catalyzes the addition of carbon monoxide and water to ethyne to give propenoic (acrylic) acid. Similar exposure to alcohols or amines instead of water results in the corresponding acid derivatives. All of these products are valuable monomers (see Section 12-15).

Industrial Chemistry of Ethyne

\[
\text{HC}≡\text{CH} + \text{CO} + \text{H}_2\text{O} \xrightarrow{\text{Ni(CO)}_2, \text{100 atm, } >250^\circ C} \text{C}≡\text{CHCOOH}
\]

Propenoic acid
(Acrylic acid)
Polymerization of propenoic (acrylic) acid and its derivatives produces materials of considerable utility. The polymeric esters (polyacrylates) are tough, resilient, and flexible polymers that have replaced natural rubber (see Section 14-10) in many applications. Poly(ethyl acrylate) is used for O-rings, valve seals, and related purposes in automobiles. Other polyacrylates are found in biomedical and dental appliances, such as dentures.

The addition of formaldehyde to ethyne is achieved with high efficiency by using copper acetylide as a catalyst.

\[
\text{HC} \equiv \text{CH} + \text{CH}_2 = \text{O} \xrightarrow{\text{Cu}_2\text{C}_2\text{SiO}_2, 125^\circ \text{C}, 5 \text{ atm}} \text{HC} \equiv \text{CCH}_2\text{OH} \quad \text{or} \quad \text{HOCH}_2\text{C} \equiv \text{CCH}_2\text{OH}
\]

2-Propyn-1-ol (Propargyl alcohol)

The resulting alcohols are useful synthetic intermediates. For example, 2-butyne-1,4-diol is a precursor for the production of oxacyclopentane (tetrahydrofuran, one of the solvents most frequently employed for Grignard and organolithium reagents) by hydrogenation, followed by acid-catalyzed dehydration.

**Oxacyclopentane (Tetrahydrofuran) Synthesis**

\[
\text{HOCH}_2\text{C} \equiv \text{CCH}_2\text{OH} \xrightarrow{\text{Catalyst, } \text{H}_2} \text{HO(CH}_2)_4\text{OH} \xrightarrow{\text{H}_2\text{PO}_4, \text{pH } 2, 260-280^\circ \text{C}, 90-100 \text{ atm}} \text{Oxacyclopentane (Tetrahydrofuran, THF)}
\]

99%

Several technical processes have been developed in which reagents $^\delta+\text{A} - \text{B}^{2-}$ in the presence of a catalyst add to the triple bond. For example, the catalyzed addition of hydrogen chloride gives chloroethene (vinyl chloride), and addition of hydrogen cyanide produces propenenitrile (acrylonitrile).

**Addition Reactions of Ethyne**

\[
\begin{align*}
\text{HC} \equiv \text{CH} + \text{HCl} & \xrightarrow{\text{Hg}^{2+}, 100-200^\circ \text{C}} \text{C} = \text{CHCl} \\
& \text{Chloroethene (Vinyl chloride)} \\
\text{HC} \equiv \text{CH} + \text{HCN} & \xrightarrow{\text{Cu}^+, \text{NH}_4\text{Cl}, 70-90^\circ \text{C}, 1.3 \text{ atm}} \text{C} = \text{CHCN} \\
& 80-90\% \text{ Propenenitrile (Acrylonitrile)}
\end{align*}
\]

In 2007, the world produced 2.5 million tons of **acrylic fibers**, polymers containing at least 85% propenenitrile (acrylonitrile). Their applications include clothing (Orlon), carpets, and insulation. Copolymers of acrylonitrile and 10–15% vinyl chloride have fire-retardant properties and are used in children’s sleepwear.

**In Summary** Ethyne was once, and may again be in the future, a valuable industrial feedstock because of its ability to react with a large number of substrates to yield useful monomers and other compounds having functional groups. It can be made from coal and H$_2$ at high temperatures, or it can be prepared from calcium carbide by hydrolysis. Some of the industrial reactions that it undergoes are carboxylation, addition of formaldehyde, and addition reactions with HX.
13-11 Naturally Occurring and Physiologically Active Alkynes

Although alkynes are not very abundant in nature, they do exist in some plants and other organisms. The first such substance to be isolated, in 1826, was dehydromatricaria ester, from the chamomile flower. More than a thousand such compounds are now known, and some of them are physiologically active. For example, some naturally occurring ethynylketones, such as capillin, an oil found in the chrysanthemum, have fungicidal activity.

\[
\text{Dehydromatricaria ester}
\]

\[
\text{Capillin (Active against skin fungi)}
\]

The alkyne ichthyothereol is the active ingredient of a poisonous substance used by the Indians of the Lower Amazon River Basin in arrowheads. It causes convulsions in mammals. Two enyne functional groups are incorporated in the compound histrionicotoxin. It is one of the substances isolated from the skin of “poison arrow frog,” a highly colorful species of the genus *Dendrobates*. The frog secretes this compound and similar ones as defensive venoms and mucosal-tissue irritants against both mammals and reptiles. How the alkyne units are constructed biosynthetically is not clear.

\[
\text{Ichthyothereol (A convulsant)}
\]

\[
\text{Histrionicotoxin}
\]

Many drugs have been modified by synthesis to contain alkyne substituents, because such compounds are frequently more readily absorbed by the body, less toxic, and more active than the corresponding alkenes or alkanes. For example, 3-methyl-1-pentyn-3-ol is available as a nonprescription hypnotic, and several other alkynols are similarly effective.

Highly reactive enediyne (\(-\text{C\equivC\text{CH\equivCH\equivC}}\)) and trisulfide (RSSSR) functional groups characterize a class of naturally occurring antibiotic–antitumor agents discovered in the late 1980s, such as calicheamicin and esperamicin.
Ethynyl estrogens, such as 17-ethynylestradiol, are considerably more potent birth-control agents than are the naturally occurring hormones (see Section 4-7). The diaminoalkyne tremorine induces symptoms characteristic of Parkinson’s disease: spasms of uncontrolled movement. Interestingly, a simple cyclic homolog of tremorine acts as a muscle relaxant and counteracts the effect of tremorine. Compounds that cancel the physiological effects of other compounds are called antagonists (antagonizesthai, Greek, to struggle against). Finally, ethynyl analogs of amphetamine have been prepared in a search for alternative, more active, more specific, and less addictive central nervous system stimulants.

In Summary The alkyne unit is present in a number of physiologically active natural and synthetic compounds.

THE BIG PICTURE

As we said at the end of the previous chapter, much of what we have encountered in our examination of the alkynes represents an extension of what we learned regarding alkenes. Addition reactions take place under very similar conditions, obeying the same rules of regio- and stereochemistry. Reagents such as the hydrogen halides and the halogens may add once or twice. Addition of the elements of water to one of the \( \pi \) bonds takes us in a new direction, however: The resulting alkenol (or enol, for short) undergoes rearrangement (tautomerism) to an aldehyde or a ketone. Finally, terminal alkynes display a form of reactivity that does not normally appear in the alkenes (or alkanes, for that matter): The \( -\text{C}≡\text{C}−\text{H} \) hydrogen is unusually acidic. Its deprotonation gives rise to nucleophilic anions capable of forming new carbon–carbon bonds by reaction with a variety of functional groups possessing electrophilic carbon atoms.
In the next chapter we shall examine compounds containing multiple double bonds, including some made by the Heck process, a new organometallic reaction that we have just encountered. The same principles that have appeared repeatedly in Chapters 11–13 will continue to underlie the behavior of the systems that we cover next.

CHAPTER INTEGRATION PROBLEMS

13-25. Propose an efficient synthesis of 2,7-dimethyl-4-octanone, using organic building blocks containing no more than four carbon atoms.

\[
\text{2,7-Dimethyl-4-octanone}
\]

SOLUTION

We begin by analyzing the problem retrosynthetically (Section 8-9). What methods do we know for the preparation of ketones? We can oxidize alcohols (Section 8-6). Is this a productive line of analysis? If we look at the corresponding alcohol precursor, we can imagine synthesizing it by addition of an appropriate organometallic reagent to an aldehyde to form either bond \(a\) or bond \(b\) (Section 8-9):

Let us count carbon atoms in the fragments necessary for each of these synthetic pathways. To make bond \(a\), we need to add a four-carbon organometallic to a six-carbon aldehyde. The bond \(b\) alternative would employ 2 five-carbon building blocks. Remember the restriction that only four-carbon starting materials are allowed. From this point of view, neither of the preceding options is overly attractive. We shall shortly look again at route \(a\) but not route \(b\). Do you see why? The latter would require initial construction of 2 five-carbon pieces, whereas the former needs formation of only 1 six-carbon unit from fragments containing four carbons or fewer.

Now let us consider a second, fundamentally different ketone synthesis—hydration of an alkyne (Section 13-7). Either of two precursors, 2,7-dimethyl-3-octyne and 2,7-dimethyl-4-octyne, will lead to the target molecule. As shown here, however, only the latter, symmetric alkyne undergoes hydration to give just one ketone, regardless of the initial direction of addition.

\[
\text{H}_2\text{SO}_4, \text{H}_2\text{O}, \text{HgSO}_4 \rightarrow \text{2,7-Dimethyl-3-octyne} \rightarrow \text{2,7-Dimethyl-4-octyne}
\]

With 2,7-dimethyl-4-octyne appearing to be the precursor of choice, we continue by investigating its synthesis from building blocks of four carbons or fewer. The alkylation of terminal alkynes
(Section 13-5) affords us a method of bond formation that divides the molecule into three suitable fragments, shown in the following analysis:

\[
\begin{align*}
\text{H}_2\text{C} & \quad \text{Li} \quad \text{H}_2\text{C} \\
& + \quad \text{H}_2\text{C} \\
& \quad \text{LiNH}_2 \\
& + \quad \text{Br}
\end{align*}
\]

The synthesis follows directly:

\[
\text{Br} \quad \text{LiC} \quad \text{CH}_2 \quad \text{DMSO} \quad \text{LiNH}_2, \text{liquid NH}_3 \quad \text{Li}, \text{DMSO} \quad 2,7\text{-dimethyl-4-octyne}
\]

Although this three-step synthesis is the most efficient answer, a related approach derives from our earlier consideration of ketone synthesis with the use of an alcohol. It, too, proceeds through an alkyne. Construction of bond \(a\) of the target molecule, shown earlier, requires addition of an organo-metallic reagent to a six-carbon aldehyde, which, in turn, may be produced through hydroboration–oxidation (Section 13-8) of the terminal alkyne shown in the preceding scheme.

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{C} & \quad \text{H} \\
\text{OH} \\
& \quad \text{OH}
\end{align*}
\]

Oxidation of this alcohol by using a Cr(VI) reagent (Section 8-6) completes a synthesis that is just slightly longer than the optimal one described first.

13-26. Predict the product you would expect from the treatment of a terminal alkyne with bromine in water solvent, i.e.,

\[
\text{CH}_3\text{CH}_2\text{C} \equiv \text{CH} \quad \text{Br}_2, \text{H}_2\text{O}
\]

**SOLUTION**

Consider the problem mechanistically. Bromine adds to \(\pi\) bonds to form a cyclic bromonium ion, which is subject to ring opening by any available nucleophile. In the similar reaction of alkenes (Sections 12-5 and 12-6), nucleophilic attack is directed to the more substituted alkene carbon, namely, the carbon atom bearing the larger partial positive charge. Following that analogy in the case at hand and using water as the nucleophile, we may postulate the following as reasonable mechanistic steps:

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{C} & \equiv \text{CH} \quad \text{Br}_2, \text{H}_2\text{O} \\
\text{CH}_3\text{CH}_2\text{C} & \equiv \text{CH} \quad \text{Br} \\
\text{CH}_3\text{CH}_2\text{C} & \equiv \text{CH} \\
\end{align*}
\]

The product of the sequence is an enol, which, as we have seen (Section 13-8), is unstable and rapidly tautomerizes into a carbonyl compound. In this case, the ultimate product is \(\text{CH}_3\text{CH}_2\text{C} \equiv \text{CH}_2\text{Br}\), a bromoketone.

**New Reactions**

1. **Acidity of 1-Alkynes (Section 13-2)**

\[
\begin{align*}
\text{RC} & \equiv \text{CH} + \text{B}^- & \text{RC} & \equiv \text{C}^- + \text{BH} \\
\text{pK}_a = 25
\end{align*}
\]

Base (B): \(\text{NaNH}_2\text{–liquid NH}_3\); \(\text{RLi–(CH}_3\text{CH}_2)_2\text{O}\); \(\text{RMgX–THF}\)
Preparation of Alkynes

2. Double Elimination from Dihaloalkanes (Section 13-4)

\[
\begin{align*}
\text{Vicinal dihaloalkane} & \quad \xrightarrow{\text{NaNH}_2, \text{liquid NH}_3, -2 \text{HX}} \quad \text{RC} = \text{CR} \\
\text{Alkenyl halide \ intermediate} & \quad \xrightarrow{\text{NaNH}_2, \text{liquid NH}_3} \quad \text{RC} = \text{CR}'
\end{align*}
\]

Conversion of Alkynes into Other Alkynes

4. Alkylation of Alkynyl Anions (Section 13-5)

\[
\text{RC} = \text{CHR} \quad \xrightarrow{1. \text{NaNH}_2, \text{liquid NH}_3, 2. \text{R} - \text{X}} \quad \text{RC} = \text{CR}'
\]

S_{2,2} reaction: R’ must be primary

5. Alkylation with Oxacyclopropane (Section 13-5)

\[
\text{RC} = \text{CH} \quad \xrightarrow{1. \text{CH}_3\text{CH}_2\text{CH}_2\text{Li}, \text{THF}, 2. \text{H}_2\text{C} = \text{CH}_2, 3. \text{H}^+, \text{H}_2\text{O}} \quad \text{RC} = \text{CCH}_2\text{CH}_2\text{OH}
\]

Attack takes place at less substituted carbon in unsymmetric oxacyclopropanes

6. Alkylation with Carbonyl Compounds (Section 13-5)

\[
\text{RC} = \text{CH} \quad \xrightarrow{1. \text{CH}_3\text{CH}_2\text{CH}_2\text{Li}, \text{THF}, 2. \text{R} - \text{CR}'', 3. \text{H}^+, \text{H}_2\text{O}} \quad \text{RC} = \text{CCHR}''
\]

Reactions of Alkynes

7. Hydrogenation (Section 13-6)

\[
\text{RC} = \text{CR} \quad \xrightarrow{\text{Catalyst, } \text{H}_2} \quad \text{RC} = \text{CHR}_2 \quad \Delta H^\circ = -70 \text{ kcal mol}^{-1}
\]

\[
\text{RC} = \text{CR} \quad \xrightarrow{\text{H}_2, \text{Lindlar catalyst}} \quad \text{RC} = \text{CHR} \quad \Delta H^\circ = -40 \text{ kcal mol}^{-1}
\]

8. Reduction with Sodium in Liquid Ammonia (Section 13-6)

\[
\text{RC} = \text{CR} \quad \xrightarrow{1. \text{Na, liquid NH}_3, 2. \text{H}^+, \text{H}_2\text{O}} \quad \text{RC} = \text{CHR}
\]

Cis alkene

\[
\text{Trans alkene}
\]
9. Electrophilic (and Markovnikov) Additions: Hydrohalogenation, Halogenation, and Hydration (Section 13-7)

\[
\begin{align*}

Important Concepts

1. The rules for naming alkynes are essentially the same as those formulated for alkenes. Molecules with both double and triple bonds are called alkenynes, the double bond receiving the lower number if both are at equivalent positions. Hydroxy groups are given precedence in numbering alkynyl alcohols (alkynols).

2. The electronic structure of the triple bond reveals two \(\pi\) bonds, perpendicular to each other, and a \(\sigma\) bond, formed by two overlapping \(sp\) hybrid orbitals. The strength of the triple bond is about 229 kcal mol\(^{-1}\); that of the alkylnyl C–H bond is 131 kcal mol\(^{-1}\). Triple bonds form linear structures with respect to other attached atoms, with short C–C (1.20 Å) and C–H (1.06 Å) bonds.

3. The high \(s\) character at C1 of a terminal alkyne makes the bound hydrogen relatively acidic (\(pK_a \approx 25\)).

4. The chemical shift of the alkylnyl hydrogen is low (\(\delta = 1.7–3.1\) ppm) compared with that of alkenyl hydrogens because of the shielding effect of an induced electron current around the molecular axis caused by the external magnetic field. The triple bond allows for long-range coupling. IR spectroscopy indicates the presence of the C–C and C–H bonds in terminal alkynes through bands at 2100–2260 cm\(^{-1}\) and 3260–3330 cm\(^{-1}\), respectively.

5. The elimination reaction with vicinal dihaloalkanes proceeds regioselectively and stereospecifically to give alkenyl halides.

6. Selective syn dihydrogenation of alkynes is possible with Lindlar catalyst, the surface of which is less active than palladium on carbon and therefore not capable of hydrogenating alkenes. Selective anti hydrogenation is possible with sodium metal dissolved in liquid ammonia because simple alkenes cannot be reduced by one-electron transfer. The stereochemistry is set by the greater stability of a trans disubstituted alkenyl radical intermediate.

7. Alkynes generally undergo the same addition reactions as alkenes; these reactions may take place twice in succession. Hydration of alkynes is unusual. It requires an Hg(II) catalyst, and the initial product, an enol, rearranges to a ketone by tautomerism.

8. To stop the hydroboration of terminal alkynes at the alkenylboron intermediate stage, modified dialkylboranes—particularly dicyclohexylborane—are used. Oxidation of the resulting alkenylboranes produces enols that tautomerize to aldehydes.

9. The Heck reaction links alkenes to alkenyl halides in a metal-catalyzed process.

Problems

27. Draw the structures of the molecules with the following names.
   (a) 1-Chloro-1-butyne  (b) (Z)-4-Bromo-3-methyl-3-penten-1-yne  (c) 4-Hexyn-1-ol

28. Name each of the compounds below, using the IUPAC system of nomenclature.

\[
\begin{align*}
(a) & \quad \begin{array}{c}
\text{Cl} \\
\text{CH}_2 = \text{CH} = \text{C} \\
\end{array} \\
(b) & \quad \begin{array}{c}
\text{OH} \\
\text{CH}_2 = \text{CH} = \text{C} \\
\end{array} \\
(c) & \quad \begin{array}{c}
\text{OH} \\
\text{CH}_2 = \text{CH} = \text{C} \\
\end{array} \\
(d) & \quad \begin{array}{c}
\text{CH}_3 \\
\text{CH}_2 = \text{CH} = \text{C} \\
\end{array} \\
(e) & \quad \begin{array}{c}
\text{CH}_3 \\
\text{CH}_2 = \text{CH} = \text{C} \\
\end{array} \\
(f) & \quad \text{C}_8H_{10} \\
\end{align*}
\]

29. Compare C–H bond strengths in ethane, ethene, and ethyne. Reconcile these data with hybridization, bond polarity, and acidity of the hydrogen.

30. Compare the C2–C3 bonds in propane, propene, and propyne. Should they be any different with respect to either bond length or bond strength? If so, how should they vary?

31. Predict the order of acid strengths in the following series of cationic species: CH\(_3\)CH\(_2\)NH\(_3^+\), CH\(_3\)CH=NH\(_3^+\), CH\(_3\)C=NH\(_3^+\). [Hint: Look for an analogy among hydrocarbons (Section 13-2).]
32. The heats of combustion for three compounds with the molecular formula C₅H₈ are as follows: cyclopentene, ΔHᶜᵒᵐᵇ = −1027 kcal mol⁻¹; 1,4-pentadiene, ΔHᶜᵒᵐᵇ = −1042 kcal mol⁻¹; and 1-pentyne, ΔHᶜᵒᵐᵇ = −1052 kcal mol⁻¹. Explain in terms of relative stability and bond strengths.

33. Rank in order of decreasing stability.
   (a) 1-Heptyne and 3-heptyne
   (b) \[ \text{structures} \]

(Hint: Make a model of the third structure. Is there anything unusual about its triple bond?)

34. Deduce structures for each of the following. (a) Molecular formula C₆H₁₀; NMR spectrum A; no strong IR bands between 2100 and 2300 or 3250 and 3350 cm⁻¹. (b) Molecular formula C₇H₁₂; NMR spectrum B; IR bands at about 2120 and 3330 cm⁻¹. (c) The percentage composition is 71.41% carbon and 9.59% hydrogen (the remainder is O), and the exact molecular mass is 84.0584; NMR and IR spectra C (next page). The inset in NMR spectrum C provides better resolution of the signals between 1.6 and 2.4 ppm.
35. The IR spectrum of 1,8-nonadiyne displays a strong, sharp band at 3300 cm\(^{-1}\). What is the origin of this absorption? Treatment of 1,8-nonadiyne with NaNH\(_2\), then with D\(_2\)O, leads to the incorporation of two deuterium atoms, leaving the molecule unchanged otherwise. The IR spectrum reveals that the peak at 3300 cm\(^{-1}\) has disappeared, but a new one is present at 2580 cm\(^{-1}\). (a) What is the product of this reaction? (b) What new bond is responsible for the IR absorption at 2580 cm\(^{-1}\)? (c) Using Hooke’s law, calculate the approximate expected position of this new band from the structure of the original molecule and its IR spectrum. Assume that \(k\) and \(f\) have not changed.

36. Write the expected product(s) of each of the following reactions.

(a) \(\text{CH}_3\text{CH}_2\text{CHCHCH}_2\text{Cl} \xrightarrow{3 \text{ NaNH}_2, \text{ liquid NH}_3} \text{Cl} \)

(b) \(\text{CH}_3\text{OCH}_2\text{CH}_2\text{CHCHCH}_3 \xrightarrow{2 \text{ NaNH}_2, \text{ liquid NH}_3} \text{Br Br} \)

(c) \(\text{meso-CH}_3\text{CHCH}_2\text{CHCHCH}_2\text{CHCH}_3 \xrightarrow{\text{NaOCH}_3, \text{(1 equivalent)}, \text{CH}_3\text{OH}} \text{Cl} \text{Cl} \text{Cl} \text{CH}_3 \)

(d) \(\text{(4R,5R)-CH}_3\text{CHCHCH}_2\text{CHCHCH}_2\text{CHCH}_3 \xrightarrow{\text{NaOCH}_3, \text{(1 equivalent)}, \text{CH}_3\text{OH}} \text{Cl} \text{Cl} \text{Cl} \text{CH}_3 \)
37. (a) Write the expected product of the reaction of 3-octyne with Na in liquid NH₃. (b) When the same reaction is carried out with cyclooctyne (Problem 33b), the product is cis-cyclooctene, not trans-cyclooctene. Explain, mechanistically.

38. Write the expected major product of reaction of 1-propynyllithium, CH₃C≡C⁻Li⁺, with each of the following molecules in THF.

(a) CH₃CH₂Br
(b) Cl
(c) Cyclohexanone
(d) O
(e) CH₃CH−CH₂
(f) O

39. Write the mechanism and final product for the reaction of 1-propynyllithium with trans-2,3-dimethyloxacyclop propane.

40. Which of the following methods is best suited as a high-yield synthesis of 2-methyl-3-hexyne, ?

(a) H, Lindlar's catalyst
(b) ClCl
(c) 1. Cl₂, CCl₄
2. NaNH₂, liquid NH₃
(d) Li/H₁₁₀₀₁₁
(e) Li/H₁₁₀₀₁₁

41. Propose reasonable syntheses of each of the following alkynes, using the principles of retrosynthetic analysis. Each alkyne functional group in your synthetic target should come from a separate molecule, which may be any two-carbon compound (e.g., ethyne, ethene, ethanal).

(a) O
(b) OH
(c) OH
(d) (CH₃)₃CC≡CH [Be careful! What is wrong with (CH₃)₃CCl + :C≡CH?]

42. Draw the structure of (R)-4-deuterio-2-hexyne. Propose a suitable retro-ŠN₂ precursor of this compound.

43. Reaction review. Without consulting the Reaction Road Map on p. 598, suggest reagents to convert a general alkyne RC≡CH into each of the following types of compounds.

(a) O
(b) O
(c) O
(Markovnikov product)
44. Give the expected major product of the reaction of propyne with each of the following reagents.

(a) D₂, Pd – CaCO₃, Pb(O₂CCH₃)₂, quinoline;
(b) Na, ND₃;
(c) 1 equivalent HI;
(d) 2 equivalents HI;
(e) 1 equivalent Br₂;
(f) 1 equivalent ICl;
(g) 2 equivalents ICl;
(h) H₂O, HgSO₄, H₂SO₄;
(i) dicyclohexylborane, then NaOH, H₂O₂.

45. What are the products of the reactions of dicyclohexylethyne with the reagents in Problem 44?

46. Write the structures of the initially formed enol tautomers in the reactions of propyne and dicyclohexylethyne with dicyclohexylborane followed by NaOH and H₂O₂ (Problems 44, part i, and 45, part i).

47. Give the products of the reactions of your first two answers to Problem 45 with each of the following reagents. (a) H₂, Pd – C, CH₃CH₂OH; (b) Br₂, CCl₄; (c) BH₃, THF, then NaOH, H₂O₂; (d) MCPBA, CH₂Cl₂; (e) OsO₄, then H₂S.

48. Propose several syntheses of cis-3-heptene, beginning with each of the following molecules. Note in each case whether your proposed route gives the desired compound as a major or minor final product. (a) 3-Chloroheptane; (b) 4-chloroheptane; (c) 3,4-dichloroheptane; (d) 3-heptanol; (e) 4-heptanol; (f) trans-3-heptene; (g) 3-heptyne.

49. Propose reasonable syntheses of each of the following molecules, using an alkyne at least once in each synthesis.

(a) Br Cl
(b) I I
(e) meso-2,3-Dibromobutane

(d) Racemic mixture of (2R,3R)- and (2S,3S)-2,3-dibromobutane

(e) Br Cl

(f) O

(g) OH

(h) O

(i)
50. Show how the Heck reaction might be employed to synthesize each of the following molecules.

(a) ![Structure](image1)

(b) ![Structure](image2)

51. Propose a reasonable structure for calcium carbide, CaC₂, on the basis of its chemical reactivity (Section 13-10). What might be a more systematic name for it?

52. Propose two different syntheses of linalool, a terpene found in cinnamon, sassafras, and orange flower oils. Start with the eight-carbon ketone shown here and use ethyne as your source of the necessary additional two carbons in both syntheses.

53. The synthesis of chamaecynone, the essential oil of the Benihí tree, requires the conversion of a chloroalcohol into an alkynyl ketone. Propose a synthetic strategy to accomplish this task.

54. **Challenge** Synthesis of the sesquiterpene bergamotene proceeds from the alcohol shown here. Suggest a sequence to complete the synthesis.

55. **Challenge** An unknown molecule displays ¹H NMR and IR spectra D (next page). Reaction with H₂ in the presence of the Lindlar catalyst gives a compound that, after ozonolysis and O treatment with Zn in aqueous acid, gives rise to one equivalent of CH₃CCH and two of HCH. What was the structure of the original molecule?

56. **Challenge** Formulate a plausible mechanism for the hydration of ethyne in the presence of mercuric chloride. (**Hint**: Review the hydration of alkenes catalyzed by mercuric ion, Section 12-7.)
57. A synthesis of the sesquiterpene farnesol requires the conversion of a dichloro compound into an alkynol, as shown below. Suggest a way of achieving this transformation. (Hint: Devise a conversion of the starting compound into a terminal alkyne.)
Team Problem
58. Your team is studying the problem of an intramolecular ring closure of enediyne systems important in the total synthesis of dynemicin A, which exhibits potent antitumor activity.

Dynemicin A

One research group tried the following approaches to effect this process. Unfortunately, all were unsuccessful. Divide the schemes among yourselves and assign structures to compounds A through D. (Note: \( R' \) and \( R'' \) are protecting groups.)

1. \( \text{CH}_3\text{O} \) \( \text{N} \) \( \text{CH}_3 \) \( \text{CH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{H} \) \( \text{LiNR}_2 \)
2. \( \text{R'}\) \( \text{R''} \) \( \text{N} \) \( \text{CH}_3 \) \( \text{CH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{H} \) \( \text{LiNR}_2 \) \( \text{R'}\) \( \text{R''} \) \( \text{N} \) \( \text{CH}_3 \) \( \text{CH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{H} \) \( \text{LiNR}_2 \)
3. \( \text{R'}\) \( \text{R''} \) \( \text{N} \) \( \text{CH}_3 \) \( \text{CH}_3 \) \( \text{Br} \) \( \text{OH} \) \( \text{OCH}_3 \) \( \text{OCH}_3 \) \( \text{H} \) \( \text{LiNR}_2 \)
A successful model study (shown here) provided an alternative strategy toward the completion of the total synthesis.

![Chemical diagram]

Discuss the advantages of this approach and apply it to the appropriate compound in approaches 1 through 3.

**Preprofessional Problems**

59. The compound whose structure is $\text{H} - \text{C} \equiv \text{C} - \text{C} - \text{Cl}$ is best named (IUPAC)
   (a) 4-chloro-1-pentyne; (b) 5-chloropent-1-yne; (c) 4-pentyne-1-chloroyn; (d) 1-chloropent-4-yne.

60. A nucleophile made by deprotonation of propyne is
   (a) $\equiv: \text{CH}_2 \text{CH}_3$; (b) $\equiv: \text{HC} \equiv \text{CH}_2$; (c) $\equiv: \text{C} \equiv \text{CH}$; (d) $\equiv: \text{C} \equiv \text{CCH}_3$;
   (e) $\equiv: \text{HC} \equiv \text{CCH}_3$.

61. When cyclooctyne is treated with dilute, aqueous sulfuric acid and HgSO$_4$, a new compound results. It is best represented as

   ![Chemical structures]

62. From the choices shown below, pick the one that best describes the structure of compound A.

   ![Chemical structures]
63. From the choices shown below, pick the one that best describes the structure of compound A.

```
Br    Br
CH₃C≡CCH₂OH \( \xrightarrow{\text{Br₂ (2 equivalents)}} \) A \( \xrightarrow{\text{H₂ (2 equivalents), Raney Ni}} \) 1-butanol
Br    Br

(A primary alcohol; 
\%C = 68.6, 
\%H = 8.6, and 
\%O = 22.9)
```

(a) CH₂=CHCH₂CH₂OH  (b) CH₃CH₂OH  (c) CH₃C≡CCH₂OH

d) CH₃CH=CH—CH=CHOH  (e) OH
We live in a universe of color. Our ability to perceive and distinguish thousands of hues and shades of color is tied to the ability of molecules to absorb different frequencies of visible light. In turn, this molecular property is frequently a consequence of the presence of multiple $\pi$ bonds.

In the preceding three chapters we introduced the topic of compounds containing carbon–carbon $\pi$ bonds, the products of overlap between two adjacent parallel $p$ orbitals. We found that addition reactions to these chemically versatile systems provided entries both to relatively simple products, of use in synthesis, and to more complex products, including polymers—substances that have affected modern society enormously. In this chapter we expand further on all these themes by studying compounds in which three or more parallel $p$ orbitals participate in $\pi$-type overlap. The electrons in such orbitals are therefore shared by three or more atomic centers and are said to be delocalized.

Our discussion begins with the 2-propenyl system—also called allyl—containing three interacting $p$ orbitals. We then proceed to compounds that contain several double bonds: dienes and higher analogs. These compounds give rise to some of the most widely used polymers in the modern world, found in everything from automobile tires to the plastic cases around the computers used to prepare the manuscript for this textbook.

The special situation of alternating double and single bonds gives rise to conjugated dienes, trienes, and so forth, possessing more extended delocalization of their $\pi$ electrons. These substances illustrate new modes of reactivity, including thermal and photochemical cycloadditions and ring closures, which are among the most powerful methods for the synthesis of cyclic compounds such as steroidal pharmaceuticals. These processes exemplify a fundamentally new class of mechanisms: pericyclic reactions, which is the last type of mechanism we shall consider.

$\beta$-Carotene is a pigment that is important for photosynthesis. It is part of the general family of carotenoids, produced in nature to the tune of 100 million tons per year and responsible for the orange color of carrots and many other fruits and vegetables. Its color is due to the presence of 11 contiguous double bonds, which cause the absorption of visible light.

\[ \text{Allylic radical} \quad \text{Conjugated diene} \]
in this book. Following this chapter, we take the opportunity in an Interlude to review all the major types of organic processes covered in this course. We conclude the chapter itself with a discussion of light absorption by molecules with delocalized $\pi$ systems. This process forms the basis of ultraviolet and visible spectroscopy.

14-1 Overlap of Three Adjacent $\rho$ Orbitals: Electron Delocalization in the 2-Propenyl (Allyl) System

What is the effect of a neighboring double bond on the reactivity of a carbon center? Three key observations answer this question.

**Observation 1.** The primary carbon–hydrogen bond in propene is relatively weak, only 87 kcal mol$^{-1}$.

\[
\begin{align*}
\text{Propene} & & \hspace{1cm} 2\text{-Propenyl radical} \\
\text{H}_2\text{C} &\equiv & \text{C} &\equiv & \text{H} & \rightarrow & \text{H}_2\text{C} &\equiv & \text{C} &\equiv & \text{H} + & \text{H} & \cdot \hspace{1cm} D\text{H}^\circ = 87 \text{ kcal mol}^{-1}
\end{align*}
\]

A comparison with the values found for other hydrocarbons (see margin) shows that it is even weaker than a tertiary C–H bond. Evidently, the 2-propenyl radical enjoys some type of special stability.

**Observation 2.** In contrast with saturated primary haloalkanes, 3-chloropropene dissociates relatively fast under S$_{N}$1 (solvolysis) conditions and undergoes rapid unimolecular substitution through a carbocation intermediate.

This finding clearly contradicts our expectations (recall Section 7-5). *It appears that the cation derived from 3-chloropropene is somehow more stable than other primary carbocations.* By how much? The ease of formation of the 2-propenyl cation in solvolysis reactions has been found to be roughly equal to that of a secondary carbocation.

**Observation 3.** The $pK_a$ of propene is about 40.

\[
\begin{align*}
\text{H}_2\text{C} &\equiv & \text{C} &\equiv & \text{H} & \rightleftharpoons & K = 10^{-40} & \text{H}_2\text{C} &\equiv & \text{C} &\equiv & \text{H} + & \text{H}^+ \\
\text{2-Propenyl anion} & & & & & & & & 2\text{-Propenyl cation}
\end{align*}
\]

Thus, propene is considerably more acidic than propane ($pK_a \approx 50$), and *the formation of the propenyl anion by deprotonation appears to be unusually favored.*

How can we explain these three observations?

**Delocalization stabilizes 2-propenyl (allyl) intermediates**

Each of the preceding three processes generates a reactive carbon center—a radical, a carbocation, or a carbanion, respectively—that is adjacent to the $\pi$ framework of a double bond. This arrangement seems to impart special stability. Why? The reason is electron delocalization: Each species may be described by a pair of equivalent contributing resonance forms (Section 1-5). These three-carbon intermediates have been given the name *allyl* (followed by the appropriate term: radical, cation, or anion). The activated carbon is called *allylic.*
Resonance Representation of Delocalization in the 2-Propenyl (Allyl) System

The 2-propenyl (allyl) \( \pi \) system is represented by three molecular orbitals. The stabilization of the 2-propenyl (allyl) system by resonance can also be described in terms of molecular orbitals. Each of the three carbons is \( sp^2 \) hybridized and bears a \( p \) orbital perpendicular to the molecular plane (Figure 14-1).

\[
\text{ Radical: } \quad [\text{CH}_2\equiv\text{CH}^\bullet\text{CH}_2] \quad \leftrightarrow \quad \text{ Cation: } \quad [\text{CH}_2\equiv\text{CH}^+\text{CH}_2] \quad \leftrightarrow \quad \text{ Anion: } \quad [\text{CH}_2\equiv\text{CH}^-\text{CH}_2]
\]

**Figure 14-1** The three \( p \) orbitals in the 2-propenyl (allyl) group overlap, giving a symmetric structure with delocalized electrons. The \( \sigma \) framework is shown as black lines.

Ignoring the \( \sigma \) framework, we can combine the three \( p \) orbitals mathematically to give three \( \pi \) molecular orbitals. This process is analogous to mixing two atomic orbitals to give two molecular orbitals describing a \( \pi \) bond (Figures 11-2 and 11-4), except that there is now a third atomic orbital. Of the three resulting molecular orbitals, shown in Figure 14-2, one (\( \pi_1 \)) is bonding and has no nodes, one (\( \pi_2 \)) is nonbonding (in other words, it has the same energy as a noninteracting \( p \) orbital) and has one node, and one (\( \pi_3 \)) is antibonding, with two nodes. We can use the Aufbau principle to fill up the \( \pi \) molecular orbitals with the appropriate number of electrons for the 2-propenyl cation, radical, and anion (Figure 14-3).

**Figure 14-2** The three \( \pi \) molecular orbitals of 2-propenyl (allyl), obtained by combining the three adjacent atomic \( p \) orbitals.

**Figure 14-3** The Aufbau principle is used to fill up the \( \pi \) molecular orbitals of 2-propenyl (allyl) cation, radical, and anion. In each case, the total energy of the \( \pi \) electrons is lower than that of three noninteracting \( p \) orbitals. Partial cation, radical, or anion character is present at the end carbons in these systems, a result of the location of the lobes in the \( \pi_2 \) molecular orbital.

Remember that resonance forms are not isomers but partial molecular representations. The true structure (the resonance hybrid) is derived by their superposition, better represented by the dotted-line drawings at the right of the classical picture.
The cation, with a total of two electrons, contains only one filled orbital, $\pi_1$. For the radical and the anion, we place one or two additional electrons, respectively, into the nonbonding orbital, $\pi_2$. The total $\pi$-electron energy of each system is lower (more favorable) than that expected from three noninteracting $p$ orbitals—because $\pi_1$ is greatly stabilized and filled with two electrons in all cases, whereas the antibonding level, $\pi_3$, stays empty throughout.

The resonance formulations for the three 2-propenyl species indicate that it is mainly the two terminal carbons that accommodate the charges in the ions or the odd electron in the radical. The molecular-orbital picture is consistent with this view: The three structures differ only in the number of electrons present in molecular orbital $\pi_2$, which possesses a node passing through the central carbon; therefore, very little of the electron excess or deficiency will show up at this position. The electrostatic potential maps of the three 2-propenyl systems show their delocalized nature. (The cation and anion have been rendered at an attenuated scale to tone down the otherwise overwhelming intensity of color). To some extent, especially in the cation and anion, you can also discern the relatively greater charge density at the termini. Remember that these maps take into account all electrons in all orbitals, $\sigma$ and $\pi$.

**Partial Electron Density Distribution in the 2-Propenyl ( Allyl) System**

In Summary  Allylic radicals, cations, and anions are unusually stable. In Lewis terms, this stabilization is readily explained by electron delocalization. In a molecular-orbital description, the three interacting $p$ orbitals form three new molecular orbitals: One is considerably lower in energy than the $p$ level, another one stays the same, and a third is higher in energy. Because only the first two are populated with electrons, the total $\pi$ energy of the system is lowered.

**14-2 Radical Allylic Halogenation**

A consequence of delocalization is that resonance-stabilized allylic intermediates can readily participate in reactions of unsaturated molecules. For example, although halogens can add to alkenes to give the corresponding vicinal dihalides (Section 12-5) by an ionic mechanism, the course of this reaction is changed with added radical initiators (or on irradiation) and with the halogen present only in low concentrations. These conditions slow the ionic addition pathway sufficiently to allow a faster radical chain mechanism to take over, leading to radical allylic substitution.*

*A complete explanation for this change requires a detailed kinetic analysis that is beyond the scope of this book. Suffice it to say that at low bromine concentrations the competing addition processes are reversible, and allylic substitution wins out.
Radical Allylic Halogenation

\[
\text{CH}_2=\text{CHCH}_3 \quad \xrightarrow{\text{X}_2 \text{ (low conc.)}, \text{ROOR or } h\nu} \quad \text{CH}_2=\text{CHCH}_2\text{X} + \text{HX}
\]

A reagent that is frequently used in allylic brominations in the laboratory is \(N\)-bromobutanimide (\(N\)-bromosuccinimide, NBS) suspended in tetrachloromethane. This species is nearly insoluble in CCl\(_4\) and is a steady source of very small amounts of bromine formed by reaction with trace impurities of HBr (see margin).

**NBS as a Source of Bromine**

\[
\begin{align*}
\text{H}_2\text{C} & \text{C} \quad \text{N} \quad \text{Br} & + \quad \text{HBr} & \quad \rightleftharpoons & \quad \text{H}_2\text{C} & \text{C} \quad \text{NH} & + \quad \text{Br}_2 \\
\text{N}-\text{Bromobutanimide} & \quad \text{(N-Bromosuccinimide, NBS)} & & & & & \\
\end{align*}
\]

For example, NBS converts cyclohexene to 3-bromocyclohexene.

\[
\text{Cyclohexene} + \quad \text{NBr} & \quad \xrightarrow{\text{hv, CCl}_4} & \quad \text{3-Bromocyclohexene} \\
& & & & & & & & 85\%
\]

The bromine reacts with the alkene by a radical chain mechanism (Section 3-4). The process is initiated by light or by traces of radical initiators that cause dissociation of Br\(_2\) into bromine atoms. Propagation of the chain involves abstraction of a weakly bound allylic hydrogen by Br\(^{-}\).

**Mechanism of Allylic Bromination**

**Initiation step**

\[
\begin{align*}
\text{Br} & \quad + \quad \text{Br} & \quad \stackrel{\text{hv}}{\rightarrow} & \quad 2 \quad \text{Br}^{-} \\
\end{align*}
\]

**Propagation steps**

\[
\begin{align*}
\text{R} & \quad \text{R} & \quad + & \quad \text{Br}^{-} & \quad \xrightarrow{\text{H Abstraction}} & \quad \left[ \quad \text{R} \quad \text{R} \quad \leftrightarrow \quad \text{R} \quad \text{R} \quad \right] & + & \quad \text{H} & \quad \text{Br}^{-} \\
\text{DHF}^* & = 87 \text{ kcal mol}^{-1} & \quad & & & & & & \quad & & \quad & \\
\end{align*}
\]

**Allylic Radical**

\[
\begin{align*}
\text{R} \quad \text{R} & \quad \leftrightarrow \quad \text{R} \quad \text{R} & \quad + & \quad \text{Br}^{-} & \quad \text{Br}^{-} & \quad \rightarrow \quad \text{R} \quad \text{R} & \quad + \quad \text{Br}^{-} \\
\end{align*}
\]

The resonance-stabilized radical may then react with Br\(_2\) at either end of the allylic system to furnish an allylic bromide and regenerate Br\(^{-}\), which continues the chain. Thus, alkenes
that form unsymmetric allylic radicals can give mixtures of products upon treatment with NBS. For example,

\[
\text{CH}_2\equiv\text{CH}(\text{CH}_2)_5\text{CH}_3 \xrightarrow{\text{NBS, ROOR, HBr}} \left\{ \begin{array}{l}
\text{CH}_2\equiv\text{CHCH}(\text{CH}_2)_4\text{CH}_3 \\
\text{Br}_2 \quad \text{(from NBS)}
\end{array} \right. \\
\text{Br} \quad \text{(from NBS)} \\
\text{Br}_2
\]

\[
\text{CH}_2\equiv\text{CHCH}(\text{CH}_2)_4\text{CH}_3 \quad 28\% \\
\text{BrCH}_2\text{CHCH}(\text{CH}_2)_4\text{CH}_3 \quad 72\% \\
\text{3-Bromo-1-octene} \quad \text{1-Bromo-2-octene} \\
\text{(Mixture of cis and trans)}
\]

**Exercise 14-1**

Ignoring stereochemistry, give all the isomeric monobromoheptenes that are possible from NBS treatment of trans-2-heptene.

Allylic chlorinations are important in industry because chlorine is relatively cheap. For example, 3-chloropropene (allyl chloride) is made commercially by the gas-phase chlorination of propene at 400°C. It is a building block for the synthesis of epoxy resin and many other useful substances.

\[
\text{CH}_3\text{CH} \equiv \text{CH}_2 + \text{Cl}_2 \xrightarrow{400\degree C} \text{ClCH}_2\text{CH} \equiv \text{CH}_2 + \text{HCl}
\]

**Exercise 14-2**

Predict the outcome of the allylic monochlorination of the following substrates.

(a) Cyclohexene  (b)  (c) 1-Methylcyclohexene

The biochemical degradation of unsaturated molecules frequently involves radical abstraction of allylic hydrogens by oxygen-containing species. Such processes will be discussed in Section 22-9.

**In Summary** Under radical conditions, alkenes containing allylic hydrogens enter into allylic halogenation. A particularly good reagent for allylic bromination is \(N\)-bromobutanimide (\(N\)-bromosuccinimide, NBS).

**14-3 Nucleophilic Substitution of Allylic Halides: \(S_N1\) and \(S_N2\)**

As our example of 3-chloropropene in Section 14-1 shows, allylic halides dissociate readily to produce allylic cations. These can be trapped at either end by nucleophiles in \(S_N1\) reactions. Allylic halides also readily undergo \(S_N2\) transformations.

**Allylic halides undergo \(S_N1\) reactions**

The ready dissociation of allylic halides has important chemical consequences. Different allylic halides may give identical products upon solvolysis if they dissociate to the same
allylic cation. For example, the hydrolysis of either 1-chloro-2-butene or 3-chloro-1-butene results in the same alcohol mixture. The reason is that the same allylic cation is the intermediate.

**Hydrolysis of Isomeric Allylic Chlorides**

\[
\begin{align*}
\text{CH}_3\text{CH}=&\text{CHCH}_2\text{Cl} & \text{Dissociation} & \rightarrow & \begin{cases}
\text{CH}_3\text{CH}=&\text{CHCH}_2^+ \\
\text{CH}_3\text{CH}=&\text{CH}_2
\end{cases} \\
\text{1-Chloro-2-butene} & \quad \text{Allylic cation} & \quad \text{3-Chloro-1-butene}
\end{align*}
\]

Nucleophilic trapping

\[
\begin{align*}
\text{CH}_3\text{CH}=&\text{CHCH}_2\text{OH} & + & \text{CH}_3\text{CH}=&\text{CH}_2 + \text{H}^+ \\
\text{2-Buten-1-ol} & \quad & \quad & \quad \text{3-Buten-2-ol}
\end{align*}
\]

**Exercise 14-3**

Hydrolysis of (R)-3-chloro-1-butene gives racemic 3-buten-2-ol in addition to 2-buten-1-ol. Explain. (Hint: Review Section 7-3.)

**Exercise 14-4**

**Working with the Concepts: Allylic Alcohols and Acid**

Treatment of 3-buten-2-ol with cold hydrogen bromide gives 1-bromo-2-butene and 3-bromo-1-butene. Explain by a mechanism.

**Strategy**

First we convert the text problem into a balanced equation. Then we examine the structure of 3-buten-2-ol, identifying its functional groups. Subsequently we consider the reaction conditions and decide how they will affect these functional groups, either individually or together.

**Solution**

- CH₃CHCH=CH₂ + HBr → CH₃CHCH=CH₂ + CH₃CH=CHCH₂Br + H₂O
- 3-Buten-2-ol is a secondary and allylic alcohol.
- Recall (Section 9-2) that alcohols are protonated in the presence of strong acids and that, depending on structure, the resulting oxonium ions can react by S_N2 or S_N1 pathways. In the present case, clearly an S_N1 reaction is indicated.
- The resonance-stabilized allylic cation is trapped by bromide at either of the two allylic termini, producing the observed products.
Allylic halides can also undergo $S_N2$ reactions

$S_N2$ reactions of allylic halides with good nucleophiles (Section 6-8) are faster than those of the corresponding saturated haloalkanes. Two factors contribute to this acceleration. One is that the allylic carbon is attached to a relatively electron-withdrawing $sp^2$ hybridized carbon (as opposed to $sp^3$; Section 13-2), making it more electrophilic. The second is that overlap between the double bond and the $p$ orbital in the transition state of the $S_N2$ displacement (see Figure 6-4) is stabilizing, resulting in a relatively low activation barrier.

**The $S_N2$ Reactions of 3-Chloro-1-propene and 1-Chloropropane**

\[
\text{CH}_2\text{C}=\text{CHCH}_2\text{Cl} + \text{I}^- \xrightarrow{\text{Acetone, 50°C}} \text{CH}_2\text{C}=\text{CHCH}_2\text{I} + \text{Cl}^- \quad 73
\]

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{Cl} + \text{I}^- \xrightarrow{\text{Acetone, 50°C}} \text{CH}_3\text{CH}_2\text{CH}_2\text{I} + \text{Cl}^- \quad 1
\]

**Exercise 14-6**

The solvolysis of 3-chloro-3-methyl-1-butene in acetic acid at $25^\circ$C gives initially a mixture containing mostly the structurally isomeric chloride with some of the acetate. After a longer period of time, no allylic chloride remains and the acetate is the only product present. Explain this result.

**In Summary** Allylic halides undergo both $S_N1$ and $S_N2$ reactions. The allylic cation intermediate of the $S_N1$ reaction may be trapped by nucleophiles at either terminus, leading to product mixtures in the case of unsymmetrical systems. With good nucleophiles, allylic halides undergo $S_N2$ reaction more rapidly than the corresponding saturated substrates.

**14-4 Allylic Organometallic Reagents: Useful Three-Carbon Nucleophiles**

Propene is appreciably more acidic than propane because of the relative stability of the conjugated carbanion that results from deprotonation (Section 14-1). Therefore, allylic lithium reagents can be made from propene derivatives by proton abstraction by an alkyllithium. The process is facilitated by $N,N',N''$-tetramethylethane-1,2-diamine (tetramethylethlenediamine, TMEDA), a good solvating agent.
Allylic Deprotonation

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Li} + \text{H}_2\text{C}==\text{C}==\text{C}==\text{C}_2\text{Li} \rightarrow \text{H}_2\text{C}==\text{C}==\text{C}_2\text{Li} + \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{H} \]

Another way of producing an allylic organometallic is Grignard formation. For example,

\[ \text{CH}_2==\text{CHCH}_2\text{Br} \underset{\text{Mg, THF, } 0^\circ \text{C}}{\rightarrow} \text{CH}_2==\text{CHCH}_2\text{MgBr} \]

Like their alkyl counterparts (Section 8-8), allylic lithium and Grignard reagents can react as nucleophiles. This is useful, because the embedded double bond allows for further functional-group transformations (Chapter 12).

**Exercise 14-7**

Show how to accomplish the following conversion in as few steps as possible. (Hint: Allylic organometallic compounds react with ketones in the same manner as ordinary organometallic reagents.)

In Summary  Alkenes tend to be deprotonated at the allylic position, a reaction resulting in the corresponding delocalized anions. Allylic lithium or Grignard reagents can be made from the corresponding halides. Like their alkyl analogs, allyl organometallics function as nucleophiles.

**14-5 Two Neighboring Double Bonds: Conjugated Dienes**

Now that we have caught a glimpse of the consequences of delocalization over three atoms, it should be interesting to learn what happens if we go one step further. Let us consider the addition of a fourth \( p \) orbital, which results in two double bonds separated by one single bond: a **conjugated diene** (*conjugatio*, Latin, union). In these compounds, delocalization again results in stabilization, as measured by heats of hydrogenation. Extended \( \pi \) overlap is also revealed in their molecular and electronic structures and in their chemistry.

**Hydrocarbons with two double bonds are named dienes**

Conjugated dienes have to be contrasted with their **nonconjugated** isomers, in which the two double bonds are separated by saturated carbons, and the **allenes** (or **cumulated** dienes), in which the \( \pi \) bonds share a single \( sp \) hybridized carbon and are perpendicular to each other (Figure 14-4). You can see the contrasting \( \pi \)-electron distribution in conjugated and nonconjugated dienes in the electrostatic potential maps in the margin. In 1,3-butadiene, the regions of \( \pi \)-electron density (red) overlap, while in 1,4-pentadiene they are separated by a methylene group devoid of \( \pi \) electrons. In 1,2-propadiene (allene), these electrons are close, but are located in orthogonal (perpendicular) regions of space.

The names of conjugated and nonconjugated dienes are derived from those of the alkenes in a straightforward manner. The longest chain incorporating both double bonds is
Conjugated dienes are more stable than nonconjugated dienes

The preceding sections noted that delocalization of electrons makes the allylic system especially stable. Does a conjugated diene have the same property? If so, that stability should be manifest in its heat of hydrogenation. We know that the heat of hydrogenation of a terminal alkene is about \(-30\) kcal mol\(^{-1}\) (see Section 11-5). A compound containing two noninteracting (i.e., separated by one or more saturated carbon atoms) terminal double bonds should exhibit a heat of hydrogenation roughly twice this value, about \(-60\) kcal mol\(^{-1}\). Indeed, catalytic hydrogenation of either 1,5-hexadiene or 1,4-pentadiene releases just about that amount of energy.

Exercise 14-8

Suggest names or draw structures, as appropriate, for the following compounds.

(a)  
\[
\begin{array}{c}
\text{Br} \\
\end{array}
\]

(b)  
\[
\begin{array}{c}
\text{H}_3C \\
\end{array}
\]

(c) cis-3,6-Dimethyl-1,4-cyclohexadiene  
(d) cis,cis-1,4-Dibromo-1,3-butadiene

Conjugated dienes are more stable than nonconjugated dienes

The preceding sections noted that delocalization of electrons makes the allylic system especially stable. Does a conjugated diene have the same property? If so, that stability should be manifest in its heat of hydrogenation. We know that the heat of hydrogenation of a terminal alkene is about \(-30\) kcal mol\(^{-1}\) (see Section 11-5). A compound containing two noninteracting (i.e., separated by one or more saturated carbon atoms) terminal double bonds should exhibit a heat of hydrogenation roughly twice this value, about \(-60\) kcal mol\(^{-1}\). Indeed, catalytic hydrogenation of either 1,5-hexadiene or 1,4-pentadiene releases just about that amount of energy.
Heat of Hydrogenation of Nonconjugated Alkenes

\[ \text{CH}_3\text{CH} = \text{CH}_2 + \text{H}_2 \xrightarrow{\text{Pt}} \text{CH}_3\text{CH}_2\text{CH}_3 \quad \Delta H^\circ = -30.3 \text{ kcal mol}^{-1} \quad (-127 \text{ kJ mol}^{-1}) \]

\[ \text{CH}_2=\text{CHCH}_2\text{CH} = \text{CH}_2 + 2 \text{H}_2 \xrightarrow{\text{Pt}} \text{CH}_3(\text{CH}_2)_2\text{CH}_3 \quad \Delta H^\circ = -60.5 \text{ kcal mol}^{-1} \quad (-253 \text{ kJ mol}^{-1}) \]

\[ \text{CH}_2=\text{CHCH}_2\text{CH} = \text{CH}_2 + 2 \text{H}_2 \xrightarrow{\text{Pt}} \text{CH}_3(\text{CH}_2)_3\text{CH}_3 \quad \Delta H^\circ = -60.8 \text{ kcal mol}^{-1} \quad (-254 \text{ kJ mol}^{-1}) \]

When the same experiment is carried out with the conjugated diene, 1,3-butadiene, less energy is produced.

Heat of Hydrogenation of 1,3-Butadiene

\[ \text{CH}_2=\text{CH} = \text{CH} = \text{CH}_2 + 2 \text{H}_2 \xrightarrow{\text{Pt}} \text{CH}_3\text{CH} = \text{CHCH}_2\text{CH}_3 \quad \Delta H^\circ = -57.1 \text{ kcal mol}^{-1} \quad (-239 \text{ kJ mol}^{-1}) \]

The difference, about 3.5 kcal mol\(^{-1}\) (15 kJ mol\(^{-1}\)), is due to a stabilizing interaction between the two double bonds, as illustrated in Figure 14-5.

Exercise 14-9

The heat of hydrogenation of trans-1,3-pentadiene is \(-54.2\) kcal mol\(^{-1}\), 6.6 kcal mol\(^{-1}\) less than that of 1,4-pentadiene, even lower than that expected from the stabilizing energy of 1,3-butadiene. Explain. (Hint: See Section 11-5.)

Conjugation in 1,3-butadiene results from overlap of the \(\pi\) bonds

How do the two double bonds in 1,3-butadiene interact? The answer lies in the alignment of their \(\pi\) systems, an arrangement that permits the \(p\) orbitals on C2 and C3 to overlap (Figure 14-6A). The \(\pi\) interaction that results is weak but nevertheless amounts to a few kilocalories per mole because the \(\pi\) electrons are delocalized over the system of four \(p\) orbitals.

Besides adding stability to the diene, this \(\pi\) interaction also raises the barrier to rotation about the single bond to more than 6 kcal mol\(^{-1}\) (25 kJ mol\(^{-1}\)). An inspection of models shows that the molecule can adopt two possible extreme coplanar conformations. In one, designated \(s\)-cis, the two \(\pi\) bonds lie on the same side of the C2–C3 axis; in the other, called \(s\)-trans, the \(\pi\) bonds are on opposite sides (Figure 14-6B). The prefix \(s\) refers to the fact that the bridge between C2 and C3 constitutes a single bond. The \(s\)-cis form is almost
Chapter 14
Delocalized Pi Systems

3 kcal mol\(^{-1}\) (12.5 kJ mol\(^{-1}\)) less stable than the \(s\)-trans conformation because of the steric interference between the two hydrogens on the inside of the diene unit.*

Exercise 14-10
The dissociation energy of the central C–H bond in 1,4-pentadiene is only 77 kcal mol\(^{-1}\). Explain. (Hint: See Sections 14-1 and 14-2 and draw the product of H atom abstraction.)

The \(\pi\)-electronic structure of 1,3-butadiene may be described by constructing four molecular orbitals out of the four \(p\) atomic orbitals (Figure 14-7).

*The \(s\)-cis conformation is very close in energy to a nonplanar conformation in which the two double bonds are gauche (Section 2-8). Whether the \(s\)-cis or the gauche conformation is more stable remains a subject of controversy.
In Summary  Dienes are named according to the rules formulated for ordinary alkenes. Conjugated dienes are more stable than dienes containing two isolated double bonds, as measured by their heats of hydrogenation. Conjugation is manifested in the molecular structure of 1,3-butadiene, which has a relatively short central carbon–carbon bond with a small barrier to rotation of more than 6 kcal mol\(^{-1}\) (25 kJ mol\(^{-1}\)). The two conformers, \(s\)-trans and \(s\)-cis, differ in energy by about 3 kcal mol\(^{-1}\) (12.5 kJ mol\(^{-1}\)). The molecular-orbital picture of the \(\pi\) system in 1,3-butadiene shows two bonding and two antibonding orbitals. The four electrons are placed in the first two bonding levels.

14-6 Electrophilic Attack on Conjugated Dienes: Kinetic and Thermodynamic Control

Does the structure of conjugated dienes affect their reactivity? Although more stable thermodynamically than dienes with isolated double bonds, conjugated dienes are actually more reactive kinetically in the presence of electrophiles and other reagents. 1,3-Butadiene, for example, readily adds 1 mol of cold hydrogen bromide. Two isomeric addition products are formed: 3-bromo-1-butene and 1-bromo-2-butene.

\[
\text{CH}_2\text{=CH—CH—CH}_2 + \text{HBr} \rightarrow 0^\circ\text{C} \quad \text{HCH}_2\text{—CH—CH=CH}_2 + \text{HCH}_2\text{—CH—CH—CH}_2
\]

\[
\begin{array}{c}
\text{3-Bromo-1-butene} \\
70\%
\end{array} \quad \begin{array}{c}
\text{1-Bromo-2-butene} \\
30\%
\end{array}
\]

The generation of the first product is readily understood in terms of ordinary alkene chemistry. It is the result of a Markovnikov addition to one of the double bonds. But what about the second product?

The presence of 1-bromo-2-butene is explained by the reaction mechanism. Initial protonation at C1 gives the thermodynamically most favored allylic cation.

Protonation of 1,3-Butadiene

This cation can be trapped by bromide in two possible ways to form the two observed products: At the terminal carbon, it yields 1-bromo-2-butene; and, at the internal carbon, it furnishes 3-bromo-1-butene. The 1-bromo-2-butene is said to result from \(1,4\)-addition of hydrogen bromide to butadiene, because reaction has taken place at C1 and C4 of the original diene. The other product arises by the normal 1,2-addition.

Nucleophilic Trapping of the Allylic Cation Formed on Protonation of 1,3-Butadiene

Many electrophilic additions to dienes give rise to product mixtures by both modes of addition, because of the intermediacy of allylic cations. For example, the bromination
Chapter 14
Delocalized Pi Systems

"Face-to-Face" Interaction of Two Double Bonds

We have seen that the $\pi$ interaction in conjugated dienes results in a small stabilization by delocalization of electrons (Section 14-5). In these systems, the two double bonds are neighbors, and orbital interaction occurs across the connecting single bond. After this effect had been established, an interesting question was posed by organic chemists: What sort of interaction can we expect if we force two double bonds to come face to face to each other?

The molecule designed to probe this question was D, synthesized from the highly strained A as shown. Thus, A is so reactive that it undergoes dimerization at 55°C, first to the diradical B, which then ring-closes to C. This species is not isolable, but spontaneously cleaves the newly formed four-membered ring, now in the opposite direction, to give D.

Diene D is reasonably stable at ambient temperature, but it decomposes eventually. Nevertheless, an X-ray structural analysis (Section 5-3) gave details of its carbon scaffold, which, as shown in the molecular model, is quite distorted. For starters, the substituent carbons to the double bonds are bent away from the $\pi$ bond by 27°. Moreover, the double bond is longer (1.354 Å) than normal (1.330 Å; Figure 11-1), and so are the bridging $C_{sp^3}-C_{sp^3}$ linkages, 1.596 Å (normal value is 1.54 Å; Figure 2-4). The distance between the two double bonds is 2.395 Å. Two ethenes attracted by London forces (Figure 2-6C) would be expected to get as close as 3.4 Å (as in graphite, see Chemical Highlight 15-1), hence the carbon frame in D does enforce a face-to-face interaction, as designed.

Is the $\pi-\pi$ interaction in D stabilizing? The answer is complicated, because of the molecular distortions caused by the unusual carbon connectivity and because there is some (weak) hyperconjugation (Section 3-2) of the $\pi$ orbitals with the adjacent $\sigma$ bonds. Nevertheless, calculations and spectroscopic measurements indicate that while there is some delocalization, electron repulsion seems to be dominant. Two double bonds appear to dislike staring into each others’ ($\pi$) faces.

of 1,3-butadiene proceeds through the (bromomethyl) allylic cation, instead of the cyclic bromonium ion encountered for normal alkenes (Section 12-5; see also Exercise 14-13).

$$\text{CH}_2=\text{CH} \rightarrow \text{CH} \rightarrow \text{CH}_2 + \text{Br} \rightarrow \text{Br}$$

$$\text{CH}_2=\text{CH} \rightarrow \text{CH} \rightarrow \text{CH}_2 + \text{CH}_2 \rightarrow \text{Br} \rightarrow \text{Br}$$

54% 3,4-Dibromo-1-butene

46% 1,4-Dibromo-2-butene
Conjugated dienes also function as monomers in polymerizations induced by electrophiles, radicals, and other initiators (see Sections 12-14 and 12-15) and, as such, will be discussed in Section 14-10.

Exercise 14-11

Conjugated dienes can be made by the methods applied to the preparation of ordinary alkenes. Propose syntheses of (a) 2,3-dimethylbutadiene from 2,3-dimethyl-1,4-butanediol; (b) 1,3-cyclohexadiene from cyclohexane.

Exercise 14-12

Write the products of 1,2-addition and 1,4-addition of (a) HBr and (b) DBr to 1,3-cyclohexadiene. (Caution: What is unusual about the products of 1,2- and 1,4-addition of HX to unsubstituted cyclic 1,3-dienes?)

Changing product ratios: kinetic and thermodynamic control

When the hydrobromination of 1,3-butadiene is carried out at 40°C rather than 0°C, a curious result is obtained: Instead of the original 70:30 mixture of 1,2- and 1,4-adducts, we now observe a 15:85 ratio of the corresponding bromobutenes:

**Hydrobromination of 1,3-Butadiene at 0°C: Kinetic Control**

\[
\text{CH}_2\equiv\text{CH}—\text{CH}=\text{CH}_2 + \text{HBr} \rightarrow \overset{0°C}{\text{HCH}_2—\text{CH}—\text{CH}—\text{CH}_2 \quad \text{Br}} \quad \overset{30\%}{\text{3-Bromo-1-butene}} \quad \overset{70\%}{\text{1-Bromo-2-butene}} \quad \text{More} \quad \text{Less}
\]

**Hydrobromination of 1,3-Butadiene at 40°C: Thermodynamic Control**

\[
\text{CH}_2\equiv\text{CH}—\text{CH}=\text{CH}_2 + \text{HBr} \rightarrow \overset{40°C}{\text{HCH}_2—\text{CH}—\text{CH}—\text{CH}_2 \quad \text{Br}} \quad \overset{85\%}{\text{1-Bromo-2-butene}} \quad \overset{15\%}{\text{3-Bromo-1-butene}} \quad \text{More} \quad \text{Less}
\]

This ratio of bromides is obtained also by simply heating the initial 70:30 mixture or, more strikingly, either one of the pure isomers. How can this be explained?

To understand these results, we have to go back to what we discussed in Section 2-1 regarding the kinetics and thermodynamics, or the rates and equilibria, that govern the outcome of reactions. From our observations, it is clear that at the higher temperature the two isomers are in equilibrium, their ratio reflecting their relative thermodynamic stability: 1-bromo-2-butene (with its internal double bond; Section 11-5) is a bit more stable than 3-bromo-1-butene. In general, a reaction whose ratio of products reflects their thermodynamic stability is said to be under thermodynamic control. Such is the case in the hydrobromination of 1,3-butadiene at 40°C.

What is happening at 0°C? At that temperature, the two isomers are not interconverting and, hence, thermodynamic control is not attained. What, then, is the origin of the nonthermodynamic ratio? The answer lies in the relative rates at which the two products are generated from the intermediate allylic cation (drawn as the central starting point of the
scheme below): 3-Bromo-1-butene, although thermodynamically less stable, is formed faster than 1-bromo-2-butene. In general, a reaction whose ratio of products reflects their relative rates of formation (hence, the relative heights of the respective activation barriers) is said to be under kinetic control. Such is the case in the hydrobromination of 1,3-butadiene at 0°C.

A potential energy diagram of our reaction (Figure 14-8) illustrates the lower activation barrier (and larger rate $k_1$) associated with the formation of the less stable product and the higher barrier (and lower rate $k_2$) leading to its more stable counterpart. The crucial feature is the reversibility (rate $k_2$) of the kinetic step of trapping the intermediate cation. At 0°C, the less stable, kinetic 3-bromo-1-butene product predominates, because reversal of its formation is relatively slow. At 40°C, this product enters into rapid equilibrium with its cationic precursor and, eventually, with the thermodynamically more stable 1-bromo-2-butene.

Why does the less stable product form with a lower activation barrier? Attack of the nucleophile (bromide, in this case) is faster at C3, the more substituted carbon, for a combination of reasons. When HBr protonates the terminal carbon atom of the diene, the freed bromide ion is initially relatively near to the adjacent carbon (C3) of the newly formed allylic cation. In addition, this cation is asymmetric; its positive charge is unequally distributed between carbons 1 and 3. More positive charge resides at the secondary carbon C3, as is reflected in the electrostatic-potential map shown in the margin. This position has less electron density (more blue) than the unsubstituted terminus. Thus, attack at C3 is favored kinetically by its greater partial positive charge and by its proximity to the newly released nucleophile.

Figure 14-8 Kinetic control (to the left) as compared to thermodynamic control (to the right) in the reaction of 1-methyl-2-propenyl cation with bromide ion (middle).
Working with the Concepts: Kinetic Versus Thermodynamic Control

Bromination of 1,3-butadiene (see p. 622) at 60°C gives 3,4-dibromo-1-butene and 1,4-dibromo-2-butene in a 10:90 ratio, whereas at −15°C this ratio is 60:40. Explain by a mechanism.

**Strategy**

To tackle problems of this type, you first need to formulate a mechanism that connects starting materials with products. Since we are dealing here with bromination of a double bond, refer back to Sections 12-5 and 12-6 for descriptions of the mechanism.

**Solution**

- **Section 12-5** described how bromine attacks a double bond, namely, by forming a bromonium ion $A$ initially, which is then subject to nucleophilic attack by bromide, leading to anti addition.
- **Section 12-6** revealed that when the double bond is substituted by alkyl groups, the bromonium ion is distorted, as in $B$, to reflect carbocation-like character on the more substituted carbon.
- In the case of butadiene, the substituent is ethenyl, and the bromonium ion exists in its open form as a delocalized allylic cation $C$.

\[
\begin{align*}
A, R &= H: \text{symmetrical} \\
B, R &= \text{alkyl: unsymmetrical} \\
C, R &= \text{ethenyl: allylic cation}
\end{align*}
\]

- Cation $C$ can now be trapped by bromide ion at either its terminal or internal carbon. For reasons explained above, attack by bromide on the internal carbon appears slightly faster (kinetic control), giving the initial low temperature ratio of 60:40 of 3,4-dibromo-1-butene and trans-1,4-dibromo-2-butene. At −15°C, these two compounds are stable and do not undergo dissociation (the reverse of their formation).

**Kinetic control:**

\[
\begin{align*}
\text{\textit{Kinetic control:}} \\
\text{Warming to 60°C provides enough energy for the allylic bromide to function as a leaving group (by an S_N1 reaction; Section 14-3) and thus to regenerate the allylic cation. At this temperature, the products and the cation are in rapid equilibrium, although the concentration of the higher-energy cation is very small. While the relative rates of bromide attack on the cation are still the same, this factor becomes irrelevant, because the product distribution is under thermodynamic control, reflecting relative stability: The 1,4-dibromo isomer is more stable than the 3,4-dibromo isomer, and the observed product ratio changes to 10:90. You can calculate by how much the two isomers differ in energy by applying the equation from Section 2-1.}
\end{align*}
\]

**Thermodynamic control:**

\[
\begin{align*}
\text{\textit{Thermodynamic control:}} \\
\text{Warming to 60°C provides enough energy for the allylic bromide to function as a leaving group (by an S_N1 reaction; Section 14-3) and thus to regenerate the allylic cation. At this temperature, the products and the cation are in rapid equilibrium, although the concentration of the higher-energy cation is very small. While the relative rates of bromide attack on the cation are still the same, this factor becomes irrelevant, because the product distribution is under thermodynamic control, reflecting relative stability: The 1,4-dibromo isomer is more stable than the 3,4-dibromo isomer, and the observed product ratio changes to 10:90. You can calculate by how much the two isomers differ in energy by applying the equation from Section 2-1.}
\end{align*}
\]

Exercise 14-14

**Try It Yourself**

In the reaction shown below, which product is the result of 1,2- and 1,4-addition, respectively, and which is the kinetic and thermodynamic product, respectively?

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{Cl} \\
\text{H}_3\text{C} & \quad \text{H}_3\text{C} \\
\text{Cl} & \quad \text{Cl}
\end{align*}
\]

\[
\begin{align*}
\text{A:} \\
\text{B:}
\end{align*}
\]
In Summary Conjugated dienes are electron rich and are attacked by electrophiles to give intermediate allylic cations on the way to 1,2- and 1,4-addition products. These reactions may be subject to kinetic control at relatively low temperatures. At relatively higher temperatures, the kinetic product ratios may change to thermodynamic product ratios, when such product formation is reversible.

14-7 Delocalization Among More than Two Pi Bonds: Extended Conjugation and Benzene

What happens when more than two conjugated double bonds are present in a molecule? Does its reactivity increase? And what happens if the molecule is cyclic? Does it react in the same way as its linear analog? In this section we begin to answer these questions.

Extended pi systems are thermodynamically stable but kinetically reactive

When more than two double bonds are in conjugation, the molecule is called an extended \( \pi \) system. An example is 1,3,5-hexatriene, the next higher double-bond homolog of 1,3-butadiene. This compound is quite reactive and polymerizes readily, particularly in the presence of electrophiles. Despite its reactivity as a delocalized \( \pi \) system, it is also relatively stable thermodynamically.

The increased reactivity of this extended \( \pi \) system is due to the low activation barriers for electrophilic additions, which proceed through highly delocalized carbocations. For example, the bromination of 1,3,5-hexatriene produces a substituted pentadienyl cation intermediate that can be described by three resonance structures.

\[
\text{Bromination of 1,3,5-Hexatriene}
\]

The final mixture is the result of 1,2-, 1,4-, and 1,6-additions, the last product being the most favored thermodynamically, because it retains an internal conjugated diene system.

Exercise 14-15

Upon treatment with two equivalents of bromine, 1,3,5-hexatriene has been reported to give moderate amounts of 1,2,5,6-tetrabromo-3-hexene. Write a mechanism for the formation of this product.
Some highly extended $\pi$ systems are found in nature. An example is $\beta$-carotene, the orange coloring agent in carrots (see Chapter Opening), and its biological degradation product, vitamin A (retinol, below; see Chemical Highlight 18-3). Compounds of this type can be very reactive because there are many potential sites for attack by reagents that add to double bonds. In contrast, some cyclic conjugated systems may be considerably less reactive, depending on the number of $\pi$ electrons (see Chapter 15). The most striking example of this effect is benzene, the cyclic analog of 1,3,5-hexatriene.

**Benzene, a conjugated cyclic triene, is unusually stable**

Cyclic conjugated systems are special cases. The most common examples are the cyclic triene $\text{C}_6\text{H}_6$, better known as benzene, and its derivatives (Chapters 15, 16, and 22). In contrast to hexatriene, benzene is unusually stable, both thermodynamically and kinetically, because of its special electronic makeup (see Chapter 15). That benzene is unusual can be seen by drawing its resonance forms: There are two equally contributing Lewis structures. Benzene does not readily undergo addition reactions typical of unsaturated systems, such as catalytic hydrogenation, hydration, halogenation, and oxidation. In fact, because of its low reactivity, benzene can be used as a solvent in organic reactions.

In the chapters that follow, we shall see that the unusual lack of reactivity of benzene is related to the number of $\pi$ electrons present in its cyclically conjugated array—namely, six. The next section introduces a reaction that is made possible only because its transition state benefits from six-electron cyclic overlap.

**In Summary** Acyclic extended conjugated systems show increasing thermodynamic stability but also kinetic reactivity because of the many sites open to attack by reagents and the ease of formation of delocalized intermediates. In contrast, the cyclohexatriene benzene is unusually stable and unreactive.
Conjugated double bonds participate in more than just the reactions typical of the alkenes, such as electrophilic addition. This section describes a process in which conjugated dienes and alkenes combine to give substituted cyclohexenes. In this transformation, known as Diels-Alder cycloaddition, the atoms at the ends of the diene add to the alkene double bond, thereby closing a ring. The new bonds form simultaneously and stereospecifically.

The cycloaddition of dienes to alkenes gives cyclohexenes

When a mixture of 1,3-butadiene and ethene is heated in the gas phase, a remarkable reaction takes place in which cyclohexene is formed by the simultaneous generation of two new carbon–carbon bonds. This is the simplest example of the Diels-Alder reaction, in which a conjugated diene adds to an alkene to yield cyclohexene derivatives. The Diels-Alder reaction is in turn a special case of the more general class of cycloaddition reactions between \( \pi \) systems, the products of which are called cycloadducts. In the Diels-Alder reaction, an assembly of four conjugated atoms containing four \( \pi \) electrons reacts with a double bond containing two \( \pi \) electrons. For that reason, the reaction is also referred to as a \([4 + 2]\) cycloaddition. The four-carbon component is simply called diene, the alkene is labeled dienophile “diene loving.”

What makes a good Diels-Alder reaction? Reactivity of the diene and dienophile

The prototype reaction of butadiene and ethene actually does not work very well and gives only low yields of cyclohexene. It is much better to use an electron-poor alkene with an electron-rich diene. Substitution of the alkene with electron-attracting groups and of the diene with electron-donating groups therefore creates excellent reaction partners (see margin).

The trifluoromethyl group, for example, is inductively (Section 8-3) electron attracting owing to its highly electronegative fluorine atoms. The presence of such a substituent enhances the Diels-Alder reactivity of an alkene. Conversely, alkyl groups are electron donating because of hyperconjugation (Sections 7-5, 11-3, and 11-5); their presence increases electron density and is beneficial to dienes in the Diels-Alder reaction. The electrostatic potential maps in the margin illustrate these effects. The double bond with the trifluoromethyl substituent has less electron density (yellow) than the double bonds bearing methyl groups (red).

Other alkenes have substituents that interact with double bonds by resonance. For example, carbonyl-containing groups and nitriles are good electron acceptors by this effect. Double bonds bearing such substituents are electron poor because of the contribution of resonance forms that place a positive charge on an alkene carbon atom.
Groups That Are Electron Withdrawing by Resonance

Some examples of the trend in reactivity of dienophiles and dienes are

Exercise 14-16
Classify each of the following alkenes as electron poor or electron rich, relative to ethene. Explain your assignments.

(a) H₂C═CHCH₂CH₃  (b)  (c)  (d)  

Exercise 14-17
The double bond in nitroethene, H₂C═CHNO₂, is electron poor, and that in methoxyethene, H₂C═CHOCH₃, is electron rich. Explain, using resonance structures.

Examples of reaction partners that undergo efficient Diels-Alder cycloaddition are 2,3-dimethyl-1,3-butadiene and propenal (acrolein).
CHEMICAL HIGHLIGHT 14-2

Conducting Polyenes: Novel Functional Materials

Can you imagine replacing all the copper wire in our electrical power lines and appliances with an organic polymer? A giant step toward achieving this goal was made in the late 1970s by Heeger, MacDiarmid, and Shirakawa,* for which they received the Nobel Prize in 2000. They synthesized a polymeric form of ethyne (acetylene) that conducts electricity as metals do. This discovery caused a fundamental change in how organic polymers ("plastics") were viewed. Indeed, normal plastics are used to insulate and protect us from electrical currents.

What is so special about polyethyne (polyacetylene)? For a material to be conductive, it has to have electrons that are free to move and sustain a current, instead of being localized, as in most organic compounds. In this chapter, we have seen how such delocalization is attained by linking \( sp^2 \) hybridized carbon atoms in a growing chain: conjugated polyenes. We have also learned how a positive charge, a single electron, or a negative charge can "spread out" along the \( \pi \) network, not unlike a molecular wire. Polyacetylene has such a polymeric structure, but the electrons are still too rigid to move with the facility required for conductivity. To achieve this goal, the electronic frame is "activated" by either removing electrons (oxidation) or adding them (reduction), a transformation called doping. The electron hole (positive charge) or electron pair (negative charge) delocalize over the polyenic structure in much the same way as that shown for extended allylic chains in Section 14-6. In the original breakthrough experiment, polyacetylene, made from acetylene by transition metal–catalyzed polymerization (see Section 12-15), was doped with iodine, resulting in a spectacular 10-million-fold increase in conductivity. Later refinement improved this figure to \( 10^{11} \), essentially organic copper!

\[ \text{trans-Polyacetylene} \quad \text{Conducting polyacetylene} \]

The black, shiny, flexible foil of polyacetylene (polyethyne) made by polymerization of gaseous ethyne on the walls of the reaction vessel shown.

*Professor Alan J. Heeger (b. 1936), University of California at Santa Barbara, California; Professor Alan G. MacDiarmid (1927–2007), University of Pennsylvania, Philadelphia, Pennsylvania; Professor Hideki Shirakawa (b. 1936), University of Tsukuba, Japan.
Because of its sensitivity to air and moisture, polyacetylene is difficult to use in practical applications. However, the idea of using extended $\pi$ systems to impart organic conductivity can be exploited with a range of materials, all of which have proven utility. Many of these contain especially stabilized cyclic 6-$\pi$-electron units, such as benzene (Section 15-2), pyrrole, and thiophene (Section 25-4).

**Organic Conductors and Applications**

- **Poly($p$-phenylene vinylene)**
  (Electroluminescent displays, such as in mobile phones)

- **Polyaniline**
  (Conductor; electromagnetic shielding of electronic circuits; antistatic, such as in carpets)

- **Polypyrrole**
  (Electrolyte; screen coating; sensing devices)

- **Polythiophene**
  (Field-effect transistors, such as in supermarket checkouts; antistatic, such as in photographic film)

Apart from these applications in electronics, conducting polymers can be made to “light up” when excited by an electric field, a phenomenon called electroluminescence that has gained enormous utility in the form of organic light-emitting diodes (OLEDs). Simply put, such organic materials can be viewed as organic light “bulbs.” They are relatively light and flexible and encompass a broad spectrum of colors. Because organic polymers are, in principle, readily processed into any shape or form, they provide novel, flexible displays, such as books, luminous cloth, and wall decorations. The future, indeed, looks bright!
The carbon–carbon double bond in the cycloadduct is electron rich and sterically hindered. Thus, it does not react further with additional diene.

The parent 1,3-butadiene, without additional substituents, is electron rich enough to undergo cycloadditions with electron-poor alkenes.

The Diels-Alder reaction is concerted

The Diels-Alder reaction takes place in one step. Both new carbon–carbon single bonds and the new \( \pi \) bond form simultaneously, just as the three \( \pi \) bonds in the starting materials break. As mentioned earlier (Section 6-4), one-step reactions, in which bond breaking happens at the same time as bond making, are \textit{concerted}. The concerted nature of this transformation can be depicted in either of two ways: by a dotted circle, representing the six delocalized \( \pi \) electrons, or by electron-pushing arrows. Just as six-electron cyclic overlap stabilizes benzene (Section 14-7), the Diels-Alder process benefits from the presence of such an array in its transition state.

### Two Pictures of the Transition State of the Diels-Alder Reaction

![Dotted-line picture and Electron-pushing picture](image)

An orbital representation (Figure 14-9) clearly shows bond formation by overlap of the \( p \) orbitals of the dienophile with the terminal \( p \) orbitals of the diene. While these four carbons rehybridize to \( sp^3 \), the remaining two internal diene \( p \) orbitals give rise to the new \( \pi \) bond.

The mechanism of the Diels-Alder reaction requires that both ends of the diene point in the same direction to be able to reach the dienophile carbons simultaneously. This means that the diene has to adopt the energetically slightly less favorable \( s \)-cis conformation, relative to the more stable \( s \)-trans form (Figure 14-6).

**Figure 14-9** Orbital representation of the Diels-Alder reaction between 1,3-butadiene and ethene. The two \( p \) orbitals at C1 and C4 of 1,3-butadiene and the two \( p \) orbitals of ethene interact, as the reacting carbons rehybridize to \( sp^3 \) to maximize overlap in the two resulting new single bonds. At the same time, \( \pi \) overlap between the two \( p \) orbitals on C2 and C3 of the diene increases to create a full double bond.
This necessity affects the rates of the cycloaddition. When the $s$-cis form is particularly hindered or impossible, the reaction slows down or does not occur. Conversely, when the diene is constrained to $s$-cis, the transformation is accelerated.

**Unreactive Dienes**

![Unreactive Dienes](image1)

**Particularly Reactive Dienes**

![Particularly Reactive Dienes](image2)

**The Diels-Alder reaction is stereospecific**

As a consequence of the concerted mechanism, the Diels-Alder reaction is stereospecific. For example, reaction of 1,3-butadiene with dimethyl cis-2-butenedioate (dimethyl maleate, a cis alkene) gives dimethyl cis-4-cyclohexene-1,2-dicarboxylate. *The stereochemistry at the original double bond of the dienophile is retained in the product.* In the complementary reaction, dimethyl trans-2-butenedioate (dimethyl fumarate, a trans alkene) gives the trans adduct.

**In the Diels-Alder Reaction, the Stereochemistry of the Dienophile Is Retained**

![MODEL BUILDING](image3)

Similarly, *the stereochemistry of the diene also is retained.* Note that the cycloadducts depicted here contain stereocenters and may be either meso or chiral. However, since we begin with achiral starting materials, the ensuing products, when chiral, are formed as racemates via two equal-energy transition states (see, for example, Sections 5-7 and 12-5).
In other words, the stereospecificity exhibited by the Diels-Alder process refers to relative, not absolute, stereochemistry. As always, we are depicting only one enantiomer of a chiral (but racemic) product, as in the case of the cycloadditions of dimethyl trans-2-butenedioate (above) and cis,trans-2,4-hexadiene (below).

**In the Diels-Alder Reaction, the Stereochemistry of the Diene Is Retained**

\[
\begin{align*}
\text{trans,trans-2,4-Hexadiene} & \quad (\text{Both methyls "outside"}) \\
\text{Tetracyanoethene} & \quad (\text{Methyls end up cis}) \\
\text{cis,trans-2,4-Hexadiene} & \quad (\text{One methyl "inside"; one methyl "outside"}) \\
\text{(Methyls end up trans)}
\end{align*}
\]

**Exercise 14-19**

**Working with the Concepts: Diels-Alder Reactions**

Draw the product of the following Diels-Alder cycloaddition:

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{H}_3\text{C} \\
\text{H}_3\text{C} & \quad \text{H}_3\text{C} \\
\text{CN} & \quad \text{CN} \\
\text{NC} & \quad \text{NC}
\end{align*}
\]

**Strategy**

In dealing with problems that feature Diels-Alder reactions, it is useful to remind yourself of the spatial approach of diene and dienophile, ideally using molecular models. Once you feel comfortable with visualizing how the reactants align in the transition state, you can practice drawing it.

**Solution**

- Using Figure 14-9 as a guide, draw, in perspective, the two components of the reaction before cycloaddition.
- Complete your drawing by moving the six participating electrons appropriately to generate the two new σ bonds and the new π bond.
- If your drawing looks distorted, straighten it out to a regular cyclohexene ring, adding the substituents, including their relative stereochemistry.
Diels-Alder cycloadditions follow the endo rule

The Diels-Alder reaction is highly stereocontrolled, not only with respect to the substitution pattern of the original double bonds, but also with respect to the orientation of the starting materials relative to each other. Consider the reaction of 1,3-cyclopentadiene with dimethyl cis-2-butenedioate. Two products are conceivable, one in which the two ester substituents on the bicyclic frame are on the same side (cis) as the methylene bridge, the other in which they are on the side opposite (trans) from the bridge. The first is called the exo adduct, the second the endo adduct (exo, Greek, outside; endo, Greek, within). The terms refer to the position of groups in bridged systems. Exo substituents are placed cis with respect to the shorter bridge; endo substituents are positioned trans to this bridge. In general, in an exo addition, the substituents on the dienophile point away from the diene. Conversely, in an endo addition they point toward the diene.

Exercise 14-20

Try It Yourself

Add structures of the missing products or starting materials to the following Diels-Alder reaction schemes.

(a) \[ \text{H}_3\text{C} = \text{C} - \text{H} + ? \rightarrow \text{H}_3\text{C} = \text{C} \text{H}_3 \]

(b) \[ ? + ? \rightarrow \text{H}_3\text{C} - \text{F} \]

Exercise 14-21

 cis,trans-2,4-Hexadiene reacts very sluggishly in [4 + 2]cycloadditions; the trans,trans isomer does so much more rapidly. Explain. [Hint: The Diels-Alder reaction requires the s-cis arrangement of the diene (Figure 14-9, and see Figure 14-6).]
The Diels-Alder reaction usually proceeds with endo selectivity, that is, the product in which the activating electron-withdrawing group of the dienophile is located in the endo position is formed faster than the alternative exo isomer. This occurs even though the exo product is often more stable than its endo counterpart. This observation is referred to as the endo rule. The preference for endo cycloaddition has its origin in a variety of steric and electronic influences on the transition state of the reaction. Although

The Diels-Alder reaction is “Green”

In the Diels-Alder reaction, both starting materials are consumed to give a new product without generating any additional materials. Such transformations are called “atom economical,” because all of the atoms of starting materials are incorporated in the product. Atom-economical reactions are a key ingredient of green chemistry (see Chemical Highlight 3-1), and the Diels-Alder reaction adheres to several of its principles. Thus, it generates no (or little) waste, incorporates all starting materials in the product(s), and retains functionality. It normally does not require protecting groups; it can be run with neat reagents, thus avoiding solvents; and it is often efficient enough to allow crystallization or distillation of pure product, thus avoiding column chromatography. Many Diels-Alder reactions need some heating to proceed at reasonable rates, but this problem can be overcome by the application of catalysts that allow room-temperature transformations. For example, Lewis acids (Section 2-2) accelerate cycloadditions greatly. A case in which this effect has been quantified is shown below. Such catalysis also affects exo/endo ratios and can result in enantioselectivity when optically active catalysts are employed (see, for example, Chemical Highlights 5-4 and 9-3, and Section 12-2). The effect of the Lewis acid is to activate the dienophile by complexation to the carbonyl oxygen lone pairs, rendering the carbonyl group even more electron withdrawing.

The Diels-Alder reaction usually proceeds with endo selectivity, that is, the product in which the activating electron-withdrawing group of the dienophile is located in the endo position is formed faster than the alternative exo isomer. This occurs even though the exo product is often more stable than its endo counterpart. This observation is referred to as the endo rule. The preference for endo cycloaddition has its origin in a variety of steric and electronic influences on the transition state of the reaction. Although
the endo transition state is only slightly lower in energy, this is sufficient to control the outcome of most Diels-Alder reactions we shall encounter. Mixtures may ensue in the case of highly substituted systems or when several different activating substituents are present.

The Endo Rule

Endo product

Methyl propenoate

The relative stereochemistry of the product of a general Diels-Alder reaction that follows the endo rule is illustrated below. As an aid to keeping track of the substituents and where they are going, we can use the general labels “o” (for outside, as in outside the half-circle marked by the diene carbon sequence) and “i” (for inside) for the two possible stereochemical orientations of groups attached to the end of the diene. We then label the substituents on the dienophile with respect to their orientation in the transition state of the reaction as either endo or exo. The structure of the expected product with all substituents in place is shown on the right of the equation. You can see that “o” is always cis to “endo.” This scheme allows you to get the structure of your product quickly, without the need for stereodrawings. However, it does not replace a thorough understanding of the principles that led to it!
Exercise 14-22

Working with the Concepts: The Endo Rule

Draw the product of the reaction of trans, trans-2,4-hexadiene with methyl propenoate (show the stereochemistry clearly).

**Strategy**
First, we draw the structures of the two reagents, trans, trans-2,4-hexadiene and methyl propenoate. Next, to get the stereochemistry of the product right, we need to line up the reagents as in the transition state picture in Figure 14-9, one above the other. The ester function of the dienophile is, according to the endo rule, expected to be positioned endo.

**Solution**
- Following the prescribed steps gives us

```
\begin{align*}
\text{trans, trans-2,4-hexadiene} & \quad \text{methyl propenoate} \\
\quad & \quad \text{Product}
\end{align*}
```

- We can check the result, using our general schematic formalism above. For this purpose, we label all substituents in the reagents: The two methyl groups in the diene are located “outside” and therefore are designated “o.” The ester function in the dienophile is labeled endo. Plugging in these labeled groups into our generalized product structure confirms our solution.

Exercise 14-23

Try It Yourself

Predict the products of the following reactions (show the stereochemistry clearly): (a) trans-1,3-pentadiene with 2-butenedioic anhydride (maleic anhydride); (b) 1,3-cyclopentadiene with dimethyl trans-2-butenedioate (dimethyl fumarate).

Exercise 14-24

The Diels-Alder reaction can also occur in an intramolecular fashion. Draw the two transition states leading to products in the following reaction.

```
\begin{align*}
\text{Product 1} & \quad \text{Product 2} \\
\text{58%} & \quad \text{42%}
\end{align*}
```
**In Summary** The Diels-Alder reaction is a concerted cycloaddition that proceeds best between electron-rich 1,3-dienes and electron-poor dienophiles to furnish cyclohexenes. It is stereospecific with respect to the stereochemistry of the double bonds and with respect to the arrangements of the substituents on diene and dienophile: It follows the endo rule.

### 14-9 Electrocyclic Reactions

The Diels-Alder reaction couples the ends of two separate $\pi$ systems. Can rings be formed by the linkage of the termini of a single conjugated di-, tri-, or polyene? Yes, and this section will describe the conditions under which such ring closures (and their reverse), called **electrocyclic reactions**, take place. Cycloadditions and electrocyclic reactions belong to a class of transformations called **pericyclic** (peri, Greek, around), because they exhibit transition states with a cyclic array of nuclei and electrons.

**Electrocyclic transformations are driven by heat or light**

Let us consider first the conversion of 1,3-butadiene into cyclobutene. This process is endothermic because of ring strain. Indeed, the reverse reaction, ring opening of cyclobutene, occurs readily upon heating. However, ring closure of cis-1,3,5-hexatriene to 1,3-cyclohexadiene is exothermic and takes place thermally. Is it possible to drive these transformations in the thermally disfavored directions?

We know that in a thermal reaction this is a difficult task, because equilibrium is governed by thermodynamics (Section 2-1). However, the problem can be surmounted in some cases by using light, so-called **photochemical reactions**. In these, absorption of a photon by the starting material excites the molecule into a higher energy state. We have seen how such absorptions form the basis for spectroscopy (Section 10-2; see also Section 14-11). Molecules can relax from such excited states to furnish thermodynamically less stable products than starting material(s). We shall not deal with the details of photochemistry in this text, but we do note that it allows electrocyclic reaction equilibria to be driven in the energetically unfavorable direction. Therefore, irradiation of 1,3-cyclohexadiene with light of appropriate frequency will cause its conversion to its triene isomer. Similarly, irradiation of 1,3-butadiene effects ring closure to cyclobutene.

**Electrocyclic Reactions**

\[
\begin{align*}
\text{cis-1,3,5-Hexatriene} & \quad \overset{\Delta}{\underset{hv}{\longrightarrow}} \quad \text{1,3-Cyclohexadiene} \\
\text{Cyclobutene} & \quad \overset{\Delta}{\underset{hv}{\longrightarrow}} \quad \text{1,3-Butadiene}
\end{align*}
\]

\[\Delta H^o = -14.5 \text{ kcal mol}^{-1} (-60.7 \text{ kJ mol}^{-1}) \]

Ring closure to six-membered ring is exothermic

\[\Delta H^o = -9.7 \text{ kcal mol}^{-1} (-40.6 \text{ kJ mol}^{-1}) \]

Ring opening of four-membered ring is exothermic

**Exercise 14-25**

Give the products obtained on heating the following compounds.

(a) ![Image](attachment:image1.png)

(b) ![Image](attachment:image2.png)
Electrocyclic reactions are concerted and stereospecific

Like the Diels-Alder cycloaddition, electrocyclic reactions are concerted and stereospecific. Thus, the thermal isomerization of cis-3,4-dimethylcyclobutene gives only cis,trans-2,4-hexadiene.

Heating its isomer, trans-3,4-dimethylcyclobutene, provides only trans,trans-2,4-hexadiene.

Figure 14-10 takes a closer look at these processes. As the bond between carbons C3 and C4 in the cyclobutene is broken, these carbon atoms must rehybridize from \( sp^3 \) to \( sp^2 \) and rotate to permit overlap between the emerging \( p \) orbitals and those originally present. In such thermal cyclobutene ring openings, the carbon atoms are found to rotate in the same direction, either both clockwise or both counterclockwise. This mode of reaction is called a conrotatory process. In the case of cis-3,4-dimethylcyclobutene, both the clockwise and counterclockwise courses result in the same product, cis,trans-2,4-hexadiene. However, for trans-3,4-dimethylcyclobutene, two products are possible. The counterclockwise mode leads
Chapter 14
Delocalized Pi Systems

to the observed trans,trans-2,4-hexadiene. Rotation in the opposite direction would form the corresponding cis,cis isomer but is sterically encumbered and not observed.

Fascinatingly, the photochemical closure (photocyclization) of butadiene to cyclobutene proceeds with stereochemistry exactly opposite that observed in the thermal opening. In this case, the products arise by rotation of the two reacting carbons in opposite directions. In other words, if one rotates clockwise, the other does so counterclockwise. This mode of movement is called disrotatory (Figure 14-11).

Can these observations be generalized? Let us look at the stereochemistry of the cis-1,3,5-hexatriene–cyclohexadiene interconversion. Surprisingly, the six-membered ring is formed thermally by the disrotatory mode, as can be shown by using derivatives. For example, heated trans,cis,trans-2,4,6-octatriene gives cis-5,6-dimethyl-1,3-cyclohexadiene, and cis,cis,trans-2,4,6-octatriene converts into trans-5,6-dimethyl-1,3-cyclohexadiene, both disrotatory closures.

Figure 14-11 Disrotatory photochemical ring closure of cis,trans- and trans,trans-2,4-hexadiene. In the disrotatory mode, one carbon rotates clockwise, the other counterclockwise.
Stereochemistry of the Thermal 1,3,5-Hexatriene Ring Closure

\[
\begin{align*}
\text{trans,cis,trans-2,4,6-Octatriene} & \quad \Delta \quad \text{Disrotatory} \\
\text{cis-5,6-Dimethyl-1,3-cyclohexadiene} & \\
\text{cis,cis,trans-2,4,6-Octatriene} & \quad \Delta \quad \text{Disrotatory} \\
\text{trans-5,6-Dimethyl-1,3-cyclohexadiene} & 
\end{align*}
\]

In contrast, the corresponding photochemical reactions occur in conrotatory fashion.

Stereochemistry of the Photochemical 1,3,5-Hexatriene Ring Closure

This stereocontrol is observed in many other electrocyclic transformations and is governed by the symmetry properties of the relevant \( \pi \) molecular orbitals. The Woodward-Hoffmann* rules describe these interactions and predict the stereochemical outcome of all electrocyclic reactions as a function of the number of electrons taking part in the process and whether the reaction is carried out photochemically or thermally. A complete treatment

*Professor Robert B. Woodward (1917–1979), Harvard University, Cambridge, Massachusetts, Nobel Prize 1965 (chemistry); Professor Roald Hoffmann (b. 1937), Cornell University, Ithaca, New York, Nobel Prize 1981 (chemistry).
Streptomyces is a group of bacteria found predominantly in soil and in decaying vegetation. You may have noticed them in action by the “earthy” odor of compost heaps. These bacteria are prolific in producing medicinally useful, biologically active compounds and have therefore been investigated thoroughly by organic chemists. Among the components of some Streptomyces cultures are polyenes, including the conjugated tetraene spectinabilin. In 2001, the promising potent immunosuppressants called SNF 4435 C and D (an acronym referring to the biological screening method) were discovered in the same cultures. Chemists noticed that these compounds were isomers of spectinabilin and speculated that they were formed by a cascade of two electrocyclizations.

Spectinabilin is an all-trans tetraene and therefore incapable of undergoing ring closure. It was found, however, that sunlight induced cis-trans isomerization of the two internal double bonds furnishing the cis,cis isomer that is perfectly set up to enter into an $8\pi$ conrotatory cyclization. Because there is a stereocenter (*), there are two modes of conrotatory movement (clockwise and counterclockwise), giving two isomeric cyclooctatrienes. These compounds then undergo subsequent $6\pi$ disrotatory closure to the two SNF isomers.
Formation of SNF 4435 Isomers from Spectinabilin

The proposed pathway was confirmed in 2004 and 2005 by so-called biomimetic syntheses that were inspired by the biogenetic proposal. These approaches centered on the direct construction of the cis,cis isomer of spectinabilin using a Stille coupling (Chemical Highlight 13-1) of the two halves of the molecule. In fact, the resulting tetraene converted to the two SNF isomers spontaneously under the conditions of the reaction.
of this subject is best left to a more advanced course in organic chemistry. However, the predicted stereochemical course of electrocyclic reactions can be summarized in the simple manner shown in Table 14-2.

**Exercise 14-26**

The cyclic polynene A (an “annulene”; see Section 15-6) can be converted to either B or C by a sequence of electrocyclic ring closures, depending on whether light or heat are used. Identify the conditions necessary to effect either transformation and identify each step as either con- or disrotatory.

**Exercise 14-27**

**Working with the Concepts: An Electrocyclic Reaction with a Twist**

Heating *cis*-3,4-dimethylcyclobutene, A, in the presence of dienophile B gave exclusively the diastereomer C. Explain by a mechanism.

**Strategy**

This reaction looks like a cycloaddition. We can confirm this idea by checking the atom stoichiometry: \( C_6H_{10}(A) + C_4H_{2}N_2(B) = C_{10}H_{12}N_2(C) \), so the reaction is atom economical. What kind of cycloaddition? To determine this, we need to do some retrosynthetic analysis on C.

**Solution**

- Working backward, we see that cyclohexene C resembles a Diels-Alder addition product of B to a 2,4-hexadiene isomer. Since the two methyl groups in C are trans to each other, the diene cannot be symmetrical: the only choice is *cis,trans*-2,4-hexadiene D:

- D must be derived from isomer A by thermal, conrotatory electrocyclic ring opening.
- Is the stereochemistry of the cycloaddition of B to D exo or endo? Inspection of the relative positioning of the substituents at the four contiguous stereocenters shows it to be endo, as in E.
In Summary  Conjugated dienes and hexatrienes are capable of (reversible) electrocyclic ring closures to cyclobutenes and 1,3-cyclohexadienes, respectively. The diene–cyclobutene system prefers thermal conrotatory and photochemical disrotatory modes. The triene–cyclohexadiene system reacts in the opposite way, proceeding through thermal disrotatory and photochemical conrotatory rearrangements. The stereochemistry of such electrocyclic reactions is governed by the Woodward-Hoffmann rules.

14-10 Polymerization of Conjugated Dienes: Rubber

Like simple alkenes (Section 12-15), conjugated dienes can be polymerized. The elasticity of the resulting materials has led to their use as synthetic rubbers. The biochemical pathway to natural rubber features an activated form of the five-carbon unit 2-methyl-1,3-butadiene (isoprene, see Section 4-7), which is an important building block in nature.

1,3-Butadiene can form cross-linked polymers

When 1,3-butadiene is polymerized at C1 and C2, it yields a polyethenylethene (polyvinylethylene).

1,2-Polymerization of 1,3-Butadiene

\[ 2n \ CH_2=CH-CH=CH_2 \rightarrow \underbrace{CH_2-CH}_n \]

Alternatively, polymerization at C1 and C4 gives either trans-polybutadiene, cis-polybutadiene, or a mixed polymer.

1,4-Polymerization of 1,3-Butadiene

\[ n \ CH_2=CH-CH=CH_2 \rightarrow \underbrace{CH_2-Ch=CH-Ch}_n \]

cis- or trans-Polybutadiene

Butadiene polymerization is unique in that the product itself may be unsaturated. The double bonds in this initial polymer may be linked by further treatment with added chemicals, such as radical initiators, or by radiation. In this way, cross-linked polymers arise (Figure 14-12), in
which individual chains have been connected into a more rigid framework. Cross-linking generally increases the density and hardness of such materials. It also greatly affects a property characteristic of butadiene polymers: elasticity. The individual chains in most polymers can be moved past each other, a process allowing for their molding and shaping. In cross-linked systems, however, such deformations are rapidly reversible: The chain snaps back to its original shape (more or less). Such elasticity is characteristic of rubbers.

**Synthetic rubbers are derived from poly-1,3-dienes**

Polymerization of 2-methyl-1,3-butadiene (isoprene, Section 4-7) by a Ziegler-Natta catalyst (Section 12-15) results in a synthetic rubber (polyisoprene) of almost 100% Z configuration. Similarly, 2-chloro-1,3-butadiene furnishes an elastic, heat- and oxygen-resistant polymer called neoprene, with trans chain double bonds. Several million tons of synthetic rubber are produced in the United States every year.

![Synthetic rubber molecules](image)

Natural *Hevea* rubber is a 1,4-polymerized (Z)-poly(2-methyl-1,3-butadiene), similar in structure to polyisoprene. To increase its elasticity, it is treated with hot elemental sulfur in a process called vulcanization (*Vulcanus*, Latin, the Roman god of fire), which creates sulfur cross-links. This reaction was discovered by Goodyear* in 1839. One of the earliest and most successful uses of the product, Vulcanite, was the manufacture of dentures that could be molded for good fit. Before the 1860s, false teeth were embedded in animal bone, ivory, or metal. The swollen appearance of George Washington’s lips (visible on U.S. currency) is attributed to his ill-fitting ivory dentures. Nowadays, dentures are made from acrylcs (Section 13-10). Rubber remains an indispensable component of many commercial products, including tires (the major use), shoes, rainwear, and other clothing incorporating elastic fibers.

Copolymers in which the double bonds of 1,3-butadiene undergo polymerization with the double bonds of other alkenes have assumed increasing importance in recent years. By varying the proportions of the different monomers in the polymerization mix, the properties of the final product may be “tuned” over a considerable range. One such substance is a three-component copolymer of propenenitrile, 1,3-butadiene, and ethenylbenzene, known as ABS (for acrylonitrile/butadiene/styrene copolymer). The diene imparts the rubberlike property of flexibility, whereas the nitrile hardens the polymer. The result is a highly versatile material that may be fashioned into sheets or molded into virtually any shape. Its strength and ability to tolerate deformation and stress have allowed its utilization in everything from clock mechanisms to camera and computer cases to automobile bodies and bumpers.

**Polyisoprene is the basis of natural rubber**

How is rubber made in nature? Plants construct the polyisoprene framework of natural rubber by using as a building block 3-methyl-3-butenyl pyrophosphate (isopentenyl pyrophosphate). This molecule is an ester of pyrophosphoric acid and 3-methyl-3-buten-1-ol. An enzyme equilibrates a small amount of this material with the 2-butenyl isomer, an allylic pyrophosphate.

---

*Charles Goodyear (1800–1860), American inventor, Washington, D.C.*
Although the subsequent processes are enzymatically controlled, they can be formulated simply in terms of familiar mechanisms (OPP = pyrophosphate).

**Mechanism of Natural Rubber Synthesis**

**Step 1.** Ionization to stabilized (allylic) cation

\[
\overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} + \overset{\text{OPP}}{\text{H}} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH}
\]

**Step 2.** Electrophilic attack

\[
\overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} + \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} \quad \overset{\text{OPP}}{\text{H}} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH}
\]

**Step 3.** Proton loss

\[
\overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} \quad \overset{\text{OPP}}{\text{H}} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH} \quad \overset{\text{OPP}}{\text{CH}}_3 \text{CH} = \text{CCH}_2\text{OH}
\]

**Step 4.** Second oligomerization

In the first step, ionization of the allylic pyrophosphate gives an allylic cation. Attack by a molecule of 3-methyl-3-butenyl pyrophosphate, followed by proton loss, yields a dimer called geranyl pyrophosphate. Repetition of this process leads to natural rubber.

**Many natural products are composed of 2-methyl-1,3-butadiene (isoprene) units**

Many natural products are derived from 3-methyl-3-butenyl pyrophosphate, including the terpenes first discussed in Section 4-7. Indeed, the structures of terpenes can be dissected into...
five-carbon units connected as in 2-methyl-1,3-butadiene. Their structural diversity can be attributed to the multiple ways in which 3-methyl-3-butenyl pyrophosphate can couple. The monoterpene geraniol and the sesquiterpene farnesol, two of the most widely distributed substances in the plant kingdom, form by hydrolysis of their corresponding pyrophosphates.

\[
\text{Geraniol} \quad \text{Farnesol}
\]

Coupling of two molecules of farnesyl pyrophosphate leads to squalene, a biosynthetic precursor of the steroid nucleus (Section 4-7).

\[
\text{Squalene} \quad \rightarrow \quad \text{steroids}
\]

Bicyclic substances, such as camphor, a chemical used in mothballs, nasal sprays, and muscle rubs, are built up from geranyl pyrophosphate by enzymatically controlled electrophilic carbon–carbon bond formations.

\[
\text{Camphor Biosynthesis from Geranyl Pyrophosphate}
\]

Other higher terpenes are constructed by similar cyclization reactions.

**In Summary** 1,3-Butadiene polymerizes in a 1,2 or 1,4 manner to give polybutadienes with various amounts of cross-linking and therefore variable elasticity. Synthetic rubber can be made from 2-methyl-1,3-butadiene and contains varied numbers of \(E\) and \(Z\) double bonds. Natural rubber is constructed by isomerization of 3-methyl-3-butenyl pyrophosphate to the 2-butenyl system, ionization, and electrophilic (step-by-step) polymerization. Similar mechanisms account for the incorporation of 2-methyl-1,3-butadiene (isoprene) units into the polycyclic structure of terpenes.

**14-11 Electronic Spectra: Ultraviolet and Visible Spectroscopy**

In Section 10-2, we explained that organic molecules may absorb radiation at various wavelengths. Spectroscopy is possible because absorption is restricted to quanta of defined energies, \(h\nu\), to effect specific excitations with energy change \(\Delta E\).

\[
\Delta E = h\nu = \frac{hc}{\lambda} \quad (c = \text{velocity of light})
\]
Figure 10-2 divided the range of electromagnetic radiation into various subsections, from high-energy X-rays to low-energy radiowaves. Among these subsections, one stood out by its representation in colors, the visible spectrum. Indeed, this is the only region of the electromagnetic spectrum that the human body, with our eyes as the “spectrometer,” is able to resolve. The effect of other forms of radiation on us is less well defined: X-rays and ultraviolet light (sunburn!) are destructive, infrared radiation is perceived as heat, and micro- and radio waves are undetectable.

To understand how colors come about, we have to go back to an experiment by Isaac Newton, who showed that white light, when passed though a prism, can be dispersed into the full color spectrum, much like a rainbow, for which water droplets fulfill the function of the prism. Thus, what we perceive as white light is actually the effect of “broad-band irradiation” (to borrow a term from NMR spectroscopy; Section 10-9) on the light receptors in our retina (see Chemical Highlight 18-3). Consequently, we see an object (or compound) as colored when it absorbs light from part of the visible spectrum, reflecting the remainder. For example, when an object absorbs blue light, we see it as orange; when it absorbs green light, we see it as purple. Orange absorption turns the object blue and purple absorption turns it green. In organic chemistry, such colored compounds are most frequently those containing an array of conjugated double bonds. The excitation of electrons in these bonds happens to match the energy of visible light (and, as it turns out, also much of the ultraviolet spectrum), giving them their color. Recall the orange color of β-carotene (Section 14-7) in the Chapter Opening, and you are certainly familiar with the effects of indigo (margin) on blue jeans.

In this section, we shall quantify the color of organic compounds by spectroscopy in the wavelength range from 400 to 800 nm, called visible spectroscopy (see Figure 10-2 and margin below). We also examine the range from 200 to 400 nm, called ultraviolet spectroscopy. Because these two wavelength ranges are so close to each other, they are typically measured simultaneously with the same spectrometer. Both techniques are particularly useful for investigating the electronic structures of unsaturated molecules and for measuring the extent of their conjugation.

A UV-visible spectrometer is constructed according to the general scheme in Figure 10-3. As in NMR, samples are usually dissolved in solvents that do not absorb in the spectral region under scrutiny. Examples are ethanol, methanol, and cyclohexane, none of which has absorption bands above 200 nm. The events triggered by electromagnetic radiation at UV and visible wavelengths lead to the excitation of electrons from filled bonding (and sometimes nonbonding) molecular orbitals to unfilled antibonding molecular orbitals. These changes in electron energies are recorded as electronic spectra. As in NMR, FT instruments have greatly improved sensitivity and ease of spectral acquisition.

### Ultraviolet and visible light give rise to electronic excitations

Consider the bonds in an average molecule: We can safely assume that, except for lone pairs, all electrons occupy bonding molecular orbitals. The compound is said to be in its ground electronic state. Electronic spectroscopy is possible because ultraviolet radiation and visible light have sufficient energy to transfer many such electrons to antibonding orbitals, thereby creating an excited electronic state (Figure 14-13). Dissipation of the absorbed energy may occur in the form of a chemical reaction (cf. Section 14-9), as emission of light (fluorescence, phosphorescence), or simply as emission of heat.

![Figure 14-13 Electronic excitation by transfer of an electron from a bonding to an antibonding orbital converts a molecule from its ground electronic state into an excited state.](image)

Organic \( \sigma \) bonds have a large gap between bonding and antibonding orbitals. To excite electrons in such bonds requires wavelengths much below the practical range (<200 nm). As a result, the technique has found its major uses in the study of \( \pi \) systems, in which filled and unfilled orbitals are much closer in energy. Excitation of such electrons gives rise to \( \pi \rightarrow \pi^* \) transitions. Nonbonding (\( n \)) electrons are even more readily promoted through \( n \rightarrow \pi^* \) transitions (Figure 14-14). Because the number of \( \pi \) molecular orbitals is equal to that of the component \( p \) orbitals, the simple picture presented in Figure 14-14 is rapidly complicated by extending conjugation: The number of possible transitions skyrockets, and with it the complexity of the spectra.

A typical UV spectrum is that of 2-methyl-1,3-butadiene (isoprene), shown in Figure 14-15. The position of a peak is defined by the wavelength at its maximum, a \( \lambda_{\text{max}} \) value (in nanometers). Its intensity is reflected in the molar extinction coefficient or molar absorptivity, \( \epsilon \), that is characteristic of the molecule. The value of \( \epsilon \) is calculated by dividing the measured peak height (absorbance, \( A \)) by the molar concentration, \( C \), of the sample (assuming a standard cell length of 1 cm).

\[
\epsilon = \frac{A}{C}
\]

The value of \( \epsilon \) can range from less than a hundred to several hundred thousand. It provides a good estimate of the efficiency of light absorption. Electronic spectral absorption bands are frequently broad, as in Figure 14-15, not the sharp lines typical of many NMR spectra.

**Electronic spectra tell us the extent of delocalization**

Electronic spectra often indicate the size and degree of delocalization in an extended \( \pi \) system. The more double bonds there are in conjugation, the longer is the wavelength for the lowest-energy excitation (and the more peaks will appear in the spectrum). For example, ethene absorbs at \( \lambda_{\text{max}} = 171 \) nm, and an unconjugated diene, such as 1,4-pentadiene, absorbs at \( \lambda_{\text{max}} = 178 \) nm. A conjugated diene, such as 1,3-butadiene, absorbs at much lower energy (\( \lambda_{\text{max}} = 217 \) nm). Further extension of the conjugated system leads to corresponding incremental increases in the \( \lambda_{\text{max}} \) values, as shown in Table 14-3. The hyperconjugation of alkyl groups and the improved \( \pi \) overlap in rigid, planar cyclic systems...

(For structure, see Section 14-7.)
Figure 14-16 The energy gap between the highest occupied and lowest unoccupied molecular orbitals (abbreviated HOMO and LUMO, respectively) decreases along the series ethene, the 2-propenyl (allyl) radical, and butadiene. Excitation therefore requires less energy and is observed at longer wavelengths.

Both seem to contribute. Beyond 400 nm (in the visible range), molecules become colored: first yellow, then orange, red, violet, and finally blue-green. For example, the contiguous array of 11 double bonds in β-carotene (Section 14-7) is responsible for its characteristic intense orange appearance ($\lambda_{\text{max}} = 480 \text{ nm}$).

Why should larger conjugated $\pi$ systems have more readily accessible and lower-energy excited states? The answer is pictured in Figure 14-16. As the overlapping $p$-orbital array gets longer, the energy gap between filled and unfilled orbitals gets smaller, and more bonding and antibonding orbitals are available to give rise to additional electronic excitations.

Finally, conjugation in cyclopolyenes is governed by a separate set of rules, to be introduced in the next two chapters. Just compare the electronic spectra of benzene, which is colorless (Figure 15-6), with that of azulene, which is deep blue (Figure 14-17), and then compare both with the data in Table 14-3.

Exercise 14-29

Arrange the following compounds in the order of their increasing $\lambda_{\text{max}}$ values.

(a) 1,3,5-Cycloheptatriene  (b) 1,5-Hexadiene  (c) 1,3-Cyclohexadiene

(d) Polyacetylene

Figure 14-17 UV–visible spectrum of azulene in cyclohexane. The absorbance is plotted as log $\varepsilon$ to compress the scale. The horizontal axis, representing wavelength, is also nonlinear.
**The Big Picture**

We have progressed from a single electron in a single \( p \) orbital, as in radicals (Sections 3-1 and 3-2), to a pair of electrons in neighboring \( p \) orbitals, as in double bonds (Chapter 12), to two pairs of electrons in neighboring \( p \) orbitals, as in triple bonds (Chapter 13), to the present chapter, which extends this theme. We now know that an infinite number of \( p \) orbitals can line up in carbon sequences that exhibit the phenomenon of conjugation.

Conjugation delocalizes electrons and therefore charges, as in a molecular wire. It can also be viewed as a way by which one end of a molecule may “communicate” with the other chemically. For example, protonation of a conjugated polyene has a profound effect on the molecule along the entire chain of \( sp^2 \)-hybridized carbons. Even more impressive are the pericyclic reactions, following the last new kind of mechanism that we shall encounter in this book. For example, in the Diels-Alder cycloaddition, the respective termini of the diene and the dienophile add to each other in concert, bond formation and bond breaking occurring at the same time. Similar communication is evident in spectral data, particularly in UV—visible spectroscopy.

Where does this lead us? Returning to the analogy of a conjugated polyene as a molecular wire, we can ask a simple question: What happens if we touch the ends of that wire to complete a closed circuit? A lot, as the next two chapters will reveal.
### CHAPTER INTEGRATION PROBLEMS

14-30. a. Propose a reasonable mechanism for the transformation of \( \text{trans,trans-2,4-hexadien-1-ol} \) (sorbyl alcohol) into \( \text{trans-5-ethoxy-1,3-hexadiene} \).

\[
\begin{align*}
\text{Sorbyl alcohol} \quad & \xrightarrow{\text{H}^+; \text{CH}_3\text{CH}_2\text{OH}} \quad \text{trans-5-Ethoxy-1,3-hexadiene} \\
\end{align*}
\]

**SOLUTION**

This process takes place in acidic ethanol solution (otherwise known as wine). We begin by inspecting the structures of the starting and final molecules to find that (1) an alcohol has become an ether and (2) the double bonds have moved. Let us consider relevant information that we have seen concerning these functional groups. The conversion of two alcohols into an ether in the presence of acid was introduced in Section 9-7. Protonation of one alcohol molecule gives an alkyloxonium ion, whose leaving group (water) may be replaced in either an \( S_N2 \) or an \( S_N1 \) fashion by a molecule of a second alcohol:

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OH}^+ + \text{CH}_3\text{CH}_2\text{OH} & \rightarrow \text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3 \\
\text{CH}_3\text{COH}^+ + \text{CH}_3\text{COH} & \rightarrow \text{CH}_3\text{COCH}_2\text{CH}_3 \\
\end{align*}
\]

Can either of these processes be adapted to the present question? Sorbyl alcohol is an allylic alcohol, and we have just seen (Section 14-3) that allylic halides readily undergo both \( S_N2 \) and \( S_N1 \) displacement reactions. A good deal of Chapter 9 dealt with comparing and contrasting the behavior of haloalkanes with that of alcohols: Protonation of the OH group of an alcohol opens the way to both substitution and elimination chemistry. We should therefore expect that allylic alcohols will be similarly reactive. We need next to consider whether the \( S_N2 \) or the \( S_N1 \) mechanism is more appropriate.

The fact that the double bonds have moved in the course of the reaction is a helpful piece of information. Referring again to Section 14-3 and also 14-6, we note that the allylic cation that results from dissociation of a leaving group in the first step of an \( S_N1 \) reaction is delocalized, and nucleophiles can therefore attach at more than one site. Let us explore this line of reasoning by examining the carbocation derived from protonation and loss of water from sorbyl alcohol:

\[
\begin{align*}
\text{Sorbyl alcohol} \quad & \xrightarrow{\text{H}^+} \quad \text{Carbocation} \quad \xrightarrow{\text{H}_2\text{O}} \\
\end{align*}
\]

Like an allylic cation, this carbocation is delocalized. However, the initial system is a more extended conjugated one, and the resulting cation is a hybrid of three, rather than two, contributing resonance forms. As in electrophilic addition to a conjugated triene (Section 14-7), an incoming nucleophile has the option of attaching to any of three positions. In this particular case, attachment of ethanol to a secondary carbon, where a relatively high fraction of the positive charge resides (Section 14-6), is the predominant (kinetic) result.

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OH}^+ + \underset{\text{Sorbyl alcohol}}{\text{carbocation}} \rightarrow \text{Ethyl trans,trans-2,4-hexadienoate} \\
\end{align*}
\]

b. Esters of sorbic acid undergo Diels-Alder reactions. Predict the major product to arise from the heating of ethyl sorbate with 2-butenedioic anhydride (maleic anhydride, see structure, Table 14-1). Consider carefully all stereochemical aspects of the process.
SOLUTION

Chapter Integration Problems

The Diels-Alder reaction is a cycloaddition between a diene, in this case the ethyl sorbate, and a dienophile, usually an electron-poor alkene (Section 14-8). We should first have a look at the two reaction partners to visualize the new bonding connections that this process will effect. To do so, we need to rotate about the single bond between carbon 3 and carbon 4 of ethyl sorbate to place its double bonds in the necessary conformation. We do this carefully, so as not to mistakenly change the stereochemistry of the double bonds: They both start out trans and must be that way after we have finished. Next, we connect the ends of the diene system to the carbon atoms of the dienophile’s alkene function (dotted lines below), giving us the connectivity of the product, but without stereochemistry specified:

\[
\begin{align*}
\text{OCH}_2\text{CH}_3 & \quad \text{CH}_3\text{CH}_2\text{O}_2\text{C} \\
\text{CH}_3 & \quad \text{CH}_3\text{CH}_2\text{O}_2\text{C}
\end{align*}
\]

To complete the problem, we must finally take into account two details of the Diels-Alder reaction: (1) Stereochemical relations in the components are retained in the course of the reaction; and (2) unsaturated substituents on the double bond of the dienophile prefer to locate themselves underneath the diene system (in endo positions) in the course of the cycloaddition. Making use of illustrations similar to those in the text, we can visualize the process as follows:

\[
\begin{align*}
\text{OCH}_2\text{CH}_3 & \quad \text{CH}_3\text{CH}_2\text{O}_2\text{C} \\
\text{CH}_3 & \quad \text{CH}_3\text{CH}_2\text{O}_2\text{C}
\end{align*}
\]

It takes some careful examination to see how the spatial arrangement of the groups in the sketch of the transition state translates into the final positions in the product. As you work on this aspect of the problem, look in particular at each carbon taking part in the formation of the two new single bonds [dotted lines in transition state (left side of reaction)]. Examine the positions of the substituents on these carbons relative to the two new bonds. A view that may be useful for this purpose is one in which the whole picture is rotated by 90° (see margin). It is reasonably clear from this perspective that the four hydrogen atoms will end up all cis to each other in the newly formed cyclohexene ring. Try Problems 56 and 68 for more practice with mechanisms.

14-31. Because of its superb stereoselectivity, the Diels-Alder reaction is often used as a key step in the construction of acyclic building blocks containing several defined stereocenters. The strategy is to retrosynthetically convert the target into a cyclohexane derivative that is accessible by \([4 + 2]\) cycloaddition. Suggest a synthesis of (racemic) compound A from starting materials containing four carbons or less.

\[
\begin{align*}
\text{A}
\end{align*}
\]

SOLUTION

On first sight, this problem seems impossible. The trick is not to focus on the immediate solution, but on the process of retrosynthetic analysis. Thus, the first task is to find a precursor to A that is an appropriately substituted cyclohexene. We can worry about how to make it (by a Diels-Alder reaction) later.
We note that A is a substituted hexane containing aldehyde functions at the two termini. Is there a retrosynthetic step that will link these two functional carbons to make a six-membered ring? The answer is in Section 12-12: (reverse) ozonolysis, a process that will connect the two carbonyl carbons through a C–C double bond. To draw the resulting cyclohexene B with the correct stereochemistry, it helps to first redraw A in an angular fashion, by rotation around the indicated bonds, before removing the two oxygens and closing the ring.

This, like any, cyclohexene can be dismantled by a retro-endo Diels-Alder process (Section 14-8), providing the two components C and D of the forward reaction in the required stereochemical form.

Dienophile D is readily available (Table 14-1). cis-1,3-Hexadiene, C, will have to be made, and there are many ways by which this task can be accomplished. The crucial feature of its construction is the stereochemistry of the double bond. How do we synthesize cis alkenes? The answer is in Section 13-6: the Lindlar-catalyzed hydrogenation of alkynes. Hence, a good precursor of C is enyne E, which can be derived from F and iodoethane (Section 13-5).

But-1-en-3-yne ("vinylacetylene"), F, is made industrially by the CuCl-catalyzed dimerization of ethyne. How would you make it? We learned that alkenes can be converted to alkynes by halogenation-double dehydrohalogenation (Section 13-4). This approach suggests 1,3-butadiene as a starting material. We have seen, however, that halogenation of 1,3-butadiene, such as bromination, is not as straightforward as that of a monoalkene: 1,2- and 1,4-addition occurs (Section 14-6). Is that a problem? Answer: No. The 1,2-dihalobutene will eliminate normally, first to 2-bromobutadiene (via deprotonation at the more acidic allylic position) and then to F:

The 1,4-dihalobutene will also eliminate, but in a manner that uses the conjugative ability of the double bond, producing 1-bromo-1,3-butadiene as an intermediate, which then goes on to product.

On the basis of this analysis, write a forward scheme for the synthesis of A, starting with 1,3-butadiene, bromoethane, and D as the sources of carbon.
New Reactions

1. Radical Allylic Halogenations (Section 14-2)

\[
RCH_2CH=CH_2 \xrightarrow{\text{NBS, CCl}_4, \text{hv}} RCHCH=CH_2 + RCH = CHCH_2Br
\]

\( \text{DH}^0 \) of allylic C–H bond = 87 kcal mol\(^{-1} \)

2. \( \text{S}_2 \text{N}_2 \) Reactivity of Allylic Halides (Section 14-3)

\[
CH_2=CHCH_2X + \text{Nu}^- \xrightarrow{\text{Acetone}} CH_2=CHCH_2\text{Nu} + X^-
\]

Faster than ordinary primary halides

3. Allylic Grignard Reagents (Section 14-4)

\[
CH_2=CHCH_2Br \xrightarrow{\text{Mg, (CH}_3\text{CH}_2)_2\text{O}} CH_2=CHCH_2\text{MgBr}
\]

Can be used in additions to carbonyl compounds

4. Allyllithium Reagents (Section 14-4)

\[
RCH_2CH=CH_2 \xrightarrow{\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Li, TMEDA}} RCHCH=CH_2 \text{Li}^+
\]

\( pK_a \) of allylic C–H bond = 40

5. Hydrogenation of Conjugated Dienes (Section 14-5)

\[
CH_2=CH=CH=CH_2 \xrightarrow{\text{H}_2, \text{Pd–C, CH}_3\text{CH}_2\text{OH}} CH_3CH_2CH_2CH_3 \quad \Delta H^\circ = -57.1 \text{ kcal mol}^{-1}
\]

but compare

\[
CH_2=CH=CH=CH_2 \xrightarrow{\text{H}_2, \text{Pd–C, CH}_3\text{CH}_2\text{OH}} CH_3(CH_2)_3CH_3 \quad \Delta H^\circ = -60.8 \text{ kcal mol}^{-1}
\]

6. Electrophilic Reactions of 1,3-Dienes: 1,2- and 1,4-Addition (Section 14-6)

\[
CH_2=CH=CH=CH_2 \xrightarrow{\text{HX}} CH_2=CHCHCH_3 + XCH_2CH=CHCH_3
\]

\[
CH_2=CH=CH=CH_2 \xrightarrow{X_1} CH_2=CHCHCH_2X + XCH_2CH=CHCH_2X
\]

7. Thermodynamic Compared with Kinetic Control in \( \text{S}_2 \text{N}_1 \) Reactions of Allylic Derivatives (Section 14-6)

\[
\text{CH}_3\text{CHCH}=\text{CHCH}_2\text{X} \quad \text{More stable product} \quad \text{CH}_3\text{CHCH}=\text{CHCH}_2\text{X} + X^- \quad \text{Less stable product}
\]

\( \text{Stability of primary allylic cation = ordinary secondary cation} \)

(Formation reversible at higher temperature)

8. Diels-Alder Reaction (Concerted and Stereospecific, Endo Rule) (Section 14-8)

\[
\begin{array}{c}
\text{R} \\
\text{R}
\end{array} + \begin{array}{c}
\text{R} \\
\text{R}
\end{array} \xrightarrow{\Delta} \begin{array}{c}
\text{R} \\
\text{R}
\end{array}
\]

\( A = \text{electron acceptor} \)

Requires \( \text{cis} \) diene; better with electron-poor dienophile
9. Electrocyclic Reactions (Section 14-9)

\[ \begin{align*}
\text{Conrotatory} & \quad \Delta \\
\text{Disrotatory} & \quad \Delta \\
\text{Disrotatory} & \quad \text{hv} \\
\text{Conrotatory} & \quad \text{hv}
\end{align*} \]

10. Polymerization of 1,3-Dienes (Section 14-10)

1,2-Polymerization

\[ 2n \text{CH}_2\equiv\text{CH} \equiv \text{CH} \equiv \text{CH}_2 \xrightarrow{\text{Initiator}} (\text{CH}_2 \equiv \text{CH} \equiv \text{CH} \equiv \text{CH}_2)_n \]

1,4-Polymerization

\[ n \text{CH}_2\equiv\text{CH} \equiv \text{CH} \equiv \text{CH}_2 \xrightarrow{\text{Initiator}} (\text{CH}_2 \equiv \text{CH} \equiv \text{CH} \equiv \text{CH}_2)_n \text{ Cis or trans} \]

11. 3-Methyl-3-butenyl Pyrophosphate as a Biochemical Building Block (Section 14-10)

\[ \text{CH}_3 \quad \begin{array}{c}
\text{Enzyme} \\
\text{3-Methyl-3-butenyl pyrophosphate}
\end{array} \xrightarrow{\text{Enzyme}} (\text{CH}_3)_2\text{C} \equiv \text{CHCH}_2\text{OPP} \xrightarrow{\text{Allylic cation, Pyrophosphate ion}} (\text{CH}_3)_2\text{C} \equiv \text{CHCH}_2^+ + \text{OPP} \]

C–C bond formation

\[ \begin{align*}
\text{OPP} + \text{Allylic cation} & \quad \xrightarrow{\text{Enzyme}} \text{OPP} \\
\text{OPP} & \quad \xrightarrow{\text{Enzyme}} \text{OPP} \\
\text{etc.}
\end{align*} \]

Important Concepts

1. The 2-propenyl (allyl) system is stabilized by resonance. Its molecular-orbital description shows the presence of three \( \pi \) molecular levels: one bonding, one nonbonding, and one antibonding. Its structure is symmetric, any charges or odd electrons being equally distributed between the two end carbons.

2. The chemistry of the 2-propenyl (allyl) cation is subject to both thermodynamic and kinetic control. Nucleophilic trapping may occur more rapidly at an internal carbon that bears relatively more positive charge, giving the thermodynamically less stable product. The kinetic product may rearrange to its thermodynamic isomer by dissociation followed by eventual thermodynamic trapping.

3. The stability of allylic radicals allows radical halogenations of alkenes at the allylic position.

4. The \( S_n2 \) reaction of allylic halides is accelerated by orbital overlap in the transition state.

5. The special stability of allylic anions allows allylic deprotonation by a strong base, such as butyllithium–TMEDA.
6. 1,3-Dienes reveal the effects of **conjugation** by their relative stability (compared to nonconjugated systems) and a relatively short internal bond (1.47 Å).

7. Electrophilic attack on 1,3-dienes leads to the preferential formation of allylic cations.

8. **Extended conjugated systems** are reactive because they have many sites for attack and the resulting intermediates are stabilized by resonance.

9. Benzene has special stability because of **cyclic delocalization**.

10. The **Diels-Alder reaction** is a concerted stereospecific **cycloaddition reaction** of an s-cis diene to a dienophile; it leads to cyclohexene derivatives. It follows the **endo rule**.

11. Conjugated dienes and trienes equilibrate with their respective cyclic isomers by concerted and stereospecific **electrocyclic reactions**.

12. **Polymerization** of 1,3-dienes results in 1,2- or 1,4-additions to give polymers that are capable of further **cross-linking**. Synthetic rubbers can be synthesized in this way. Natural rubber is made by electrophilic carbon–carbon bond formation involving biosynthetic five-carbon cations derived from 3-methyl-3-butenyl pyrophosphate.

13. **Ultraviolet and visible spectroscopy** gives a way of estimating the extent of conjugation in a molecule. Peaks in **electronic spectra** are usually broad and are reported as $\lambda_{\text{max}}$ (nm). Their relative intensities are given by the **molar absorptivity** (extinction coefficient) $\epsilon$.

**Problems**

32. Draw all resonance forms and a representation of the appropriate resonance hybrid for each of the following species.

![Resonance forms](image)

33. For each species in Problem 32, indicate the resonance form that is the major contributor to the resonance hybrid. Explain your choices.

34. Illustrate by means of appropriate structures (including all relevant resonance forms) the initial species formed by (a) breaking the weakest C–H bond in 1-butene; (b) treating 4-methylcyclohexene with a powerful base (e.g., butyllithium–TMEDA); (c) heating a solution of 3-chloro-1-methylcyclopentene in aqueous ethanol.

35. Rank primary, secondary, tertiary, and allylic radicals in order of decreasing stability. Do the same for the corresponding carbocations. Do the results indicate something about the relative ability of hyperconjugation and resonance to stabilize radical and cationic centers?

36. Give the major product(s) of each of the following reactions.

![Reactions](image)

37. Formulate detailed mechanisms for the reactions in Problem 36 (a, c, e, f).

38. Rank primary, secondary, tertiary, and (primary) allylic chlorides in approximate order of (a) decreasing $S_N1$ reactivity; (b) decreasing $S_N2$ reactivity.
39. Rank the following six molecules in approximate order of decreasing S_N1 reactivity and decreasing S_N2 reactivity.

(a) \( \text{Cl} \)  
(b) \( \text{Cl} \)  
(c) \( \text{Cl} \)  
(d) \( \text{Cl} \)  
(e) \( \text{Cl} \)  
(f) \( \text{Cl} \)

40. How would you expect the S_N2 reactivities of simple saturated primary, secondary, and tertiary chloroalkanes to compare with the S_N2 reactivities of the compounds in Problem 39? Make the same comparison for S_N1 reactivities.

41. Give the major product(s) of each of the following reactions.

(a) \( \text{H}_3\text{C} \quad \text{H}_2\text{O} \)  
(b) \( \text{NBS}, \text{CCL}, \text{ROOR} \)  
(c) \( \text{NBS}, \text{CCL}, \text{ROOR} \)  
(d) \( \text{CH}_3\text{CH}_2\text{CHCH=CH}_2 \)  
(e) Product of (d) \( \text{CH}_3\text{CH}_2\text{H} \)  
(f) \( \text{KSCH}_3, \text{DMSO} \)

42. Write a detailed step-by-step mechanism to show how each of the products arises from the reaction in Problem 41, part (a).

43. The following reaction sequence gives rise to two isomeric products. What are they? Explain the mechanism of their formation.

\( \text{Cl} \quad 1. \text{Mg} \quad 2. \text{D}_2\text{O} \)

44. Starting with cyclohexene, propose a reasonable synthesis of the cyclohexene derivative shown in the margin.

45. Give a systematic name to each of the following molecules.

(a)  
(b) \( \text{OH} \)
(c)  
(d) 

46. Compare the allylic bromination reactions of 1,3-pentadiene and 1,4-pentadiene. Which should be faster? Which is more energetically favorable? How do the product mixtures compare?

\( \text{CH}_2=\text{CH}--\text{CH}=\text{CH}--\text{CH}_3 \quad \text{NBS}, \text{ROOR}, \text{CCL} \)  
\( \text{CH}_2=\text{CH}--\text{CH}_2=\text{CH}--\text{CH}_2 \quad \text{NBS}, \text{ROOR}, \text{CCL} \)
47. We learned in Section 14-6 that electrophilic additions to conjugated dienes at low reaction temperatures give kinetic product ratios. Furthermore, these kinetic mixtures may change to mixtures with thermodynamic product ratios when the temperature is raised. Do you think that cooling the thermodynamic product mixture back to the original low reaction temperature will change it back to the original kinetic ratio? Why or why not?

48. Compare the addition of $H^+$ to 1,3-pentadiene and 1,4-pentadiene (see Problem 46). Draw the structures of the products. Draw a qualitative reaction profile showing both dienes and both proton addition products on the same graph. Which diene adds the proton faster? Which one gives the more stable product?

49. What products would you expect from the electrophilic addition of each of the following reagents to 1,3-cycloheptadiene?
   (a) HI;  (b) Br$_2$ in H$_2$O;  (c) IN$_3$;  (d) H$_2$SO$_4$ in CH$_3$CH$_2$OH. (Hint: For b and c, see Exercise 14-13, specifically drawings A–C).

50. Give the products of the reaction of trans-1,3-pentadiene with each of the reagents in Problem 49.

51. What are the products of reaction of 2-methyl-1,3-pentadiene with each of the reagents in Problem 49?

52. Write a detailed step-by-step mechanism to show how each of the products arises from the reactions in Problem 51, above.

53. Give the products expected from reaction of deuterium iodide (DI) with (a) 1,3-cycloheptadiene; (b) trans-1,3-pentadiene; (c) 2-methyl-1,3-pentadiene. In what way does the observable result of reaction of DI differ from that of reaction of HI with these same substrates [compare with Problems 49(a), 50(a), and 51(a)]?

54. Arrange the following carbocations in order of decreasing stability. Draw all possible resonance forms for each of them.
   (a) CH$_3$═CH$^+$CH$_2$
   (b) CH$_2$═CH$^+$
   (c) CH$_3$CH$_2$
   (d) CH$_3$═CH$^+$CH═CHCH$_3$
   (e) CH$_2$═CH—CH═CH—CH$_2$

55. Sketch the molecular orbitals for the pentadienyl system in order of ascending energy (see Figures 14-2 and 14-7). Indicate how many electrons are present, and in which orbitals, for (a) the radical; (b) the cation; (c) the anion (see Figures 14-3 and 14-7). Draw all reasonable resonance forms for any one of these three species.

56. Dienes may be prepared by elimination reactions of substituted allylic compounds. For example,

   \[
   \text{CH}_3\text{C}═\text{C}═\text{CH}—\text{CH}_2\text{OH} \xrightarrow{\text{Catalytic } \text{H}_2\text{SO}_4, \Delta} \text{CH}_3\text{C}═\text{C}═\text{CH}—\text{CH}_3 \xleftarrow{\text{LDA, THF}} \text{CH}_3\text{C}═\text{C}═\text{CH}—\text{CH}_2\text{Cl}
   \]

   Propose detailed mechanisms for each of these 2-methyl-1,3-butadiene (isoprene) syntheses.

57. Give the structures of all possible products of the acid-catalyzed dehydration of vitamin A (Section 14-7).

58. Propose a synthesis of each of the following molecules by Diels-Alder reactions.

   (a) \[ \text{CN} \]
   (b) \[ \text{H}_3\text{C}═\text{C}═\text{O} ]
   (c) \[ \text{CH}_3\text{C}═\text{C}═\text{CH}—\text{CH}_2\text{OH} \]

59. The haloconduritols are members of a class of compounds called glycosidase inhibitors. These substances possess an array of intriguing biological activity, from antidiabetic and antifungal to activity against HIV virus and cancer metastasis. Stereoisomeric mixtures of bromoconduritol (margin) are commonly used in studies of these properties. One recent synthesis of these compounds proceeds via the bicyclic ethers A and B. (a) Identify the starting materials for a one-step preparation of both of these ethers via a Diels-Alder reaction. (b) Which of the starting molecules in your answer is the diene, and which is the dienophile? (c) This Diels-Alder reaction gives an 80:20 mixture of B and A. Explain.
60. Give the product(s) of each of the following reactions.
(a) 3-Chloro-1-propene (allyl chloride) + NaOCH₃
(b) cis-2-Butene + NBS, peroxide (ROOR)
(c) 3-Bromo-1-cyclopentene + LDA
(d) trans,trans-2,4-Hexadiene + HCl
(e) trans,trans-2,4-Hexadiene + Br₂, H₂O
(f) 1,3-Cyclohexadiene + methyl propenoate (methyl acrylate)
(g) 1,2-Dimethylcyclohexane + methyl propenoate (methyl acrylate)

61. Propose an efficient synthesis of the cyclohexenol in the margin, beginning exclusively with acyclic starting materials and employing sound retrosynthetic analysis strategy. [Hint: A Diels-Alder reaction may be useful, but take note of structural features in dienes and dienophiles that permit Diels-Alder reactions to work well (Section 14-8).]

62. Dimethyl azodicarboxylate (see margin) takes part in the Diels-Alder reaction as a dienophile. Write the structure of the product of cycloaddition of this molecule with each of the following dienes. (a) 1,3-Butadiene; (b) trans,trans-2,4-hexadiene; (c) 5,5-dimethoxycyclopentadiene; (d) 1,2-dimethylcyclohexane. Ignore the stereochemistry at nitrogen in the products (amines undergo rapid inversion, as we shall see in Section 21-2).

63. Bicyclic diene A reacts readily with appropriate alkenes by the Diels-Alder reaction, whereas diene B is totally unreactive. Explain.

64. Formulate the expected product of each of the following reactions.

65. Which of the reactions shown below will occur under the influence of heat? Light?

66. Explain the following reaction sequence.

67. Give abbreviated structures of each of the following compounds: (a) (E)-1,4-poly-2-methyl-1,3-butadiene [(E)-1,4-polysoprene]; (b) 1,2-poly-2-methyl-1,3-butadiene (1,2-polysoprene); (c) 3,4-poly-2-methyl-1,3-butadiene (3,4-polysoprene); (d) copolymer of 1,3-butadiene and ethenylbenzene
(styrene, \(\text{C}_6\text{H}_5\text{CH} = \text{CH}_2\), SBR, used in automobile tires); (e) copolymer of 1,3-butadiene and propenenitrile (acrylonitrile, \(\text{CH}_2\equiv\text{CHCN}\), latex); (f) copolymer of 2-methyl-1,3-butadiene (isoprene) and 2-methylpropene (butyl rubber, for inner tubes).

68. The structure of the terpene limonene is shown in the margin (see also Exercise 5-29). Identify the two 2-methyl-1,3-butadiene (isoprene) units in limonene. (a) Treatment of isoprene with catalytic amounts of acid leads to a variety of oligomeric products, one of which is limonene. Devise a detailed mechanism for the acid-catalyzed conversion of two molecules of isoprene into limonene. Take care to use sensible intermediates in each step. (b) Two molecules of isoprene may also be converted into limonene by a completely different mechanism, which takes place in the strict absence of catalysts of any kind. Describe this mechanism. What is the name of the reaction?

69. **CHALLENGE** The carbocation derived from geranyl pyrophosphate (Section 14-10) is the biosynthetic precursor of not only camphor, but also limonene (Problem 68) and \(\alpha\)-pinene (Chapter 4, Problem 46). Formulate mechanisms for the formation of the latter two compounds.

70. What is the longest-wavelength electronic transition in each of the following species? Use molecular-orbital designations such as \(n\to\pi^*\), \(\pi_1\to\pi_2\), in your answer. (Hint: Prepare a molecular-orbital energy diagram, like that in Figure 14-16, for each.) (a) 2-Propenyl (allyl) cation; (b) 2-propenyl (allyl) radical; (c) formaldehyde, \(\text{H}_2\text{C} = \text{O}\); (d) \(\text{N}_2\); (e) pentadienyl anion (Problem 55); (f) 1,3,5-hexatriene.

71. Ethanol, methanol, and cyclohexane are commonly used solvents for UV spectroscopy because they do not absorb radiation of wavelength longer than 200 nm. Why not?

72. The ultraviolet spectrum of a \(2 \times 10^{-4}\) M solution of 3-penten-2-one exhibits a \(\pi\to\pi^*\) absorption at 224 nm with \(A = 1.95\) and an \(n\to\pi^*\) band at 314 nm with \(A = 0.008\). Calculate the molar absorptivities (extinction coefficients) for these bands.

73. In a published synthetic procedure, acetone is treated with ethenyl (vinyl) magnesium bromide, and the reaction mixture is then neutralized with strong aqueous acid. The product exhibits the \(^1\text{H}\) NMR spectrum shown below. What is its structure? When the reaction mixture is (improperly) allowed to remain in contact with aqueous acid for too long, an additional new compound is observed. Its \(^1\text{H}\) NMR spectrum has peaks at \(\delta = 1.70\) (s, 3 H), 1.79 (s, 3 H), 2.25 (broad s, 1 H), 4.10 (d, \(J = 8\) Hz, 2 H), and 5.45 (t, \(J = 8\) Hz, 1 H) ppm. What is the structure of the second product, and how did it get there?
Farnesol is a molecule that makes flowers smell good (lilacs, for instance). Treatment with hot concentrated H₂SO₄ converts farnesol first into bisabolene and finally into cadinene, a compound of the essential oils of junipers and cedars. Propose detailed mechanisms for these conversions.

The ratio of 1,2- to 1,4-addition of Br₂ to 1,3-butadiene (Section 14-6) is temperature dependent. Identify the kinetic and thermodynamic products, and explain your choices.

Diels-Alder cycloaddition of 1,3-butadiene with the cyclic dienophile shown in the margin takes place at only one of the two carbon–carbon double bonds in the latter to give a single product. Give its structure and explain your answer. Watch stereochemistry.

This transformation was the initial step in the total synthesis of cholesterol (Section 4-7), completed by R. B. Woodward (see Section 14-9) in 1951. This achievement, monumental for its time, revolutionized synthetic organic chemistry.

As a team, consider the following historic preparation of a tris(1,1-dimethylethyl) derivative of Dewar benzene, B, by the photochemical isomerisation of 1,2,4-tris(1,1-dimethylethyl)benzene by van Tamelen and Pappas (1962). B does not revert to A via either a thermal or a photochemical electrocyclic mechanism. Formulate a mechanism for the conversion of A to B and explain the kinetic robustness of B with respect to the regeneration of A.

How many nodes are present in the LUMO (lowest unoccupied molecular orbital) of 1,3-butadiene?
(a) Zero; (b) one; (c) two; (d) three; (e) four

Arrange the following three chlorides in decreasing order of S₈₁ reactivity.

(a) A > B > C; (b) B > C > A; (c) B > A > C; (d) C > B > A.
80. When cyclopentadiene is treated with tetracyanoethylene, a new product results. Its most likely structure is

(a) \[
\begin{array}{c}
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN}
\end{array}
\]

(c) \[
\begin{array}{c}
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN}
\end{array}
\]

(d) \[
\begin{array}{c}
\text{NC} \\
\text{CN} \\
\text{CN} \\
\text{CN} \\
\text{CN}
\end{array}
\]

81. Which common analytical method will most clearly and rapidly distinguish A from B?

(a) IR spectroscopy; (b) UV spectroscopy; (c) combustion analysis; (d) visible spectroscopy.
A Summary of Organic Reaction Mechanisms

Although we are only just past the halfway point in our survey of organic chemistry, with the completion of Chapter 14 we have in fact now seen examples of each of the three major classes of organic transformations: radical, polar, and pericyclic processes. This section summarizes all of the individual mechanism types that we have so far encountered in each of these reaction classes.

Radical reactions follow chain mechanisms

Radical reactions begin with the generation of a reactive odd-electron intermediate by means of an initiation step and convert starting materials into products through a chain of propagation steps. We have seen both radical substitutions (Chapter 3) and radical additions (Chapter 12). Substitution is capable of introducing a functional group into a previously unfunctionalized molecule; radical addition is an example of functional-group interconversion. These individual subcategories are summarized in Table 1.

Polar reactions constitute the largest class of organic transformations

Interactions of polarized, or charged, species lead to the greatest variety in organic chemistry and to the largest number of reaction mechanism types: the typical chemistry of the organic functional groups. Two mechanisms each for substitution and elimination were first presented in Chapters 6 and 7. Both unimolecular and bimolecular pathways were found to be possible for each mechanism, depending on the structure of the substrate and, in some cases, the reaction conditions. With the introduction of functional groups containing π bonds, we encountered polar addition reactions in two distinct forms: nucleophilic in Chapter 8 and electrophilic in Chapter 12. These processes are summarized in Table 2.

Pericyclic reactions lack intermediates

The final class of reactions is those characterized by cyclic transition states in which there is continuous overlap of a cyclic array of orbitals. These processes take place in a single step, without the intervention of any intermediate species. They may combine multiple components to introduce new rings, as in the Diels-Alder and other cycloaddition reactions, or they may take the form of ring-opening and ring-closing processes—the electrocyclic reactions. Examples are presented in Table 3.

*(Section 14-8)*

*(Section 14-9)*
During the early nineteenth century, the oil used to illuminate the streets of London and other cities came from rendered whale fat (called “blubber”). Eager to determine its components, in 1825 the English scientist Michael Faraday* heated whale oil to obtain a colorless liquid (b.p. 80.1°C, m.p. 5.5°C) that had the empirical formula CH. This compound posed a problem for the theory that carbon had to have four valences to other atoms, and it was of particular interest because of its unusual stability and chemical inertness. The molecule was named benzene and was eventually shown to have the molecular formula C₆H₆. Annual production in the United States alone is 8 million liters per year.

Benzene has four degrees of unsaturation (see Table 11-6), satisfied by a 1,3,5-cyclohexatriene structure (one ring, three double bonds) first proposed by Kekulé† and Loschmidt‡ yet it does not exhibit the kind of reactivity expected for a conjugated triene. In other words, its structure does not seem to correlate with its observed function. However, benzene is not completely unreactive. For example, it reacts with bromine, albeit only in the

---

*Professor Michael Faraday (1791–1867), Royal Institute of Chemistry, London.
†Professor F. August Kekulé; see Section 1-4.
‡Professor Josef Loschmidt (1821–1895), University of Vienna, Austria.
presence of catalytic amounts of a Lewis acid, such as iron tribromide, FeBr₃ (Section 15-9). Surprisingly, the result is not addition but substitution to furnish bromobenzene.

\[
\begin{align*}
\text{Benzene} & \quad + \quad \text{Br}_2 \quad \text{FeBr}_3 \\
& \rightarrow \quad \text{Bromobenzene} \quad \text{(Substitution product)} \\
& \quad + \quad \text{HBr}
\end{align*}
\]

The formation of only one monobromination product is nicely consistent with the sixfold symmetry of the structure of benzene. Further reaction with bromine introduces a second halogen atom to give the three isomeric 1,2-, 1,3-, and 1,4-dibromobenzenes.

\[
\begin{align*}
\text{Br}_2, \text{FeBr}_3 & \rightarrow \quad \text{1,2-Dibromobenzene} \quad \text{1,3-Dibromobenzene} \quad \text{1,4-Dibromobenzene} \\
& \quad \text{(the same as 1,6-dibromobenzene)}
\end{align*}
\]

Historically, the observation of only one 1,2-dibromobenzene product posed another puzzle. If the molecule has a cyclohexatriene topology with alternating single and double bonds, two isomers should have been formed: 1,2- and 1,6-dibromobenzene, in which the two substituents are connected by double or single carbon–carbon bonds, respectively. Kekulé solved this puzzle brilliantly by boldly proposing that benzene should be viewed as a set of two rapidly equilibrating (he used the word “oscillating”) cyclohexatriene isomers, which would render 1,2- and 1,6-dibromobenzene indistinguishable. We now know that this notion was not quite right. In terms of modern electronic theory, benzene is a single compound, best described by two equivalent cyclohexatrienic resonance forms (Section 14-7).

Why does the cyclic array of π electrons in benzene impart unusual stability? How can we quantify this observation? Considering the diagnostic power of NMR (Section 11-4) and electronic spectroscopy (Section 14-11) in establishing the presence of delocalized π systems, can we expect characteristic spectral signals for benzene? In this chapter we shall answer these questions. We look first at the system of naming substituted benzenes, second at the electronic and molecular structure of the parent molecule, and third at the evidence for its unusual stabilizing energy, the aromaticity of benzene. This aromaticity and the special structure of benzene affect its spectral properties and reactivity. We shall see what happens when two or more benzene rings are fused to give more extended π systems. Similarly, we shall compare the properties of benzene with those of other cyclic conjugated polyenes. Finally, we shall study the special mechanism by which substituents are introduced into the benzene ring: electrophilic aromatic substitution.

15-1 Naming the Benzenes

Benzene and its derivatives were originally called aromatic compounds because many of them have a strong aroma. Benzene, even though its odor is not particularly pleasant, is viewed as the “parent” aromatic molecule. Whenever the symbol for the benzene ring with its three double bonds is written, it should be understood to represent only one of a pair of contributing resonance forms. Alternatively, the ring is sometimes drawn as a regular hexagon with an inscribed circle.
Many monosubstituted benzenes are named by adding a substituent prefix to the word “benzene.”

![Benzenes with substituents](image)

Fluorobenzene  Nitrobenzene  (1,1-Dimethylethyl)benzene (tert-Butylbenzene)

There are three possible arrangements of disubstituted benzenes. These arrangements are designated by the prefixes 1,2- (ortho, or o-) for adjacent substituents, 1,3 (meta-, or m-) for 1,3-disubstitution, and 1,4 (para-, or p-) for 1,4-disubstitution. The substituents are listed in alphabetical order.

![Disubstituted benzenes](image)

1,2-Dichlorobenzene  1,2,4-Trinitrobenzene  1-Ethenyl-3-ethyl-5-ethynylbenzene

1-Bromo-2,3-dimethylbenzene  1-Ethyl-4-(1-methylethyl)benzene

To name tri- and more highly substituted derivatives, the six carbons of the ring are numbered so as to give the substituents the lowest set of numbers, as in cyclohexane nomenclature.

![Tri- and more highly substituted benzenes](image)

1-Bromo-2,3-dimethylbenzene  1,2,4-Trinitrobenzene  1-Ethenyl-3-ethyl-5-ethynylbenzene

The following benzene derivatives will be encountered in this book.
We shall employ IUPAC nomenclature for all but three systems. In accord with the indexing preferences of Chemical Abstracts, the common names phenol, benzaldehyde, and benzoic acid will be used in place of their systematic counterparts.

Ring-substituted derivatives of such compounds are named by numbering the ring positions or by using the prefixes \( o\)-, \( m\)-, and \( p\)-. The substituent that gives the compound its base name is placed at carbon 1.

A number of the common names for aromatic compounds refer to their fragrance and natural sources. Several of them have been accepted by IUPAC. As before, a consistent logical naming of these compounds will be adhered to as much as possible, with common names mentioned in parentheses.

The generic term for substituted benzenes is arene. An arene as a substituent is referred to as an aryl group, abbreviated \( \text{Ar} \). The parent aryl substituent is phenyl, \( \text{C}_6\text{H}_5 \). The \( \text{C}_6\text{H}_4\text{CH}_2 \) group, which is related to the 2-propenyl (allyl) substituent (Sections 14-1 and 22-1), is called phenylmethyl (benzyl) (see examples in margin).
Chapter 15

Exercise 15-1

Write systematic and common names of the following substituted benzenes.

(a) ClNO₂
(b) CH₃D
(c) OHNO₂

Exercise 15-2

Draw the structures of (a) (1-methylbutyl)benzene; (b) 1-ethenyl-4-nitrobenzene (p-nitrostyrene); (c) 2-methyl-1,3,5-trinitrobenzene (2,4,6-trinitrotoluene—the explosive TNT; see also Chemical Highlight 16-1).

Exercise 15-3

The following names are incorrect. Write the correct form. (a) 3,5-Dichlorobenzene; (b) o-aminophenyl fluoride; (c) p-fluorobromobenzene.

In Summary Simple monosubstituted benzenes are named by placing the substituent name before the word “benzene.” For more highly substituted systems, 1,2-, 1,3-, and 1,4- (or ortho-, meta-, and para-) prefixes indicate the positions of disubstitution. Alternatively, the ring is numbered, and substituents labeled with these numbers are named in alphabetical order. Many simple substituted benzenes have common names.

15-2 Structure and Resonance Energy of Benzene:
A First Look at Aromaticity

Benzene is unusually unreactive: At room temperature, benzene is inert to acids, H₂, Br₂, and KMnO₄—reagents that readily add to conjugated alkenes (Section 14-6). The reason for this poor reactivity is that the cyclic six-electron arrangement imparts a special stability in the form of a large resonance energy (Section 14-7). We shall first review the evidence for the structure of benzene and then estimate its resonance energy by comparing its heat of hydrogenation with those of model systems that lack cyclic conjugation, such as 1,3-cyclohexadiene.

The benzene ring contains six equally overlapping p orbitals

If benzene were a conjugated triene, a “cyclohexatriene,” we should expect the C–C bond lengths to alternate between single and double bonds. In fact, experimentally, the benzene molecule is a completely symmetrical hexagon (Figure 15-1), with equal C–C bond lengths of 1.39 Å, between the values found for the single bond (1.47 Å) and the double bond (1.34 Å) in 1,3-butadiene (Figure 14-6).

Figure 15-2 shows the electronic structure of the benzene ring. All carbons are sp² hybridized, and each p orbital overlaps to an equal extent with its two neighbors. The resulting delocalized electrons form circular π clouds above and below the ring. The
symmetrical structure of benzene is a consequence of the interplay between the $\sigma$ and $\pi$ electrons in the molecule. The symmetrical $\sigma$ frame acts in conjunction with the delocalized $\pi$ frame to enforce the regular hexagon.

### Benzene is especially stable: heats of hydrogenation

A way to establish the relative stability of a series of alkenes is to measure their heats of hydrogenation (Sections 11-5 and 14-5). We may carry out a similar experiment with benzene, relating its heat of hydrogenation to those of 1,3-cyclohexadiene and cyclohexene. These molecules are conveniently compared because hydrogenation changes all three into cyclohexane.

The hydrogenation of cyclohexene is exothermic by $-28.6$ kcal mol$^{-1}$, a value expected for the hydrogenation of a cis double bond (Section 11-5). The heat of hydrogenation of 1,3-cyclohexadiene ($\Delta H^o = -54.9$ kcal mol$^{-1}$) is slightly less than double that of cyclohexene because of the resonance stabilization in a conjugated diene (Section 14-5); the energy of that stabilization is $(2 \times 28.6) - 54.9 = 2.3$ kcal mol$^{-1}$ ($9.6$ kJ mol$^{-1}$).

\[
\begin{align*}
\text{HC-H} & + \text{H}_2 \xrightarrow{\text{Catalytic Pt}} \text{C}_6\text{H}_{12} \quad \Delta H^o = -28.6 \text{ kcal mol}^{-1} (-120 \text{ kJ mol}^{-1}) \\
\text{HC-H} & + 2 \text{H}_2 \xrightarrow{\text{Catalytic Pt}} \text{C}_6\text{H}_{12} \quad \Delta H^o = -54.9 \text{ kcal mol}^{-1} (-230 \text{ kJ mol}^{-1})
\end{align*}
\]

Armed with these numbers, we can calculate the expected heat of hydrogenation of benzene, as though it were simply composed of three double bonds like that of cyclohexene, but with the extra resonance stabilization of conjugation as in 1,3-cyclohexadiene.

\[
\begin{align*}
\text{HC-H} & + 3 \text{H}_2 \xrightarrow{\text{Catalyst}} \text{C}_6\text{H}_{12} \quad \Delta H^o = ? \\
\Delta H^o &= 3 (\Delta H^o \text{ of hydrogenation of } \text{HC-H}) + 3 \text{ (resonance correction in } \text{HC-H}) \\
&= (3 \times -28.6) + (3 \times 2.3) \text{ kcal mol}^{-1} \\
&= -85.8 + 6.9 \text{ kcal mol}^{-1} \\
&= -78.9 \text{ kcal mol}^{-1} (-330 \text{ kJ mol}^{-1})
\end{align*}
\]
Now let us look at the experimental data. Although benzene is hydrogenated only with difficulty (Section 14-7), special catalysts carry out this reaction, so the heat of hydrogenation of benzene can be measured:

\[
\Delta H^\circ = 49.3 \text{ kcal mol}^{-1} \quad (206 \text{ kJ mol}^{-1})
\]

much less than the

\[
\Delta H^\circ = 78.9 \text{ kcal mol}^{-1} \quad (330 \text{ kJ mol}^{-1})
\]

predicted.

Figure 15-3 summarizes these results. It is immediately apparent that benzene is much more stable than a cyclic triene containing alternating single and double bonds. The difference is the resonance energy of benzene, about 30 kcal mol\(^{-1}\) (126 kJ mol\(^{-1}\)). Other terms used to describe this quantity are delocalization energy, aromatic stabilization, or simply the aromaticity of benzene. The original meaning of the word aromatic has changed with time, now referring to a thermodynamic property rather than to odor.

**In Summary** The structure of benzene is a regular hexagon made up of six \(sp^2\)-hybridized carbons. The C–C bond length is between those of a single and a double bond. The electrons occupying the \(p\) orbitals form a \(\pi\) cloud above and below the plane of the ring. The structure of benzene can be represented by two equally contributing cyclohexatriene resonance forms. Hydrogenation to cyclohexane releases about 30 kcal mol\(^{-1}\) less energy than is expected on the basis of nonaromatic models. This difference is the resonance energy of benzene.

### 15-3 Pi Molecular Orbitals of Benzene

We have just examined the atomic orbital picture of benzene. Now let us look at the molecular orbital picture, comparing the six \(\pi\) molecular orbitals of benzene with those of 1,3,5-hexatriene, the open-chain analog. Both sets are the result of the contiguous overlap of six \(p\) orbitals, yet the cyclic system differs considerably from the acyclic one. A comparison of the energies of the bonding orbitals in these two compounds shows that cyclic conjugation of three double bonds is better than acyclic conjugation.
Cyclic overlap modifies the energy of benzene’s molecular orbitals

Figure 15-4 compares the π molecular orbitals of benzene with those of 1,3,5-hexatriene. The orbitals are shown at equal size for simplicity. Favorable overlap (bonding) takes place between orbital lobes of equal sign. A sign change is indicated by a nodal plane (dashed line). As the number of such planes increases, so does the energy of the orbitals. Note that benzene has two sets of degenerate (equal energy) orbitals, the lower energy set occupied (ψ₂, ψ₃), the other not (ψ₄, ψ₅), as shown in Figure 15-5.

Is the cyclic π system more stable than the acyclic one? To answer this question, we have to compare the combined energies of the three filled bonding orbitals in both. Figure 15-5 shows the answer: The cyclic π system is stabilized relative to the acyclic one. On going from 1,3,5-hexatriene to benzene, two of the bonding orbitals (π₁ and π₃) are lowered in energy and one is raised; the effect of the one raised in energy is more than offset by the two that are lowered.
Inspection of the signs of the wave functions at the terminal carbons of 1,3,5-hexatriene (Figure 15-4) explains why the orbital energies change in this way: Linkage of C1 and C6 causes $p$ orbital overlap that is in phase for $\pi_1$ and $\pi_3$ but out of phase for $\pi_2$.

**Some reactions have aromatic transition states**

The relative stability of six cyclically overlapping orbitals accounts in a simple way for several reactions that proceed readily by what has seemed to be a complicated, concerted movement of three electron pairs: the Diels-Alder reaction (Section 14-8), osmium tetroxide addition to alkenes (Section 12-11), and the first step of ozonolysis (Section 12-12). In all three processes, a transition state occurs with cyclic overlap of six electrons in $\pi$ orbitals (or orbitals with $\pi$ character). This electronic arrangement is similar to that in benzene and is energetically more favored than the alternative, sequential bond breaking and bond making. Such transition states are called aromatic.

**Aromatic Transition States**

![Diagram of aromatic transition states]

**Exercise 15-4**

If benzene were a cyclohexatriene, 1,2-dichloro- and 1,2,4-trichlorobenzene should each exist as two isomers. Draw them.
In Summary Two of the filled \( \pi \) molecular orbitals of benzene are lower in energy than are those in 1,3,5-hexatriene. Benzene is therefore stabilized by considerably more resonance energy than is its acyclic analog. A similar orbital structure also stabilizes aromatic transition states.

### 15-4 Spectral Characteristics of the Benzene Ring

The electronic arrangement in benzene and its derivatives gives rise to characteristic ultraviolet spectra. The hexagonal structure is also manifest in specific infrared bands. What is most striking, cyclic delocalization causes induced ring currents in NMR spectroscopy, resulting in unusual deshielding of hydrogens attached to the aromatic ring. Moreover, the different coupling constants of 1,2- (ortho), 1,3- (meta), and 1,4- (para) hydrogens in substituted benzenes indicate the substitution pattern.

The UV–visible spectrum of benzene reveals its electronic structure

Cyclic delocalization in benzene gives rise to a characteristic arrangement of energy levels for its molecular orbitals (Figure 15-4). In particular, the energetic gap between bonding and antibonding orbitals is relatively large (Figure 15-5). Is this manifested in its electronic spectrum? As shown in Section 14-11, the answer is yes: Compared with the spectra of the acyclic trienes, smaller \( \lambda_{\text{max}} \) values are expected for benzene and its derivatives. You can verify this effect in Figure 15-6: The highest-wavelength absorption for benzene occurs at 261 nm, closer to that of 1,3-cyclohexadiene (259 nm, Table 14-3) than to that of 1,3,5-hexatriene (268 nm).

The ultraviolet and visible spectra of aromatic compounds vary with the introduction of substituents; this phenomenon has been exploited in the tailored synthesis of dyes (Section 22-11). Simple substituted benzenes absorb between 250 and 290 nm. For example, the water-soluble 4-aminobenzoic acid (\( p \)-aminobenzoic acid, or PABA, see margin), \( 4\)-H\(_2\)N–C\(_6\)H\(_4\)–CO\(_2\)H, has a \( \lambda_{\text{max}} \) at 289 nm, with a rather high extinction coefficient of 18,600. Because of this property, it is used in suntan lotions, in which it filters out the dangerous ultraviolet radiation emanating from the sun in this wavelength region. Some individuals cannot tolerate PABA because of an allergic skin reaction, and many recent sun creams use other compounds for protection from the sun (“PABA-free”).

**Figure 15-6** The distinctive ultraviolet spectra of benzene: \( \lambda_{\text{max}}(\epsilon) = 234(30), 238(50), 243(100), 249(190), 255(220), 261(150) \) nm; and 1,3,5-hexatriene: \( \lambda_{\text{max}}(\epsilon) = 247(33,900), 258(43,700), 268(36,300) \) nm. The extinction coefficients \( \epsilon \) of the absorptions of 1,3,5-hexatriene are very much larger than those of benzene; therefore the spectrum at the right was taken at lower concentration.
The infrared spectrum reveals substitution patterns in benzene derivatives

The infrared spectra of benzene and its derivatives show characteristic bands in three regions. The first is at 3030 cm\(^{-1}\) for the phenyl–hydrogen stretching mode. The second ranges from 1500 to 2000 cm\(^{-1}\) and includes aromatic ring C–C stretching vibrations. Finally, a useful set of bands due to C–H out-of-plane bending motions is found between 650 and 1000 cm\(^{-1}\).

![Typical Infrared C–H Out-of-Plane Bending Vibrations for Substituted Benzenes (cm\(^{-1}\))](image)

Their precise location indicates the specific substitution pattern. For example, 1,2-dimethylbenzene (o-xylene) has this band at 738 cm\(^{-1}\), the 1,4 isomer at 793 cm\(^{-1}\); the 1,3 isomer (Figure 15-7) shows two absorptions in this range, at 690 and 765 cm\(^{-1}\).

![Figure 15-7 The infrared spectrum of 1,3-dimethylbenzene (m-xylene). There are two C–H stretching absorptions, one due to the aromatic bonds (3030 cm\(^{-1}\)), the other to saturated C–H bonds (2920 cm\(^{-1}\)). The two bands at 690 and 765 cm\(^{-1}\) are typical of 1,3-disubstituted benzenes.](image)

The mass spectrum of benzene indicates stability

Figure 15-8 depicts the mass spectrum of benzene. Noticeable is the lack of any significant fragmentation, attesting to the unusual stability of the cyclic six-electron framework (Section 15-2). The (M + 1)\(^{13}\) peak has a relative height of 6.8%, as expected for the relative abundance of \(^{13}\)C in a molecule made up of six carbon atoms.

The NMR spectra of benzene derivatives show the effects of an electronic ring current

\(^1\)H NMR is a powerful spectroscopic technique for the identification of benzene and its derivatives. The cyclic delocalization of the aromatic ring gives rise to unusual deshielding, which causes the ring hydrogens to resonate at very low field (\(\delta = 6.5–8.5\) ppm), even lower than the already rather deshielded alkenyl hydrogens (\(\delta = 4.6–5.7\) ppm, see Section 11-4).
The $^1$H NMR spectrum of benzene, for example, exhibits a sharp singlet for the six equivalent hydrogens at $\delta = 7.27$ ppm. How can this strong deshielding be explained? In a simplified picture, the cyclic $\pi$ system with its delocalized electrons may be compared to a loop of conducting metal. When such a loop is exposed to a perpendicular magnetic field ($H_0$), the electrons circulate (called a ring current), generating a new local magnetic field ($h_{\text{local}}$). This induced field opposes $H_0$ on the inside of the loop (Figure 15-9), but it reinforces $H_0$ on the outside—just where the hydrogens are located. Such reinforcement results in deshielding. The effect is strongest close to the ring and diminishes rapidly with increasing distance from it. Thus, benzylic nuclei are deshielded only about 0.4 to 0.8 ppm more than their allylic counterparts, and hydrogens farther away from the $\pi$ system have chemical shifts that do not differ much from each other and are similar to those in the alkanes.
Whereas benzene exhibits a sharp singlet in its NMR spectrum, substituted derivatives may have more complicated patterns. For example, introduction of one substituent renders the hydrogens positioned ortho, meta, and para nonequivalent and subject to mutual coupling. An example is the NMR spectrum of bromobenzene, in which the signal for the ortho hydrogens is shifted slightly downfield relative to that of benzene. Moreover, all the protons are coupled to one another, thus giving rise to a complicated spectral pattern (Figure 15-10).

Figure 15-11 shows the NMR spectrum of 4-(N,N-dimethylamino)benzaldehyde. The large chemical shift difference between the two sets of hydrogens on the ring results in a near-first-order pattern of two doublets. The observed coupling constant is 9 Hz, a typical splitting between ortho protons.

A first-order spectrum revealing all three types of coupling is shown in Figure 15-12. 1-Methoxy-2,4-dinitrobenzene (2,4-dinitroanisole) bears three ring hydrogens with different chemical shifts and distinct splittings. The hydrogen ortho to the methoxy group appears at...
\[ \delta = 7.23 \text{ ppm as a doublet with a 9-Hz ortho coupling. The hydrogen flanked by the two nitro groups (at } \delta = 8.76 \text{ ppm) also appears as a doublet, with a small (3-Hz) meta coupling. Finally, we find the remaining ring hydrogen absorbing at } \delta = 8.45 \text{ ppm as a doublet of doublets because of simultaneous coupling to the two other ring protons. Para coupling between the hydrogens at C3 and C6 is too small (<1 Hz) to be resolved; it is evident as a slight broadening of the resonances of these protons.} \\

In contrast with \(^1\text{H NMR, } \text{\^{13}}\text{C NMR chemical shifts in benzene derivatives are dominated by hybridization and substituent effects. Because the induced ring current flows directly above and below the aromatic carbons (Figure 15-9), they are less affected by it. Moreover, the relatively large } \text{\^{13}}\text{C chemical shift range, about 200 ppm, makes ring current contributions (only a few ppm) less noticeable. Therefore, benzene carbons exhibit chemical shifts similar to those in alkenes, between 120 and 135 ppm when unsubstituted (see margin). Benzene itself exhibits a single line at } \delta = 128.7 \text{ ppm.} \\

### Exercise 15-6

Can the three isomeric trimethylbenzenes be distinguished solely on the basis of the number of peaks in their proton-decoupled \(^{13}\text{C NMR spectra?} \text{ Explain.} 

### Exercise 15-7

**Working with the Concepts: Using Spectral Data to Assign the Structure of a Substituted Benzene**

A hydrocarbon shows a molecular-ion peak in the mass spectrum at \(m/z\ 134\). The associated \([M + 1]\) ion at \(m/z\ 135\) has about 10% of the intensity of the molecular ion. The largest peak in the spectrum is a fragment ion at \(m/z\ 119\). The other spectral data for this compound are as follows: \(^1\text{H NMR (90 MHz)} \ \delta = 7.02\ (\text{broad s, 4 H}), 2.82\ (\text{septet, } J = 7.0\ Hz, 1\ H), 2.28\ (\text{s, 3 H}), \text{ and } 1.22\ \text{ppm (d, } J = 7.0\ Hz, 6\ H); \text{ } ^{13}\text{C NMR } \delta = 21.3, 24.2, 38.9, 126.6, 128.6, 134.8, \text{ and } 145.7\ \text{ppm; IR } \tilde{\nu} = 3030, 2970, 2880, 1515, 1465, \text{ and } 813\ \text{cm}^{-1}; \text{ UV } \lambda_{\text{max}}(\epsilon) = 265(450)\ \text{nm. What is its structure?}

**Strategy**

The spectra supply a lot of information, so your first problem is \textit{Where do I start?} Typically, researchers look at the most important data first—the mass and the \(^1\text{H NMR spectrum—and then use the other spectra as corroborating evidence. The following solution employs only one of several strategies that you could apply. It is often not necessary to dwell in such depth on the information embedded in the individual spectra, and you may find it more useful first to identify the most important pieces, such as the molecular ion in the mass spectrum, the spectral regions and/or splitting patterns in the \(^1\text{H NMR spectrum, the number of } ^{13}\text{C} \text{signals, and a characteristic IR frequency or UV absorption. Whenever you are ready to formulate a (sub)structure, you should do so, and keep validating (or discarding) it as you analyze additional data. Trial and error is the key!}

**Solution**

- The mass spectrum is already quite informative. There are not many hydrocarbons with a molecular ion of \(m/z\ 134\) for which a sensible molecular formula can be derived. For example, the maximum number of carbons has to be less than \(C_{12}\) (mass 144, too large). If it were \(C_{11}\), the molecular formula would have to be \(C_{11}H_{12}\), ruled out by a quick look at the \(^1\text{H NMR spectrum, which shows more than two hydrogens in the molecule. (Besides, how many structures can you formulate with the composition } C_{11}H_{12}?\) The next choice, \(C_{10}H_{14}\), looks good, especially since going down once again in the number of carbons to \(C_9\) would require the presence of 26 hydrogens, an impossible proposition, because the maximum number of hydrogens is dictated by the generic formula \(C_nH_{2n+2}\) (Section 2-4).
- \(C_{10}H_{14}\) means four degrees of unsaturation (Section 11-11), suggesting the presence of a combination of rings, double bonds, and triple bonds. The last option is less likely because of the absence of a band at \(\approx 2200\ \text{cm}^{-1}\) in the IR spectrum (Section 13-3). This leaves us with double bonds and/or rings.
- A check of the \(^1\text{H NMR spectrum does not show signals for normal double bonds, but instead an aromatic peak. A benzene ring has the postulated four degrees of unsaturation. Hence we are dealing with an aromatic compound.}
In Summary

Benzene and its derivatives can be recognized and structurally characterized by their spectral data. Electronic absorptions take place between 250 and 290 nm. The infrared vibrational bands are found at 3030 cm$^{-1}$ (C aromatic – H), from 1500 to 2000 cm$^{-1}$ (C – C), and from 650 to 1000 cm$^{-1}$ (C – H out-of-plane bending). Most informative is NMR, with low-field resonances for the aromatic hydrogens and carbons. Coupling is largest between the ortho hydrogens, smaller in their meta and para counterparts.

**15-5 Polycyclic Aromatic Hydrocarbons**

When several benzene rings are fused together to give more extended $\pi$ systems, the molecules are called **polycyclic benzenoid** or **polycyclic aromatic hydrocarbons (PAHs)**. In these structures, two or more benzene rings share two or more carbon atoms. Do these compounds also enjoy the special stability of benzene? The next two sections will show that they largely do.

There is no simple system for naming these structures, so we shall use their common names. The fusion of one benzene ring to another results in a compound called naphthalene. Further fusion can occur in a linear manner to give anthracene, tetracene, pentacene, and so on,

### **Exercise 15-8**

**Try It Yourself**

Deduce the structure of a compound C$_{16}$H$_{16}$Br$_{2}$ that exhibits the following spectral data: UV $\lambda_{\text{max}}$ (log $\epsilon$) = 226sh(4.33), 235sh(4.55), 248(4.78), 261(4.43), 268(4.44), 277(4.36) nm (sh = shoulder); IR $\tilde{\nu}$ = 3030, 2964, 2933, 2233, 1456, 1362, 1060, 892, 614 cm$^{-1}$; $^1$H NMR (300 MHz) $\delta$ = 7.75 (s, 1 H), 7.45 (s, 1 H), 2.41 (t, $J = 7.0$ Hz, 4 H), 1.64 (sextet, $J = 7.0$, 4 H), 1.06 (t, $J = 7.4$ Hz, 6 H); $^{13}$C NMR $\delta$ = 13.51, 21.54, 21.89, 78.26, 96.68, 124.4, 125.2, 135.2, 136.8 ppm. (Caution: Look closely at the NMR spectra with reference to the molecular formula. Moreover, the IR spectrum contains important information. **Hint:** There is symmetry in the molecule.)
CHEMICAL HIGHLIGHT 15-1

The Allotropes of Carbon: Graphite, Diamond, and Fullerenes

Elements can exist in several forms, called allotropes, depending on conditions and modes of synthesis. Thus, elemental carbon can arrange in more than 40 configurations, most of them amorphous (i.e., noncrystalline), such as coke (Sections 3-3 and 13-10), soot, carbon black (as used in printing ink), and activated carbon (as used in air and water filters). You probably know best two crystalline modifications of carbon: graphite and diamond. Graphite, the most stable carbon allotrope, is a completely fused polycyclic benzenoid system, consisting of layers arranged in an open honeycomb pattern and 3.35 Å apart. The fully delocalized nature of these sheets (all carbons are $sp^2$ hybridized) gives rise to their black color and conductive capability. Graphite’s lubricating property is the result of the ready mutual sliding of its component planes. The “lead” of pencils is graphitic carbon, and the black pencil marks left on a sheet of paper consist of rubbed-off layers of the element.

In the colorless diamond, the carbon atoms (all $sp^3$ hybridized) form an insulating network of cross-linked cyclohexane chair conformers. Diamond is the densest and hardest (least deformable) material known. It is also less stable than graphite, by 0.45 kcal/g C atom, and transforms into graphite at high temperatures or when subjected to high-energy radiation, a little-appreciated fact in the jewelry business.

A spectacular discovery was made in 1985 by Curl, Kroto, and Smalley* (for which they received the Nobel Prize in 1996): buckminsterfullerene, $C_{60}$, a new, spherical allotrope of carbon in the shape of a soccer ball. They found that laser evaporation of graphite generated a variety of carbon clusters in the gas phase, the most abundant of which contained 60 carbon atoms. The best way of assembling such a cluster while satisfying the tetravalency of carbon is to formally “roll up” 20 fused benzene rings and to connect the dangling valencies in such a way as to generate 12 pentagons: a so-called truncated icosahedron with 60 equivalent vertices—the shape of a soccer ball. The molecule was named after Buckminster Fuller† because its shape is reminiscent of the “geodesic domes” designed by him. It is soluble in organic solvents, greatly aiding in the proof of its structure and the exploration of its chemistry. For example, the $^{13}$C NMR spectrum shows a single line at $\delta = 142.7$ ppm, in the expected range (Sections 15-4 and 15-6). Because of its curvature, the constituent benzene rings in $C_{60}$ are strained and the energy content relative to graphite is 10.16 kcal/g C atom. This strain is manifested in a rich chemistry, including electrophilic, nucleophilic, radical, and concerted addition reactions (Chapter 14). The enormous interest spurred by the discovery of $C_{60}$ rapidly led to a number of exciting developments, such as the design of multigram synthetic methods (commercial material sells for as low as $1 per gram); the isolation of many other larger carbon clusters, dubbed “fullerenes.”

*Professor Robert F. Curl (b. 1933), Rice University, Houston, Texas; Professor Harold W. Kroto (b. 1939), University of Sussex, England; Professor Richard E. Smalley (1943–2005), Rice University, Houston, Texas.

†Richard Buckminster Fuller (1895–1983), American architect, inventor, and philosopher.
such as the rugby-ball–shaped C_{70}; chiral systems (e.g., as in C_{64}); isomeric forms; fullerenes encaging host atoms, such as He and metal nuclei (“endohedral fullerenes”); and the synthesis of conducting salts (e.g., Cs_{3}C_{60}, which becomes superconducting at 40 K). Moreover, reexamination of the older literature and newer studies have revealed that C_{60} and other fullerenes are produced simply upon incomplete combustion of organic matter under certain conditions or by varied heat treatments of soot and therefore have probably been “natural products” on our planet since early in its formation.

From a materials point of view, perhaps most useful has been the synthesis of graphitic tubules, so-called nanotubes, based on the fullerene motif. Nanotubes are even harder than diamond, yet elastic, and show unusual magnetic and electrical (metallic) properties. There is the real prospect that nanotubes may replace the computer chip as we currently know it in the manufacture of a new generation of faster and smaller computers (see also Chemical Highlight 14-2). Nanotubes also function as a molecular “packaging material” for other structures, such as metal catalysts and even biomolecules. Thus, carbon in the fullerene modification has taken center stage in the new field of nanotechnology, aimed at the construction of devices at the molecular level.
a series called the **acenes**. **Angular fusion** (“annulation”) results in phenanthrene, which can be further annulated to a variety of other benzenoid polycycles.

![Diagram of acenes](image)

Each structure has its own numbering system around the periphery. A quaternary carbon is given the number of the preceding carbon in the sequence followed by the letters *a*, *b*, and so on, depending on how close it is to that carbon.

### Exercise 15-9

Name the following compounds or draw their structures.

(a) 2,6-Dimethylnaphthalene (b) 1-Bromo-6-nitrophenanthrene (c) 9,10-Diphenylanthracene (d) [Structure image] (e) [Structure image]

**Naphthalene is aromatic: a look at spectra**

In contrast with benzene, which is a liquid, naphthalene is a colorless crystalline material with a melting point of 80°C. It is probably best known as a moth repellent and insecticide, although in these capacities it has been partly replaced by chlorinated compounds such as 1,4-dichlorobenzene (*p*-dichlorobenzene).

The spectral properties of naphthalene strongly suggest that it shares benzene’s delocalized electronic structure and thermodynamic stability. The ultraviolet and NMR spectra are particularly revealing. The ultraviolet spectrum of naphthalene (Figure 15-13) shows a pattern typical of an extended conjugated system, with peaks at wavelengths as long as 320 nm. On the basis of this observation, we conclude that the electrons are delocalized more extensively than in benzene (Section 15-2 and Figure 15-6). Thus, the added four π electrons enter into efficient overlap with those of the attached benzene ring. In fact, it is possible to draw several resonance forms.

![Resonance Forms of Naphthalene](image)

Alternatively, the continuous overlap of the 10 π orbitals and the fairly even distribution of electron density can be shown as in Figure 15-14.

According to these representations, the structure of naphthalene should be symmetric, with planar and almost hexagonal benzene rings and two perpendicular mirror planes bisecting the
molecule. X-ray crystallographic measurements confirm this prediction (Figure 15-15). The C–C bonds deviate only slightly in length from those in benzene (1.39 Å), and they are clearly different from pure single (1.54 Å) and double bonds (1.33 Å).

Further evidence of aromaticity is found in the ¹H NMR spectrum of naphthalene (Figure 15-16). Two symmetric multiplets can be observed at δ = 7.49 and 7.86 ppm, characteristic of aromatic hydrogens deshielded by the ring-current effect of the π-electron loop (see Section 15-4, Figure 15-9). Coupling in the naphthalene nucleus is very similar to that in substituted benzenes: Jₜₜₜ = 7.5 Hz, Jₗₗₗ = 1.4 Hz, and Jₜₚₜ = 0.7 Hz. The ¹³C NMR spectrum shows three lines with chemical shifts that are in the range of other benzene derivatives (see margin). Thus, on the basis of structural and spectral criteria, naphthalene is aromatic.

Exercise 15-10

A substituted naphthalene, C₁₀H₈O₂, gave the following spectral data: ¹H NMR δ = 5.20 (broad s, 2 H), 6.92 (dd, J = 7.5 Hz and 1.4 Hz, 2 H), 7.00 (d, J = 1.4 Hz, 2 H), and 7.60 (d, J = 7.5 Hz, 2 H) ppm; ¹³C NMR δ = 107.5, 115.3, 123.0, 129.3, 136.8, and 155.8 ppm; IR ν = 3300 cm⁻¹ (broad). What is its structure? [Hints: Review the values for Jₜₜₜ, Jₗₗₗ, and Jₜₚₜ in benzene (Section 15-4). The number of NMR peaks is less than maximum.]
Most fused benzenoid hydrocarbons are aromatic

These aromatic properties of naphthalene hold for most of the other polycyclic benzenoid hydrocarbons. It appears that the cyclic delocalization in the individual benzene rings is not significantly perturbed by the fact that they have to share at least one \( \pi \) bond. Linear and angular fusion of a third benzene ring onto naphthalene result in the systems anthracene and phenanthrene. Although isomeric and seemingly very similar, they have different thermodynamic stabilities: Anthracene is about 6 kcal mol\(^{-1}\) (25 kJ mol\(^{-1}\)) less stable than phenanthrene, even though both are aromatic. Enumeration of the various resonance forms of the molecules explains why. Anthracene has only four, and only two contain two fully aromatic benzene rings (red in the structures shown here). Phenanthrene has five, three of which incorporate two aromatic benzenes, one even three benzenes.

**Exercise 15-11**

Draw all the possible resonance forms of tetracene (naphthacene, Section 15-5). What is the maximum number of completely aromatic benzene rings in these structures?
In Summary The physical properties of naphthalene are typical of an aromatic system. Its UV spectrum reveals extensive delocalization of all $\pi$ electrons, its molecular structure shows bond lengths and bond angles very similar to those in benzene, and its $^1$H NMR spectrum reveals deshielded ring hydrogens indicative of an aromatic ring current. Other polycyclic benzenoid hydrocarbons have similar properties and are considered aromatic.

15-6 Other Cyclic Polyenes: Hückel's Rule

The special stability and reactivity associated with cyclic delocalization is not unique to benzene and polycyclic benzenoids. Thus, we shall see that other cyclic conjugated polyenes can be aromatic, but only if they contain $(4n + 2)$ $\pi$ electrons ($n = 0, 1, 2, 3, \ldots$). In contrast, $4n$ $\pi$ circuits may be destabilized by conjugation, or are antiaromatic. This pattern is known as Hückel's* rule. Nonplanar systems in which cyclic overlap is disrupted sufficiently to impart alkenelike properties are classified as nonaromatic. Let us look at some members of this series, starting with 1,3-cyclobutadiene.

1,3-Cyclobutadiene, the smallest cyclic polyene, is antiaromatic

1,3-Cyclobutadiene, a $4n$ $\pi$ system ($n = 1$), is an air-sensitive and extremely reactive molecule in comparison to its analogs 1,3-butadiene and cyclobutene. Not only does the molecule have none of the attributes of an aromatic molecule like benzene, it is actually destabilized through $\pi$ overlap by more than 35 kcal mol$^{-1}$ (146 kJ mol$^{-1}$) and therefore is antiaromatic. As a consequence, its structure is rectangular, and the two diene forms represent isomers, equilibrating through a symmetrical transition state, rather than resonance forms.

Free 1,3-cyclobutadiene can be prepared and observed only at very low temperatures. The reactivity of cyclobutadiene can be seen in its rapid Diels-Alder reactions, in which it can act as both diene (shown in red) and dienophile (blue).

---

*Professor Erich Hückel (1896–1984), University of Marburg, Germany.
Substituted cyclobutadienes are less reactive because of steric protection, particularly if the substituents are bulky; they have been used to probe the spectroscopic features of the cyclic system of four \( \pi \) electrons. For example, in the \(^1\)H NMR spectrum of 1,2,3-tris(1,1-dimethylethyl)cyclobutadiene (1,2,3-tri-tert-butylcyclobutadiene), the ring hydrogen resonates at \( \delta = 5.38 \) ppm, at much higher field than expected for an aromatic system. This and other properties of cyclobutadiene show that it is quite unlike benzene.
Chapter 15

1,3,5,7-Cyclooctatetraene is nonplanar and nonaromatic

Let us now examine the properties of the next higher cyclic polyene analog of benzene, 1,3,5,7-cyclooctatetraene, another 4n π cycle (n = 2). Is it antiaromatic, like 1,3-cyclobutadiene? First prepared in 1911 by Willstätter,* this substance is now readily available from a special reaction, the nickel-catalyzed cyclotetramerization of ethyne. It is a yellow liquid (b.p. 152°C) that is stable if kept cold but that polymerizes when heated. It is oxidized by air, catalytically hydrogenated to cyclooctane, and subject to electrophilic additions and to cycloaddition reactions. This chemical reactivity is diagnostic of a normal polyene (Section 14-7).

Spectral and structural data confirm the ordinary alkene nature of cyclooctatetraene. Thus, the 1H NMR spectrum shows a sharp singlet at δ = 5.68 ppm, typical of an alkene. The molecular-structure determination reveals that cyclooctatetraene is actually nonplanar

These conclusions are based on the observed spectral, X-ray structural, and chemical properties of A–C. For example, the δ value for the center “aromatic” hydrogens in B is 6.13 ppm, reflecting the presence of a diminished benzenoid ring current (Section 15-4). The extent of bond alternation between single (1.50 Å) and double (1.34 Å) bonds is maximal in the center cyclohexatriene of C, and both B and C undergo addition reactions typical of alkenes (Chapter 12). Most convincingly, the ΔH_hydrogenation of C [−83.0 to −84.2 kcal mol⁻¹ (−347 to −352 kJ mol⁻¹)] is that expected for three minimally interacting double bonds, as in the “hypothetical” cyclohexatriene discussed in Section 15-2!

Hydrocarbons like the phenylenes are not only of fundamental interest in efforts to understand aromaticity, but also constitute potential building blocks for a new generation of organic electronic materials (see also Chemical Highlight 14-2). They are flat, like graphite (Chemical Highlight 15-1), but they have activated electronic structures, a prerequisite for electron mobility.

---

*Professor Richard Willstätter (1872–1942), Technical University, Munich, Germany, Nobel Prize 1915 (chemistry).
Only cyclic conjugated polyenes containing \((4n + 2)\) \(\pi\) electrons are aromatic

Unlike cyclobutadiene and cyclooctatetraene, certain higher cyclic conjugated polyenes are aromatic. All of them have two properties in common: They contain \((4n + 2)\) \(\pi\) electrons, and they are sufficiently planar to allow for delocalization.

The first such system was prepared in 1956 by Sondheimer*; \textit{it was} \(1,3,5,7,9,11,13,15,17\)-cyclooctadecanonaene, containing 18 \(\pi\) electrons \((4n + 2, n = 4)\). To avoid the use of such cumbersome names, Sondheimer introduced a simpler system for naming cyclic conjugated

*Professor Franz Sondheimer (1926–1981), University College, London.
polyenes. He named completely conjugated monocyclic hydrocarbons (CH)\(N\) as \([N]\)annulenes, in which \(N\) denotes the ring size. Thus, cyclobutadiene would be called \([4]\)annulene; benzene, \([6]\)annulene; cyclooctatetraene, \([8]\)annulene. The first almost unstrained aromatic system in the series after benzene is \([18]\)annulene.

\[
\text{[18]Annulene} \\
(1,3,5,7,9,11,13,15,17-Cyclooctadecanonaene)
\]

**Exercise 15-15**

The three isomers of \([10]\)annulene shown here have been prepared and exhibit nonaromatic behavior. Why? (Hint: Build models!)

\[
\begin{align*}
\text{cis,cis,cis,cis,cis-} & \quad \text{trans,cis,cis,cis,cis-} \\
\text{[10]Annulene} & \quad \text{trans,cis,trans,cis,cis-} & \quad \text{[10]Annulene}
\end{align*}
\]

\([18]\)Annulene is fairly planar and shows little alternation of the single and double bonds. The extent of the delocalization of its \(\pi\) electrons is pictured in the electrostatic potential map in the margin. Like benzene, it can be described by a set of two equivalent resonance forms. In accord with its aromatic character, the molecule is relatively stable and undergoes electrophilic aromatic substitution. It also exhibits a benzenelike ring-current effect in its \(^1\)\(^H\) NMR spectrum (see Problems 64 and 65).

Since the preparation of \([18]\)annulene, many other annulenes have been made. As long as they are planar and delocalized, those with \((4n + 2)\) \(\pi\) electrons, such as benzene and \([18]\)annulene, are aromatic, whereas those with \(4n\) \(\pi\) electrons, such as cyclobutadiene and \([16]\)annulene, are antiaromatic. When cyclic delocalization is prohibited by angle or steric strain, such as in cyclooctatetraene or \([10]\)annulene (Exercise 15-15), the systems are nonaromatic. Of course, cyclic polyenes in which there is no contiguous array of \(p\) orbitals are not annulenes and therefore also nonaromatic.

**The Annulenes and Other Cyclic Polyenes**

\begin{align*}
\text{Cyclobutadiene:} & \quad \text{planar, antiaromatic} \\
\text{Benzene:} & \quad \text{planar, aromatic} \\
\text{Cyclooctatetraene:} & \quad \text{nonplanar = nonaromatic} \\
\text{[10]Annulene:} & \quad \text{nonplanar = nonaromatic} \\
\text{[12]Annulene:} & \quad \text{planar = antiaromatic}
\end{align*}
The alternating behavior of the annulenes between aromatic and antiaromatic had been predicted earlier by the theoretical chemist Hückel, who formulated this \((4n + 2)\) rule in 1931. Hückel’s rule expresses the regular molecular-orbital patterns calculated for planar, cyclic conjugated polyenes. The \(p\) orbitals mix to give an equal number of \(\pi\) molecular orbitals, as shown in Figure 15-18. For example, the four \(p\) orbitals of cyclobutadiene result in four molecular orbitals, the six \(p\) orbitals of benzene in six molecular orbitals, and so on. These orbitals occur in symmetrically disposed degenerate pairs, except for the lowest bonding and highest antibonding ones, which are unique. Thus, cyclobutadiene has one such degenerate pair of molecular orbitals, benzene has two, and so on. A closed-shell system is possible only if all bonding molecular orbitals are occupied (see Section 1-7), that is, only if there are \((4n + 2)\pi\) electrons. On the other hand, \(4n\) \(\pi\) cycles always contain a pair of singly occupied orbitals, an unfavorable electronic arrangement.

**Figure 15-18** (A) Hückel’s \(4n + 2\) rule is based on the regular pattern of the \(\pi\) molecular orbitals in cyclic conjugated polyenes. They are equally spaced and degenerate, except for the highest and lowest ones, which are unique. (B) Molecular-orbital levels in 1,3-cyclobutadiene. Four \(\pi\) electrons are not enough to result in a closed shell (in other words, doubly filled molecular orbitals), so the molecule is not aromatic. (C) The six \(\pi\) electrons in benzene produce a closed-shell configuration, so benzene is aromatic.

**Exercise 15-16**

On the basis of Hückel’s rule, label the following molecules as aromatic or antiaromatic. (a) [30]Annulene; (b) [20]Annulene; (c) trans-15,16-dihydropyrene; (d) the deep blue (see Figure 14-17) azulene; (e) S-indacene.
In Summary  Cyclic conjugated polyenes are aromatic if their $\pi$ electron count is $4n + 2$. This number corresponds to a completely filled set of bonding molecular orbitals. Conversely, $4n\pi$ systems have open-shell, antiaromatic structures that are unstable, are reactive, and lack aromatic ring-current effects in $^1H$ NMR. Finally, when steric constraints impose nonplanarity, cyclic polyenes behave as nonaromatic alkenes.

15-7 Hückel’s Rule and Charged Molecules

Hückel’s rule also applies to charged molecules, as long as cyclic delocalization can occur. Their aromaticity is reflected in relative thermodynamic and kinetic stability, the observation of ring currents in the NMR experiment, and the absence of bond alternation in crystal structures. This section shows how charged aromatic systems can be prepared.

The cyclopentadienyl anion and the cycloheptatrienyl cation are aromatic

1,3-Cyclopentadiene is unusually acidic [$pK_a \approx 16$; comparable to alcohols (Section 8-3)] because the cyclopentadienyl anion resulting from deprotonation contains a delocalized, aromatic system of six $\pi$ electrons. The negative charge is equally distributed over all five carbon atoms. For comparison, the $pK_a$ of propene is 40. An electrostatic potential map of the molecule is shown in the margin, on a scale that attenuates the otherwise overwhelming effect of the negative charge.

Aromatic Cyclopentadienyl Anion

\[
\begin{align*}
&\text{H} \quad \text{H} \\
&\text{H} \quad \text{H} \\
&\text{H} \quad \text{H}
\end{align*}
\]

\[pK_a = 16\]

In contrast, the cyclopentadienyl cation, a system of four $\pi$ electrons, can be produced only at low temperature and is extremely reactive.

When 1,3,5-cycloheptatriene is treated with bromine, a stable salt is formed, cycloheptatrienyl bromide. In this molecule, the organic cation contains six delocalized $\pi$ electrons, and the positive charge is equally distributed over seven carbons (as shown in the electrostatic potential map in the margin). Even though it is a carbocation, the system is remarkably unreactive, as is expected for an aromatic system. In contrast, the cycloheptatrienyl anion is antiaromatic, as indicated by the much lower acidity of cycloheptatriene ($pK_a = 39$) compared with that of cyclopentadiene.

Aromatic Cycloheptatrienyl Cation

\[
\begin{align*}
&\text{H} \quad \text{H} \\
&\text{H} \quad \text{H} \\
&\text{H} \quad \text{H} \\
&\text{H} \quad \text{H}
\end{align*}
\]

\[\text{Br}_2, \Delta \rightarrow \text{HBr} \]

Exercise 15-17

Draw an orbital picture of (a) the cyclopentadienyl anion and (b) the cycloheptatrienyl cation (consult Figure 15-2).
Nonaromatic cyclic polyenes can form aromatic dianions and dications

Cyclic systems of $4n\pi$ electrons can be converted into their aromatic counterparts by two-electron oxidations and reductions. For example, cyclooctatetraene is reduced by alkali metals to the corresponding aromatic dianion. This species is planar, contains fully delocalized electrons, and is relatively stable. It also exhibits an aromatic ring current in $^1$H NMR.

**Nonaromatic Cyclooctatetraene Forms an Aromatic Dianion**

$$\text{Nonaromatic Cyclooctatetraene Forms an Aromatic Dianion}$$

$$\text{K, THF} \quad \text{Reduction by two electrons} \quad \text{Eight } \pi \text{ electrons, nonaromatic} \quad \Rightarrow \quad \text{Ten } \pi \text{ electrons, aromatic}$$

Similarly, [16]annulene can be either reduced to its dianion or oxidized to its dication, both products being aromatic. On formation of the dication, the configuration of the molecule changes.

$$\text{Aromatic [16]Annulene Dication and Dianion from Antiaromatic [16]Annulene}$$

$$\text{K, THF} \quad \text{Reduction by two electrons} \quad \text{Eighteen } \pi \text{ electrons, aromatic}$$
In Summary Charged species may be aromatic, provided they exhibit cyclic delocalization and obey the $4n + 2$ rule.

15-8 Synthesis of Benzene Derivatives: Electrophilic Aromatic Substitution

In this section we begin to explore the reactivity of benzene, the prototypical aromatic compound. The aromatic stability of benzene makes it relatively unreactive, despite the presence of three formal double bonds. As a result, its chemical transformations require forcing...
conditions and proceed through new pathways. Not surprisingly, however, most of the chemistry of benzene features attack by electrophiles. We shall see in Section 22-4 that attack by nucleophiles is rare but possible, provided that a suitable leaving group is present.

**Benzene undergoes substitution reactions with electrophiles**

Benzene is attacked by electrophiles, but, in contrast to the corresponding reactions of alkenes, this reaction results in substitution of hydrogens—electrophilic aromatic substitution—not addition to the ring.

Under the conditions employed for these processes, nonaromatic conjugated polyenes would rapidly polymerize. However, the stability of the benzene ring allows it to survive. Let us begin with the general mechanism of electrophilic aromatic substitution.

**Electrophilic aromatic substitution in benzene proceeds by addition of the electrophile followed by proton loss**

The mechanism of electrophilic aromatic substitution has two steps. First, the electrophile $E^+$ attacks the benzene nucleus, much as it would attack an ordinary double bond. The resonance stabilized cationic intermediate thus formed then loses a proton to regenerate the aromatic ring. Note two important points in the formulation of this general mechanism. First, always show the hydrogen at the site of the initial electrophilic attack. Second, the positive charge in the resulting cation is indicated by three resonance forms and is located ortho and para to the carbon that has been attacked, a result of the rules for drawing resonance forms (Sections 1-5 and 14-1).

**Mechanism of Electrophilic Aromatic Substitution**

**Step 1.** Electrophilic attack

```
  + E^+X^-   \[\rightarrow\]  + H^+X^-  
```

**Step 2.** Proton loss

```
  + E^+X^-   \[\rightarrow\]  + H^+X^-  
```

The first step in this mechanism is not favored thermodynamically. Although charge is delocalized in the cationic intermediate, the formation of the C–E bond generates an $sp^3$-hybridized carbon in the ring, which interrupts cyclic conjugation: The intermediate is
not aromatic (Figure 15-19). However, the next step, loss of the proton at the \( sp^3 \)-hybridized carbon, regenerates the aromatic ring. This process is more favored than nucleophilic trapping by the anion that accompanies \( E^+ \). Such trapping would give a nonaromatic addition product. The overall substitution is exothermic, because the bonds formed are stronger than the bonds broken.

Figure 15-20 depicts a potential energy diagram in which the first step is rate determining, a kinetic finding that applies to most electrophiles that we shall encounter. The subsequent loss of proton is much faster than initial electrophilic attack because it leads to the aromatic product in an exothermic step, which furnishes the driving force for the overall sequence.

The following sections look more closely at the most common reagents employed in this transformation and the details of the mechanism.

**Exercise 15-22**

We learned in Section 11-5 that the \( \Delta H^\circ \) of the hydrogenation of \( cis \)-2-butene is \(-28.6\) kcal mol\(^{-1}\). Taking this system as a model for a double bond in benzene, estimate the corresponding \( \Delta H^\circ \) of the hydrogenation of benzene to 1,3-cyclohexadiene. What is the difference between these two double bonds? (Hint: Consult Figure 15-3.)

**In Summary** The general mechanism of electrophilic aromatic substitution begins with electrophilic attack by \( E^+ \) to give an intermediate, charge-delocalized but nonaromatic cation in a rate-determining step. Subsequent fast proton loss regenerates the (now substituted) aromatic ring.
### 15-9 Halogenation of Benzene: The Need for a Catalyst

An example of electrophilic aromatic substitution is halogenation. Benzene is normally unreactive in the presence of halogens, because halogens are not electrophilic enough to disrupt its aromaticity. However, the halogen may be activated by Lewis acidic catalysts, such as ferric halides (FeX₃) or aluminum halides (AlX₃), to become a much more powerful electrophile.

How does this activation work? Lewis acids have the ability to accept electron pairs. When a halogen such as bromine is exposed to FeBr₃, the two molecules combine in a Lewis acid-base reaction.

In this complex, the Br–Br bond is polarized, thereby imparting electrophilic character to the bromine atoms. Electrophilic attack on benzene is at the terminal bromine, allowing the other bromine atom to depart with the good leaving group FeBr₄⁻. In terms of electron flow, you can also view this process as a nucleophilic substitution of [Br₂FeBr₃] by the benzene double bond, not unlike an S_N2 reaction (see also Figure 15-21).

The FeBr₄⁻ formed in this step now functions as a base, abstracting a proton from the cyclohexadienyl cation intermediate. This transformation not only furnishes the two products of the reaction, bromobenzene and hydrogen bromide, but also regenerates the FeBr₃ catalyst.

A quick calculation confirms that electrophilic bromination of benzene is exothermic. A phenyl–hydrogen bond (approximately 112 kcal mol⁻¹, Table 15-1) and a bromine molecule (46 kcal mol⁻¹) are lost in the process. Counterbalancing this loss is the formation of a phenyl–bromine bond ($DH^o = 81$ kcal mol⁻¹) and an H–Br bond ($DH^o = 87.5$ kcal mol⁻¹). Thus, the overall reaction is exothermic by $158 - 168.5 = -10.5$ kcal mol⁻¹ (43.9 kJ mol⁻¹).

As in the radical halogenation of alkanes (Section 3-7), the exothermic nature of aromatic halogenation decreases down the periodic table. Fluorination is so exothermic that direct reaction of fluorine with benzene is explosive. Chlorination, on the other hand, is controllable but requires the presence of an activating catalyst, such as aluminum chloride or ferric chloride. The mechanism of this reaction is identical with that of bromination. Finally, electrophilic iodination with iodine is endothermic and thus not normally possible. Much like the radical halogenation of alkanes, electrophilic chlorination and bromination of benzene (and substituted benzenes, Chapter 16) introduces functionality that can be
Chapter 15

In Summary

The halogenation of benzene becomes more exothermic as we proceed from I₂ (endothermic) to F₂ (exothermic and explosive). Chlorinations and brominations are achieved with the help of Lewis acid catalysts that polarize the X–X bond and activate the halogen by increasing its electrophilic power.

15-10 Nitration and Sulfonation of Benzene

In two other typical electrophilic substitutions of benzene, the electrophiles are the nitronium ion (NO₂⁺), leading to nitrobenzene, and sulfur trioxide (SO₃), giving benzenesulfonic acid.

**Benzene is subject to electrophilic attack by the nitronium ion**

To bring about nitration of the benzene ring at moderate temperatures, it is not sufficient just to treat benzene with concentrated nitric acid. Because the nitrogen in HNO₃ has little electrophilic power, it must somehow be activated. Addition of concentrated sulfuric acid serves this purpose by protonating the nitric acid. Loss of water then yields the nitronium ion, NO₂⁺, a strong electrophile, with much of its positive charge residing on nitrogen, as shown in the electrostatic potential map.

---

**Exercise 15-23**

When benzene is dissolved in D₂SO₄, its ¹H NMR absorption at δ = 7.27 ppm disappears and a new compound is formed having a molecular weight of 84. What is it? Propose a mechanism for its formation. (Caution: In all mechanisms of electrophilic aromatic substitution, always draw the H atom at the site of electrophilic attack.)

---

**Exercise 15-24**

Professor G. Olah* and his colleagues exposed benzene to the especially strong acid system HF–SbF₅ in an NMR tube and observed a new ¹H NMR spectrum with absorptions at δ = 5.69 (2 H), 8.22 (2 H), 9.42 (1 H), and 9.58 (2 H) ppm. Propose a structure for this species.

---

*Professor George A. Olah (b. 1927), University of Southern California, Los Angeles, Nobel Prize 1994 (chemistry).
The nitronium ion, with its positively charged nitrogen, then attacks benzene.

**Mechanism of Aromatic Nitration**

\[
\text{H}_2\text{C} + \text{O}^+\text{N}^+\text{O}^- \rightarrow \text{H}_2\text{C-NO}_2 + \text{HOSO}_3\text{H}
\]

Nitrobenzene

Aromatic nitration is the best way to introduce nitrogen-containing substituents into the benzene ring. The nitro group functions as a directing group in further substitutions (Chapter 16) and as a masked amino function (Section 16-5), as unraveled in benzenamines (anilines; Section 22-10).

**Sulfonation is reversible**

Concentrated sulfuric acid does not sulfonate benzene at room temperature. However, a more reactive form, called *fuming sulfuric acid*, permits electrophilic attack by $\text{SO}_3$. Commercial fuming sulfuric acid is made by adding about 8% of sulfur trioxide, $\text{SO}_3$, to the concentrated acid. Because of the strong electron-withdrawing effect of the three oxygens, the sulfur in $\text{SO}_3$ is electrophilic enough to attack benzene directly. Subsequent proton transfer results in the sulfonated product, benzenesulfonic acid.

**Mechanism of Aromatic Sulfonation**

\[
\begin{align*}
\text{H}_2\text{C} + \text{O}^-\text{S}^+\text{O}^- \rightleftharpoons \text{H}_2\text{C-S}^+\text{O}^- \rightleftharpoons \text{H}_2\text{C-S}^-\text{OH}^- \rightleftharpoons \text{H}_2\text{C} + \text{H}_2\text{SO}_4^- \\
\end{align*}
\]

Benzenesulfonic acid

Aromatic sulfonation is readily reversible. The reaction of sulfur trioxide with water to give sulfuric acid is so exothermic that heating benzenesulfonic acid in dilute aqueous acid completely reverses sulfonation.

**Hydration of SO$_3$**

\[
\begin{align*}
\text{S}^+\text{O}^- + \text{H}_2\text{O} \rightarrow \text{S}^-\text{OH}^- + \text{H}^+ \\
\end{align*}
\]

**Reverse Sulfonation: Hydrolysis**

\[
\begin{align*}
\text{H}_2\text{C-S}^-\text{O}^- \xrightarrow{\text{H}_2\text{O, catalytic H}_2\text{SO}_4, 100^\circ\text{C}} \text{H}_2\text{C} + \text{HOSO}_3\text{H} \\
\end{align*}
\]

The reversibility of sulfonation may be used to control further aromatic substitution processes. The ring carbon containing the substituent is blocked from attack, and electrophiles are directed to other positions. Thus, the sulfonic acid group can be introduced to serve as a *directing blocking group* and then removed by reverse sulfonation. Synthetic applications of this strategy will be discussed in Section 16-5.
Benzenesulfonic acids have important uses

Sulfonation of substituted benzenes is used in the synthesis of detergents. Thus, long-chain branched alkylbenzenes are sulfonated to the corresponding sulfonic acids, then converted into their sodium salts. Because such detergents are not readily biodegradable, they have been replaced by more environmentally acceptable alternatives. We shall examine this class of compounds in Chapter 19.

**Aromatic Detergent Synthesis**

\[
\text{R} \xrightarrow{\text{SO}_2\text{H}, \text{H}_2\text{SO}_4} \text{SO}_2\text{H} \text{NaOH} \rightarrow \text{SO}_3^\text{Na}^+ + \text{H}_2\text{O}
\]

Another application of sulfonation is to the manufacture of dyes, because the sulfonic acid group imparts water solubility (Chapter 22).

**Sulfonyl chlorides**, the acid chlorides of sulfonic acids (see Section 9-4), are usually prepared by reaction of the sodium salt of the acid with PCl\(_5\) or SOCl\(_2\).

**Preparation of Benzenesulfonyl Chloride**

\[
\text{SO} + \text{O}^-\text{Na}^+ + \text{PCl}_5 \rightarrow \text{SO}_2\text{Cl} + \text{POCl}_3 + \text{Na}^+\text{Cl}^-
\]

Sulfonyl chlorides are frequently employed in synthesis. For example, recall that the hydroxy group of an alcohol may be turned into a good leaving group by conversion of the alcohol into the 4-methylbenzenesulfonate (\(p\)-toluenesulfonate, tosylate; Sections 6-7 and 9-4).

Sulfonyl chlorides are important precursors of sulfonamides, many of which are chemotherapeutic agents, such as the sulfa drugs discovered in 1932 (Section 9-11). Sulfonamides are derived from the reaction of a sulfonyl chloride with an amine. Sulfa drugs specifically contain the 4-aminobenzenesulfonamide (sulfanilamide) function. Their mode of action is to interfere with the bacterial enzymes that help to synthesize folic acid (Chemical Highlight 25-3), thereby depriving them of an essential nutrient and thus causing bacterial cell death.

**Sulfa Drugs**

- **General structure**
  - \(\text{RHN} \xrightarrow{\text{SO}_2\text{NHR}'}\)

- **Sulfamethoxazole**
  - (Gantanol)
  - (Antibacterial, used to treat urinary infections)

- **Sulfalene**
  - (Kelfizina)
  - (Antiparasitic)

- **Sulfadiazine**
  - (Antimalarial)
About 15,000 sulfa derivatives have been synthesized and screened for antibacterial activity; some have become new drugs. With the advent of newer generations of antibiotics, the medicinal use of sulfa drugs has greatly diminished, but their discovery was a milestone in the systematic development of medicinal chemistry.

**Exercise 15-25**

Formulate mechanisms for (a) the reverse of sulfonation; (b) the hydration of SO₃.

**In Summary** Nitrination of benzene requires the generation of the nitronium ion, NO₂⁺, which functions as the active electrophile. The nitronium ion is formed by the loss of water from protonated nitric acid. Sulfonation is achieved with fuming sulfuric acid, in which sulfur trioxide, SO₃, is the electrophile. Sulfonation is reversed by hot aqueous acid. Benzenesulfonic acids are used in the preparation of detergents, dyes, compounds containing leaving groups, and sulfa drugs.

**15-11 Friedel-Crafts Alkylation**

None of the electrophilic substitutions mentioned so far has led to carbon–carbon bond formation, one of the primary challenges in organic chemistry. In principle, such reactions could be carried out with benzene in the presence of a sufficiently electrophilic carbon-based electrophile. This section introduces the first of two such transformations, the **Friedel-Crafts* reactions**. The secret to the success of both processes is the use of a Lewis acid, usually aluminum chloride. In the presence of this reagent, haloalkanes attack benzene to form alkylbenzenes.

In 1877, Friedel and Crafts discovered that a haloalkane reacts with benzene in the presence of an aluminum halide. The resulting products are the alkylbenzene and hydrogen halide. This reaction, which can be carried out in the presence of other Lewis acid catalysts, is called the **Friedel-Crafts alkylation** of benzene.

The reactivity of the haloalkane increases with the polarity of the C–X bond in the order RI < RBr < RCl < RF. Typical Lewis acids are BF₃, SbCl₅, FeCl₃, AlCl₃, and AlBr₃.

*Professor Charles Friedel (1832–1899), Sorbonne, Paris; Professor James M. Crafts (1839–1917), Massachusetts Institute of Technology, Cambridge, MA.
With primary halides, the reaction begins with coordination of the Lewis acid to the halogen of the haloalkane, much as in the activation of halogens in electrophilic halogenation. This coordination places a partial positive charge on the carbon bearing the halogen, rendering it more electrophilic. Attack on the benzene ring is followed by proton loss in the usual manner, giving the observed product.

Mechanism of Friedel-Crafts Alkylation with Primary Haloalkanes

**Step 1.** Haloalkane activation

\[
\text{RCH}_2\text{X} + \text{AlX}_3 \rightleftharpoons \text{RCH}_2\text{X}^+ \text{AlX}_3
\]

**Step 2.** Electrophilic attack

\[
\text{CH}_2\text{R}^+ + \text{X}^- \rightleftharpoons \text{CH}_2\text{R} + \text{X}^- + \text{AlX}_3
\]

**Step 3.** Proton loss

\[
\text{CH}_2\text{R} + \text{HX} + \text{AlX}_3
\]

With secondary and tertiary halides, free carbocations are usually formed as intermediates; these species attack the benzene ring in the same way as the cation NO\textsubscript{2}\textsuperscript{+}.

**Exercise 15-26**

Write a mechanism for the formation of (1,1-dimethylethyl)benzene (tert-butylbenzene) from 2-chloro-2-methylpropane (tert-butyl chloride), benzene, and catalytic AlCl\textsubscript{3}.

Intramolecular Friedel-Crafts alkylations can be used to fuse a new ring onto the benzene nucleus.

**An Intramolecular Friedel-Crafts Alkylation**

\[
\text{Friedel-Crafts alkylations can be carried out with any starting material that functions as a precursor to a carbocation, such as an alcohol or alkene (Sections 9-2 and 12-3).}
\]
Friedel-Crafts Alkylations Using Other Carbocation Precursors

\[
\text{H} + \text{CH}_3\text{CH}_2\text{CHCH}_3 \xrightarrow{\text{BF}_3, 60^\circ\text{C}, 9 \text{ h}} \text{CH}_3\text{CH}_2\text{CHCH}_3
\]

Forms \(\text{CH}_3\text{CH}_2\text{CHCH}_3\) (1-Methylpropyl)benzene

\[
\text{H} + \text{H}_2\text{C} = \text{CH}_2 \xrightarrow{\text{HF, 0}^\circ\text{C}} \text{H}_2\text{C} = \text{CH}_2\text{C}_6\text{H}_5
\]

Forms \(\text{H}_2\text{C} = \text{CH}_2\text{C}_6\text{H}_5\) Cyclohexylbenzene

Friedel-Crafts vinylations or arylations employing haloalkenes or haloarenes do not work (margin). The reason is that the corresponding cations are energetically inaccessible (Sections 13-9 and 22-10).

Exercise 15-27

In 2007, more than 3.7 million tons of (1-methylethyl)benzene (isopropylbenzene or cumene), an important industrial intermediate in the manufacture of phenol (Section 22-4), was synthesized in the United States from propene and benzene in the presence of phosphoric acid. Write a mechanism for its formation in this reaction.

Exercise 15-28

Working with the Concepts: Reversible Friedel-Crafts Alkylations

Heating any of the three isomeric dimethylbenzenes with HF in the presence of BF₃ to 80°C leads to the equilibrium mixture shown below. Formulate a mechanism for these isomerizations, starting with 1,2-dimethylbenzene and simply using \(\text{H}^+\) to represent the acid. Why is the equilibrium concentration of the 1,2-isomer the lowest?

<table>
<thead>
<tr>
<th>Compound</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>1,2-Dimethylbenzene (o-Xylene)</td>

</tr>
<tr>
<td>1,3-Dimethylbenzene (m-Xylene)</td>
<td>58%</td>
</tr>
<tr>
<td>1,4-Dimethylbenzene (p-Xylene)</td>
<td>24%</td>
</tr>
</tbody>
</table>

Strategy

Topologically, these isomerizations are reminiscent of alkyl shifts, which we studied earlier in connection with carbocation rearrangements (Section 9-3). To generate a carbocation from a benzene derivative, we protonate with acid (Section 15-8, Exercises 15-23 and 15-24). Protonation can occur anywhere on the ring and is reversible.
In Summary

The Friedel-Crafts alkylation produces carbocations (or their equivalents) capable of electrophilic aromatic substitution by formation of aryl–carbon bonds. Haloalkanes, alkenes, and alcohols can be used to achieve aromatic alkylation in the presence of a Lewis or mineral acid.

Solution

- There are three possible distinct delocalized carbocations (write them), but the one of interest results from protonation at the methyl-bearing carbon, shown below as its resonance forms.

- Inspection of the resonance contributors reveals that one of them, form A, looks exactly like the type of carbocation drawn in Section 9-3 for H and alkyl shifts.
- Execution of a methyl shift from A gives a new carbocation, which can deprotonate to give 1,3-dimethylbenzene.

Alternatively, another methyl shift (best visualized from resonance form B) gives C, which then loses a proton to give the 1,4-isomer. Therefore, the mechanism is indeed a sequence of simple alkyl shifts occurring in protonated benzene.

- Why is 1,2-dimethylbenzene the minor component of the mixture? You have probably guessed the answer: steric hindrance, like that seen in cis alkenes (Figure 11-13).

Exercise 15-29

Try It Yourself

Intramolecular Friedel-Crafts alkylation of A provided the expected B, but also 10% of C, suggesting the operation of a competing pathway to the normal mechanism. Propose such a pathway.
Limitations of Friedel-Crafts Alkylations

The alkylation of benzenes under Friedel-Crafts conditions is accompanied by two important side reactions: One is polyalkylation; the other, carbocation rearrangement. Both cause the yield of the desired products to diminish and lead to mixtures that may be difficult to separate.

Consider first polyalkylation. Benzene reacts with 2-bromopropane in the presence of FeBr₃ as a catalyst to give products of both single and double substitution. The yields are low because of the formation of many by-products.

$$\text{H} \quad \text{FeBr}_3 \quad \text{CH(CH}_3\text{)}_2\text{CHBr} \quad \text{H}$$

25%  (1-Methylethyl)benzene  (Isopropylbenzene)

15%  1,4-Bis(1-methylethyl)benzene  (p-Diisopropylbenzene)

The electrophilic aromatic substitutions that we studied in Sections 15-9 and 15-10 can be stopped at the monosubstitution stage. Why do Friedel-Crafts alkylations have the problem of multiple electrophilic substitution? It is because the substituents differ in electronic structure (a subject discussed in more detail in Chapter 16). Bromination, nitration, and sulfonation introduce an electron-withdrawing group into the benzene ring, which renders the product less susceptible than the starting material to electrophilic attack. In contrast, an alkylated benzene is more electron rich than unsubstituted benzene and thus more susceptible to electrophilic attack.

Exercise 15-30

Treatment of benzene with chloromethane in the presence of aluminum chloride results in a complex mixture of tri-, tetra-, and pentamethylbenzenes. One of the components in this mixture crystallizes out selectively: m.p. = 80°C; molecular formula = C₁₀H₁₄; ¹H NMR δ = 2.27 (s, 12 H) and 7.15 (s, 2 H) ppm; ¹³C NMR δ = 19.2, 131.2, and 133.8 ppm. Draw a structure for this product.

The second side reaction in aromatic alkylation is skeletal rearrangement (Section 9-3). For example, the attempted propylation of benzene with 1-bromopropane and AlCl₃ produces (1-methylethyl)benzene.

$$\text{H} \quad \text{AlCl}_3 \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{Br} \quad \text{H}$$

The starting haloalkane rearranges by a hydride shift to the thermodynamically favored 1-methylethyl (isopropyl) cation in the presence of the Lewis acid.
Exercise 15-31

Working with the Concepts: Rearrangements in Friedel-Crafts Alkylations

Attempted alkylation of benzene with 1-chlorobutane in the presence of AlCl₃ gave not only the expected butylbenzene, but also, as a major product, (1-methylpropyl)benzene. Write a mechanism for this reaction.

**Strategy**
First write an equation for the described transformation:

\[
\text{C}_6\text{H}_5 + \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl} \xrightarrow{\text{AlCl}_3, \text{HCl}} \text{Butylbenzene} + (1\text{-Methylpropyl})\text{-benzene}
\]

Consider the mechanism for each product separately.

**Solution**

- The first product is derived readily by a normal Friedel-Crafts alkylation:

\[
\begin{align*}
\text{C}_6\text{H}_5 + \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl} \xrightarrow{\text{AlCl}_3, \text{HCl}} & \quad \text{Butylbenzene} + \text{Cl}^- \xrightarrow{\text{H}^+} \\
& \quad \text{HCl} + \text{AlCl}_3
\end{align*}
\]

- The second product contains a rearranged butyl group, the result of electrophilic aromatic substitution by a secondary butyl cation. The required rearrangement is brought about by a Lewis acid–catalyzed hydride shift:

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH} = \text{CH}_2\text{Cl} + \text{AlCl}_3 & \quad \overset{\text{Cl}^- \xrightarrow{\text{H}^+}}{\xrightarrow{\text{H}^+}} \text{CH}_3\text{CH}_2\text{CH} - \text{CH}_3 + \text{AlCl}_4 \\
\text{CH}_3\text{CH}_2\text{CHCH}_3 + \text{C}_6\text{H}_5 & \quad \overset{\text{Cl}^- \xrightarrow{\text{H}^+}}{\xrightarrow{\text{H}^+}} \text{C}_6\text{H}_5\text{CH} - \text{CH}_2\text{CH}_2\text{Cl} + \text{H}^+
\end{align*}
\]

Exercise 15-32

**Try It Yourself**

Write a mechanism for the following reaction:

\[
\text{Cl} + \text{C}_6\text{H}_5 \xrightarrow{\text{AlCl}_3} \text{C}_6\text{H}_5\text{CH} - \text{CH}_2\text{CH}_2\text{Cl}
\]
Because of these limitations, Friedel-Crafts alkylations are rarely used in synthetic chemistry. Can we improve this process? A more useful reaction would require an electrophilic carbon species that could not rearrange and that would, moreover, deactivate the ring to prevent further substitution. There is such a species—an acylium cation—and it is used in the second Friedel-Crafts reaction, the topic of the next section.

**In Summary** Friedel-Crafts alkylation suffers from overalkylation and skeletal rearrangements by both hydrogen and alkyl shifts.

### 15-13 Friedel-Crafts Acylation (Alkanoylation)

The second electrophilic aromatic substitution that forms carbon–carbon bonds is **Friedel-Crafts alkanoylation** (as in butanoylation, pentanoylation, and so on). A more popular alternative systematic name for this process is **acylation**, which is the term we shall use. IUPAC retains the common naming of formyl for HC= and acetyl for CH₃C= (Section 17-1), hence the corresponding acylations are called formylation and acetylation. Acylation proceeds through the intermediacy of **acylium cations**, with the general structure RC≡O⁺. This section describes how these ions readily attack benzene to form ketones.

**Friedel-Crafts Acylation**

![Diagram of Friedel-Crafts Acylation](image)

**Friedel-Crafts acylation employs acyl chlorides**

Benzene reacts with acyl halides in the presence of an aluminum halide to give 1-phenylalkanones (phenyl ketones). An example is the preparation of 1-phenylethanone (acetophenone) from benzene and acetyl chloride, by using aluminum chloride as the Lewis acid.

![REACTION](image)

**Friedel-Crafts Acylation of Benzene with Acetyl Chloride**

![Reaction](image)

Acyl chlorides are reactive derivatives of carboxylic acids. They are readily formed from carboxylic acids by reaction with thionyl chloride, SOCl₂. (We shall explore this process in detail in Chapter 19.)

**Preparation of an Acyl Chloride**

![Preparation](image)

**Acyl halides react with Lewis acids to produce acylium ions**

The key reactive intermediates in Friedel-Crafts acylations are acylium cations. These species can be formed by the reaction of acyl halides with aluminum chloride. The Lewis acid initially
coordinates to the carbonyl oxygen because of resonance (see Exercise 2-11). This complex is in equilibrium with an isomer in which the aluminum chloride is bound to the halogen. Dissociation then produces the acylium ion, which is stabilized by resonance and, unlike alkyl cations, is not prone to rearrangements. As shown in the electrostatic potential map of the acetyl cation in the margin, most of the positive charge (blue) resides on the carbonyl carbon.

_Acylium Ions from Acyl Halides_

Sometimes carboxylic anhydrides are used in acylation in place of the halides. These molecules react with Lewis acids in a similar way.

_Acylium Ions from Carboxylic Anhydrides_

**Acylium ions undergo electrophilic aromatic substitution**

The acylium ion is sufficiently electrophilic to attack benzene by the usual aromatic substitution mechanism.

_Electrophilic Acylation_

Because the newly introduced acyl substituent is electron withdrawing (see Sections 14-8 and 16-1), it deactivates the ring and protects it from further substitution. Therefore polyacylation does not occur, whereas polyalkylation does (Section 15-12). The effect is accentuated by the formation of a strong complex between the aluminum chloride catalyst and the carbonyl function of the product ketone.

_Lewis Acid Complexation with 1-Phenylalkanones_
This complexation removes the AlCl₃ from the reaction mixture and necessitates the use of at least one full equivalent of the Lewis acid to allow the reaction to go to completion. Aqueous work-up is necessary to liberate the ketone from its aluminum chloride complex, as illustrated by the following examples.

![Chemical reaction diagram]

The selectivity of the Friedel-Crafts acylation for single substitution allows for the selective introduction of carbon chains into the benzene nucleus, a task that proved difficult to accomplish by Friedel-Crafts alkylation (Section 15-12). Since we know how to convert the carbonyl function into an alcohol by hydride reduction (Section 8-6) and the hydroxy substituent into a leaving group that can be further reduced by hydride (Section 8-7), we can synthesize the corresponding hydrocarbon. This sequence of acylation–reduction constitutes a roundabout alkylation protocol that occurs selectively. We shall encounter more direct “deoxygenations” of carbonyl groups later (Sections 16-5 and 17-10).

**Preparation of Hexylbenzene by Hexanoylation–Reduction of Benzene**

![Chemical reaction diagram]

**Exercise 15-33**

The simplest acyl chloride, formyl chloride, H–C–Cl, is unstable, decomposing to HCl and CO upon attempted preparation. Therefore, direct Friedel-Crafts formylation of benzene is impossible. An alternative process, the Gattermann-Koch reaction, enables the introduction of the formyl group, –CHO, into the benzene ring by treatment with CO under pressure, in the presence of HCl and Lewis acid catalysts. For example, methylbenzene (toluene) can be formylated at the para position in this way in 51% yield. The electrophile in this process was observed directly for the first time in 1997 by treating CO with HF–SbF₅ under high pressure: ¹³C NMR: δ 139.5 ppm; IR: ν = 2110 cm⁻¹. What is the structure of this species and the mechanism of its reaction with...
Chapter Integration Problems

15-34. Compound A, C₈H₁₀, was treated with Br₂ in the presence of FeBr₃ to give product B, C₈H₉Br. The spectral data for A and B are given below. Assign structures to A and B.

A: ¹H NMR (CDCl₃): δ = 2.28 (s, 6 H), 6.95 (m, 3 H), 7.11 (td, J = 7.8, 0.4 Hz, 1 H) ppm.
¹³C NMR (CDCl₃): δ = 21.3, 126.1, 128.2, 130.0, 137.7 ppm.
IR (neat) selected values: ν = 3016, 2946, 2921, 769, 691 cm⁻¹.
UV (CH₃OH): λ_max = 261 nm.

B: ¹H NMR (CDCl₃): δ = 2.25 (s, 3 H), 2.34 (s, 3 H), 6.83 (dd, J = 7.9, 2.0 Hz, 1 H), 7.02 (dd, J = 2.0, 0.3 Hz, 1 H), 7.36 (dd, J = 7.9, 0.3 Hz, 1 H) ppm.
¹³C NMR (CDCl₃): δ = 20.7, 22.7, 121.6, 128.1, 131.6, 132.1, 136.9, 137.4 ppm.
IR (neat) selected values: ν = 3012, 2961, 2923 cm⁻¹.
UV (CH₃OH): λ_max = 265 nm.

SOLUTION

A cursory glance at the molecular formulas and the spectral data confirms that bromination of a substituted benzene is taking place: One hydrogen in A (C₈H₁₀) is replaced by a bromine atom (C₈H₉Br), and both compounds show aromatic peaks in both the ¹H and ¹³C NMR spectra. The IR spectra confirm this assignment by the presence of a C₆H₄–H stretching signal for A and B, and the UV spectra are consistent with a phenyl chromophore. A closer look reveals that both compounds contain two methyl groups attached to the aromatic system at δ ≈ 2.3 ppm (Table 10-2). Subtracting 2 × CH₃ from C₈H₁₀ (A) leaves C₆H₆, a phenyl fragment: Compound A must be a dimethylbenzene isomer. Consequently, B must be a bromo(dimethyl) benzene isomer. The question for both is: Which isomer? To find the answers, it is useful to write down all the possible options. For A, there are three isomers: ortho-, meta-, and para-dimethylbenzene (xylene; Section 15-1).
Is it possible to distinguish between them on the basis of NMR spectroscopy? The answer is yes, because of the varying degrees of symmetry inherent to each ring. Thus, the ortho isomer should exhibit only two types of aromatic hydrogens (two each) and three phenyl carbon signals in the respective NMR spectra. The para isomer is even more symmetrical, containing only one type of benzene hydrogen and two types of phenyl carbons. Both of these predictions are incompatible with the observed data for A. Thus, while some of the aromatic hydrogens are unresolved and appear as a multiplet (3 H), the presence of a single unique proton at $\delta = 7.11$ ppm is consistent only with meta-dimethylbenzene. (Which one of the two possible unique hydrogens gives rise to this signal? \textbf{Hint:} Look at the coupling pattern of the $^1$H NMR signal.) Similarly, this isomer contains four distinct ring carbons, as seen in the $^{13}$C NMR spectrum.

Armed with the knowledge of the structure of A, we can now formulate the possible products of its electrophilic aromatic bromination:

\textbf{The Three Possible Structures for B}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure}
\caption{Structures of the possible products of the reaction of A with Br$_2$.}
\end{figure}

Which one is B? Symmetry (or lack thereof) provides the answer. The $^1$H NMR spectrum of B reveals two distinct methyl groups and three separate ring hydrogen resonances, whereas the $^{13}$C NMR spectrum exhibits two methyl carbon peaks, in addition to six aromatic carbon absorptions. The combined data are only compatible with the center structure above, 1-bromo-2,4-dimethylbenzene. The reaction of A to provide B is therefore:

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure}
\caption{Mechanism for the electrophilic aromatic bromination of A.}
\end{figure}

Why does single bromination of A give only isomer B? Read on to Chapter 16! But first try Problem 43 for more practice with spectroscopy.

\textbf{15-35.} The insecticide DDT (see Chemical Highlight 3-2) has been made in ton quantities by treatment of chlorobenzene with 2,2,2-trichloroacetaldehyde in the (required) presence of concentrated H$_2$SO$_4$. Formulate a mechanism for this reaction.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure}
\caption{Mechanism for the synthesis of DDT.}
\end{figure}
Chapter 15

SOLUTION

Let us first take an inventory of what is given:

1. The product is composed of two subunits derived from chlorobenzene and one subunit derived from the aldehyde.

2. In the process, the starting materials—two chlorobenzenes and one trichloroacetaldehyde, which amount to a combined atomic total of $\text{C}_{14}\text{H}_{11}\text{Cl}_{5}\text{O}$—turn into DDT, with the molecular formula $\text{C}_{14}\text{H}_{9}\text{Cl}_{5}$. Conclusion: The elements of $\text{H}_2\text{O}$ are extruded.

3. Topologically, the transformation constitutes a replacement of an aromatic hydrogen by an alkyl carbon substituent, strongly implicating the occurrence of a Friedel-Crafts alkylation (Section 15-12).

We can now address the details of a possible mechanism. Friedel-Crafts alkylations require positively polarized or cationic carbon electrophiles. In our case, inspection of the product suggests that the carbonyl carbon in the aldehyde is the electrophilic aggressor. This carbon is positively polarized to begin with, because of the presence of the electron-withdrawing oxygen and chlorine substituents. A nonoctet dipolar resonance form (Section 1-5) illustrates this point.

**Activation of 2,2,2-Trichloroacetaldehyde as an Electrophile**

In the presence of strong acid, protonation of the negatively polarized oxygen of the neutral species generates a positively charged intermediate in which the electrophilic character of the carbonyl carbon is further accentuated in the resonance form depicting a hydroxy carbocation. The stage is now set for the first of two electrophilic aromatic substitution steps (Section 15-11).

**First Electrophilic Aromatic Substitution Step**

The product of this step is an alcohol, which can be readily converted into the corresponding carbocation by acid (Section 9-2), partly because the ensuing charge is resonance stabilized by the adjacent benzene ring (benzylic resonance, Section 22-1, related to allylic resonance, Sections 14-1 and 14-3). The cation subsequently enables the second electrophilic aromatic substitution step to provide DDT. Another more advanced mechanism is the subject of Problem 66.

**Alcohol Activation and Second Electrophilic Aromatic Substitution Step**
New Reactions

1. Hydrogenation of Benzene (Section 15-2)

\[
\text{H}_2, \text{catalyst} \quad \xrightarrow{} \quad \text{hydrogenated benzene}
\]

\[\Delta H^\circ = -49.3 \text{ kcal mol}^{-1}\]

Resonance energy: \(-30 \text{ kcal mol}^{-1}\)

Electrophilic Aromatic Substitution

2. Chlorination, Bromination, Nitration, and Sulfonation (Sections 15-9 and 15-10)

\[
\text{C}_6\text{H}_6 \xrightarrow{X, \text{FeX}_3} \text{C}_6\text{H}_5X + \text{HX} \quad X = \text{Cl, Br}
\]

\[
\text{C}_6\text{H}_6 \xrightarrow{\text{HNO}_3, \text{H}_2\text{SO}_4} \text{C}_6\text{H}_5\text{NO}_2 + \text{H}_2\text{O}
\]

\[
\text{C}_6\text{H}_6 \xrightarrow{\text{SO}_3, \text{H}_2\text{SO}_4} \text{C}_6\text{H}_5\text{SO}_3\text{H} \quad \text{Reversible}
\]

3. Benzenesulfonyl Chlorides (Section 15-10)

\[
\text{C}_6\text{H}_5\text{SO}_3\text{Na} + \text{POCl}_3 \xrightarrow{} \text{C}_6\text{H}_5\text{SO}_2\text{Cl} + \text{POCl}_3 + \text{NaCl}
\]

4. Friedel-Crafts Alkylation (Section 15-11)

\[
\text{C}_6\text{H}_6 + \text{RX} \xrightarrow{\text{AlCl}_3} \text{C}_6\text{H}_5\text{R} + \text{HX} + \text{overalkylated product}
\]

\[\text{R}^+ \text{ is subject to carbocation rearrangements}\]

Intramolecular

Alcohols and alkenes as substrates

\[
\text{C}_6\text{H}_5 + \text{RCHR'} \xrightarrow{\text{BF}_3, 60^\circ \text{C}} \text{C}_6\text{H}_5\text{CHR}
\]

\[\text{C}_6\text{H}_5 + \text{RCH}==\text{CH}_2 \xrightarrow{\text{HF, 0}^\circ \text{C}} \text{C}_6\text{H}_5\text{CHCH}_3\]

5. Friedel-Crafts Acylation (Section 15-13)

Acyl halides

\[
\text{C}_6\text{H}_6 + \text{RCCl} \xrightarrow{1. \text{AlCl}_3, 2. \text{H}_2\text{O}} \text{C}_6\text{H}_5\text{CR} + \text{HCl}
\]

Requires at least one full equivalent of Lewis acid

Anhydrides

\[
\text{C}_6\text{H}_6 + \text{CH}_3\text{COCCH}_3 \xrightarrow{1. \text{AlCl}_3, 2. \text{H}_2\text{O}} \text{C}_6\text{H}_5\text{CCH}_3 + \text{CH}_3\text{COOH}
\]
Important Concepts

1. Substituted benzenes are named by adding prefixes or suffixes to the word benzene. Disubstituted systems are labeled as 1,2-, 1,3-, and 1,4- or ortho, meta, and para, depending on the location of the substituents. Many benzene derivatives have common names, sometimes used as bases for naming their substituted analogs. As a substituent, an aromatic system is called aryl; the parent aryl substituent, C₆H₅, is called phenyl; its homolog C₆H₅CH₂ is named phenylmethyl (benzyl).

2. Benzene is not a cyclohexatriene but a delocalized cyclic system of six π electrons. It is a regular hexagon of six sp²-hybridized carbons. All six π orbitals overlap equally with their neighbors. Its unusually low heat of hydrogenation indicates a resonance energy or aromaticity of about 30 kcal mol⁻¹ (126 kJ mol⁻¹). The stability imparted by aromatic delocalization is also evident in the transition state of some reactions, such as the Diels-Alder cycloaddition and ozonolysis.

3. The special structure of benzene gives rise to unusual UV, IR, and NMR spectral data. ¹H NMR spectroscopy is particularly diagnostic because of the unusual deshielding of aromatic hydrogens by an induced ring current. Moreover, the substitution pattern is revealed by examination of the o, m, and p coupling constants.

4. The polycyclic benzenoid hydrocarbons are composed of linearly or angularly fused benzene rings. The simplest members of this class of compounds are naphthalene, anthracene, and phenanthrene.

5. In these molecules, benzene rings share two (or more) carbon atoms, whose π electrons are delocalized over the entire ring system. Thus, naphthalene shows some of the properties characteristic of the aromatic ring in benzene: The electronic spectra reveal extended conjugation, ¹H NMR exhibits deshielding ring-current effects, and there is little bond alternation.

6. Benzene is the smallest member of the class of aromatic cyclic polyenes following Hückel’s (4n + 2) rule. Most of the 4n π systems are relatively reactive anti- or nonaromatic species. Hückel’s rule also extends to aromatic charged systems, such as the cyclopentadienyl anion, cycloheptatrienyl cation, and cyclooctatetraene diion.

7. The most important reaction of benzene is electrophilic aromatic substitution. The rate-determining step is addition by the electrophile to give a delocalized hexadienyl cation in which the aromatic character of the original benzene ring has been lost. Fast deprotonation restores the aromaticity of the (now substituted) benzene ring. Exothermic substitution is preferred over endothermic addition. The reaction can lead to halo- and nitrobenzenes, benzenesulfonic acids, and alkylated and acylated derivatives. When necessary, Lewis acid (chlorination, bromination, Friedel-Crafts reaction) or mineral acid (nitration, sulfonation) catalysts are applied. These enhance the electrophilic power of the reagents or generate strong, positively charged electrophiles.

8. Sulfonation of benzene is a reversible process. The sulfonic acid group is removed by heating with dilute aqueous acid.

9. Benzenesulfonic acids are precursors of benzenesulfonyl chlorides. The chlorides react with alcohols to form sulfonic esters containing useful leaving groups and with amines to give sulfonamides, some of which are medicinally important.

10. In contrast with other electrophilic substitutions, including Friedel-Crafts acylations, Friedel-Crafts alkylations activate the aromatic ring to further electrophilic substitution, leading to product mixtures.

Problems

36. Name each of the following compounds by using the IUPAC system and, if possible, a reasonable common alternative. (Hint: The order of functional group precedence is –COOH > –CHO > –OH > –NH₂.)

![Chemical Structures](attachment:image.png)
37. Give a proper IUPAC name for each of the following commonly named substances.

(a) Durene

(b) Hexylresorcinol

(c) Eugenol

38. Draw the structure of each of the following compounds. If the name itself is incorrect, give a correct systematic alternative. (a) o-Chlorobenzaldehyde; (b) 2,4,6-trihydroxybenzene; (c) 4-nitro-o-xylene; (d) m-isopropylbenzoic acid; (e) 4,5-dibromoaniline; (f) p-methoxy-m-nitroacetophenone.

39. The complete combustion of benzene is exothermic by approximately −789 kcal mol⁻¹. What would this value be if benzene lacked aromatic stabilization?

40. The ¹H NMR spectrum of naphthalene shows two multiplets (Figure 15-16). The upfield absorption (δ = 7.49 ppm) is due to the hydrogens at C2, C3, C6, and C7, and the downfield multiplet (δ = 7.86 ppm) is due to the hydrogens at C1, C4, C5, and C8. Explain why one set of hydrogens is deshielded more than the other.

41. Complete hydrogenation of 1,3,5,7-cyclooctatetraene is exothermic by −101 kcal mol⁻¹. Hydrogenation of cyclooctene proceeds with Δ𝐻^° = −23 kcal mol⁻¹. Are these data consistent with the description of cyclooctatetraene presented in the chapter?

42. Which of the following structures qualify as being aromatic, according to Hückel’s rule?

(a) 

(b) 

(c) 

(d) 

(e) 

(f) 

(g)
43. Following are spectroscopic and other data for several compounds. Propose a structure for each of them. (a) Molecular formula = C₆H₄Br₂. ¹H NMR spectrum A. ¹³C NMR: 3 peaks. IR: $\nu = 745$ (s, broad) cm⁻¹. UV: $\lambda_{max}(e) = 263(150)$, 270(250), and 278(180) nm. (b) Molecular formula = C₇H₇BrO. ¹H NMR spectrum B. ¹³C NMR: 7 peaks. IR: $\nu = 765$ (s) and 680 (s) cm⁻¹. (c) Molecular formula = C₉H₁₁Br. ¹H NMR spectrum C. ¹³C NMR: $\delta = 20.6$ (CH₃), 23.6 (CH₃), 124.2 (C quaternary), 129.0 (CH), 136.0 (C quaternary), and 137.7 (C quaternary) ppm.

44. Both methylbenzene (toluene) and 1,6-heptadiyne have molecular formulas of C₇H₈ and molecular masses of 92. Which of the two mass spectra shown below corresponds to which compound? Explain your reasoning.
45. (a) Is it possible to distinguish the three isomers of dimethoxybenzene solely on the basis of the number of peaks in their proton-decoupled $^{13}$C NMR spectra? Explain. (b) How many different isomers of dimethoxynaphthalene exist? How many peaks should each one exhibit in the proton-decoupled $^{13}$C NMR spectrum?

46. The species resulting from the addition of benzene to HF–SbF$_5$ (Exercise 15-24) shows the following $^{13}$C NMR absorptions: $\delta = 52.2$(CH$_2$), 136.9(CH), 178.1(CH), and 186.6(CH) ppm. The signals at $\delta = 136.9$ and $\delta = 186.6$ are twice the intensity of the other peaks. Assign this spectrum.

47. Reaction review. Without consulting the Reaction Road Map on p. 721, suggest a reagent to convert benzene into each of the following compounds.

48. Give the expected major product of addition of each of the following reagent mixtures to benzene. (Hint: Look for analogies to the reactions presented in this chapter.)

(a) Cl$_2$ + AlCl$_3$
(b) T$_2$O + T$_2$SO$_4$ (T = tritium, $^3$H)
(c) (CH$_3$)$_3$COH + H$_3$PO$_4$
(d) N$_2$O$_4$ (which tends to dissociate into NO$_2^+$ and NO$_3^-$)
(e) (CH$_3$)$_3$C=CH$_2$ + H$_3$PO$_4$
(f) (CH$_3$)$_3$CCH$_2$CH$_2$Cl + AlCl$_3$
(g) (CH$_3$)$_3$CCH$_2$CH$_2$C(CH$_3$)$_2$ + AlBr$_3$
(h) H$_3$C – COCl + AlCl$_3$

49. Write mechanisms for reactions (c) and (f) in Problem 48.

50. Hexadeuteriobenzene, C$_6$D$_6$, is a very useful solvent for $^1$H NMR spectroscopy because it dissolves a wide variety of organic compounds and, being aromatic, is very stable. Suggest a method for the preparation of C$_6$D$_6$.

51. Propose a mechanism for the sulfonation of benzene using chlorosulfuric acid, ClSO$_3$H (in the margin).
52. Benzene reacts with sulfur dichloride, \( \text{SCl}_2 \), in the presence of \( \text{AlCl}_3 \) to give diphenyl sulfide, \( \text{C}_6\text{H}_5\text{–S–C}_6\text{H}_5 \). Propose a mechanism for this process.

53. (a) \( 3\text{-Phenylpropanoyl chloride, C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{COCl} \), reacts with \( \text{AlCl}_3 \) to give a single product with the formula \( \text{C}_9\text{H}_8\text{O} \) and an \( ^1\text{H} \) NMR spectrum with signals at \( \delta = 2.53 \) (t, \( J = 8 \text{ Hz} \), 2 H), 3.02 (t, \( J = 8 \text{ Hz} \), 2 H), and 7.2–7.7 (m, 4 H) ppm. Propose a structure and a mechanism for the formation of this product.

(b) The product of the process described in (a) is subjected to the following reaction sequence: (1) \( \text{NaBH}_4 \), \( \text{CH}_3\text{CH}_2\text{OH} \); (2) Conc. \( \text{H}_2\text{SO}_4 \), 100°C; (3) \( \text{H}_2 \), Pd–C, \( \text{CH}_3\text{CH}_2\text{OH} \). The final product exhibits five resonance lines in its \( ^{13}\text{C} \) NMR spectrum. What is the structure of the substance formed after each of the steps in this sequence?

54. The text states that alkylated benzenes are more susceptible to electrophilic attack than is benzene itself. Draw a graph like that in Figure 15-20 to show how the energy profile of electrophilic substitution of methylbenzene (toluene) would differ quantitatively from that of benzene.

55. Like haloalkanes, haloarenes are readily converted into organometallic reagents, which are sources of nucleophilic carbon.

\[ \begin{align*}
\text{Br} & \quad \text{Mg, (CH}_3\text{CH}_2\text{),O, 25°C} \\
\text{Cl} & \quad \text{Mg, THF, 50°C}
\end{align*} \]

The chemical behavior of these reagents is very similar to that of their alkyl counterparts. Write the main product of each of the following sequences.

\( \begin{align*}
\text{C}_6\text{H}_5\text{Br} & \quad 1. \text{Li, (CH}_3\text{CH}_2\text{),O} \\
& \quad 2. \text{CH}_3\text{CHO} \\
& \quad 3. \text{H}_2\text{O} \\
\text{C}_6\text{H}_5\text{Cl} & \quad 1. \text{Mg, THF} \\
& \quad 2. \text{H}_2\text{C}–\text{CH}_2 \\
& \quad 3. \text{H}_2\text{O}
\end{align*} \)

56. Give efficient syntheses of the following compounds, beginning with benzene. (a) \( 1\text{-Phenyl-1-heptanol} \); (b) \( 2\text{-phenyl-2-butanol} \); (c) \( 1\text{-phenyloctane} \). (Hint: Use a method from Section 15-14. Why will Friedel-Crafts alkylation not work?)

57. Vanillin, whose structure is shown in the margin and is the subject of the Chapter Opening, is a benzene derivative with several functional groups, each one of which displays its characteristic reactivity. What would you expect to be the products of reaction of vanillin with each of the following reagents?

(a) \( \text{NaBH}_4 \), \( \text{CH}_3\text{CH}_2\text{OH} \)
(b) \( \text{NaOH} \), then \( \text{CH}_3\text{I} \)

Vanillin is obtained by extraction from the seed pods of plants in the \textit{Vanilla} genus in a process that dates back at least 500 years: The Mexican Aztecs used it to flavor xocoatl, a chocolate drink. Cortez discovered it in the court of Montezuma and was responsible for introducing it to Europe. Increasing demand for vanillin necessitated development of synthetic procedures, which involve extraction of related compounds from other plant-derived sources. One of the most important of these sources is the wood-derived waste from the manufacture of paper. The conversion of eugenol (an extract from cloves) into vanillin is very similar chemically. First, treatment
of eugenol with KOH at 150°C in a high-boiling solvent causes positional isomerization of its side-chain double bond:

\[
\begin{align*}
\text{Eugenol} & \quad \xrightarrow{\text{KOH, 150°C, 1.5 h}} \quad \text{Vanillin}
\end{align*}
\]

Subsequently, oxidative cleavage, (see Section 12-12) completes the synthesis of vanillin.

\(\text{(c)}\) Propose a mechanism for the isomerization depicted in the scheme.

58. Because of cyclic delocalization, structures A and B shown here for o-dimethylbenzene (o-xylene) are simply two resonance forms of the same molecule. Can the same be said for the two dimethylcyclooctatetraene structures C and D? Explain.

59. The energy levels of the 2-propenyl (allyl) and cyclopropenyl \(\pi\) systems (see margin) are compared qualitatively in the diagram below. (a) Draw the three molecular orbitals of each system, using plus and minus signs and dotted lines to indicate bonding overlap and nodes, as in Figure 15-4. Does either of these systems possess degenerate molecular orbitals? (b) How many \(\pi\) electrons would give rise to the maximum stabilization of the cyclopropenyl system, relative to 2-propenyl (allyl)? (Compare Figure 15-5, for benzene.) Draw Lewis structures for both systems with this number of \(\pi\) electrons and any appropriate atomic charges. (e) Could the cyclopropenyl system drawn in (b) qualify as being “aromatic”? Explain.

60. **CHALLENGE** 2,3-Diphenylcyclopropenone (see structure in the margin) forms an addition product with HBr that exhibits the properties of an ionic salt. Suggest a structure for this product and a reason for its existence as a stable entity.

61. **CHALLENGE** Is cyclobutadiene dication \((\text{C}_4\text{H}_4)^{2+}\) aromatic according to Hückel’s rule? Sketch its \(\pi\) molecular orbital diagram to illustrate.

62. All the molecules shown below are examples of “fulvenes,” or methylenecyclopentadienes.

\[
\begin{align*}
\text{5-Methylene-1,3-cyclopentadiene} & \quad \text{6-Dimethylamino-fulvene} & \quad \text{6,6-Dimethylfulvene} & \quad \text{6,6-Diphenylfulvene}
\end{align*}
\]
Chapter 15
Benzene and Aromaticity

(a) One of these structures is considerably more acidic than the others, with a $pK_a$ around 20. Identify it and its most acidic hydrogen(s), and explain why it is an unusually strong acid for a molecule with only carbon-hydrogen bonds.

(b) None of the 7-methylene-1,3,5-cycloheptatrienes that correspond to the fulvene structures above show any unusual acidity. Explain.

63. A characteristic reaction of fulvenes is nucleophilic addition. To which carbon in a fulvene would you expect nucleophiles to add, and why?

64. **CHALLENGE** (a) The $^1$H NMR spectrum of [18]annulene shows two signals, at $\delta = 9.28$ (12 H) and $-2.99$ (6 H) ppm. The negative chemical shift value refers to a resonance *upfield* (to the right) of (CH$_3$)$_4$Si. Explain this spectrum. (Hint: Consult Figure 15-9.) (b) The unusual molecule 1,6-methano[10]annulene (shown in the margin) exhibits two sets of signals in the $^1$H NMR spectrum at $\delta = 7.10$ (8 H) and $-0.50$ (2 H) ppm. Is this result a sign of aromatic character?

65. The $^1$H NMR spectrum of the most stable isomer of [14]annulene shows two signals, at $\delta = -0.61$ (4 H) and 7.88 (10 H) ppm. Two possible structures for [14]annulene are shown here. How do they differ? Which one corresponds to the NMR spectrum described?

66. Explain the following reaction and the indicated stereochemical result mechanistically.

67. Metal-substituted benzenes have a long history of use in medicine. Before antibiotics were discovered, phenylarsenic derivatives were the only treatment for a number of diseases. Phenylmercury compounds continue to be used as fungicides and antimicrobial agents to the present day. On the basis of the general principles explained in this chapter and your knowledge of the characteristics of compounds of Hg$^{2+}$ (see Section 12-7), propose a sensible synthesis of phenylmercury acetate (shown in the margin).

Team Problem

68. As a team, discuss the following complementary experimental results as they pertain to the mechanism of electrophilic aromatic substitution.

(a) A solution of HCl and benzene is colorless and does not conduct electricity, whereas a solution of HCl and AlCl$_3$ and benzene is colored and does conduct electricity.

(b) The following are $^{13}$C NMR chemical shifts for the species below (see also Exercise 15-24):

<table>

72. Which set of reagents will best carry out the conversion shown?

\[
\text{苯} \rightarrow \text{苯} \text{Br}
\]

(a) HBr, peroxides; (b) Br₂, FeBr₃; (c) Br₂ in CCl₄; (d) KBr.

73. One of the compounds shown here contains carbon–carbon bonds that are 1.39 Å long. Which one?

(a) \(\text{五}\)
(b) \(\text{八}\)
(c) \(\text{ THERE IS NO IMAGE FOR (C)}\)
(d) \(\text{苯} \text{CH}_3\)
(e) \(\text{H}_2\text{CC=CCH}_3\)
At some time in your life you have probably ingested at least one of the painkillers aspirin, acetaminophen, naproxen, or ibuprofen, perhaps better known under one of their respective brand names, aspirin, Tylenol, Naprosyn, and Advil. Aspirin, acetaminophen, and ibuprofen are ortho- or para-disubstituted benzenes; naproxen is a disubstituted naphthalene. How are such compounds synthesized? The answer is by electrophilic aromatic substitution.

Aspirin, prepared industrially by selective electrophilic aromatic substitution of phenol, is arguably the blockbuster drug of all times. Its active metabolite, 2-hydroxybenzoic acid (salicylic acid), obtained from the bark of the white willow tree, has been used for four millennia for the treatment of inflammation and to relieve pain or discomfort caused by arthritis, soft-tissue injuries, and fever. Aspirin was discovered by the German company Bayer in the late 19th century and ironically marketed together with another drug, heroin, whose addictive side effects were not recognized then.
Chapter 15 described the use of this transformation in the preparation of monosubstituted benzenes. In this chapter we analyze the effect of such a first substituent on the reactivity and regioselectivity (orientation) of a subsequent electrophilic substitution reaction. Specifically, we shall see that substituents on benzene can be grouped into (1) activators (electron donors), which generally direct a second electrophilic attack to the ortho and para positions, and (2) deactivators (electron acceptors), which generally direct electrophiles to the meta positions. We will then devise strategies toward the synthesis of polysubstituted arenes, such as the analgesics depicted on the previous page.

![Activated ring and Deactivated ring diagram]

16-1 Activation or Deactivation by Substituents on a Benzene Ring

In Section 14-8 we discussed the effect that substituents have on the efficiency of the Diels-Alder reaction: Electron donors on the diene and acceptors on the dienophile are beneficial to the outcome of the cycloaddition. Chapter 15 revealed another manifestation of these effects: Introduction of electron-withdrawing substituents into the benzene ring (e.g., as in nitration) caused further electrophilic aromatic substitution (EAS) to slow down, whereas the incorporation of donors, as in the Friedel-Crafts alkylation, caused substitution to accelerate. What are the factors that contribute to the activating or deactivating nature of substituents in these processes? How do they make a monosubstituted benzene more or less susceptible to further electrophilic attack?

![Increasing rate of EAS diagram]

The electronic influence of any substituent is determined by an interplay of two effects that, depending on the structure of the substituent, may operate simultaneously: induction and resonance. Induction occurs through the $\sigma$ framework, tapers off rapidly with distance, and is mostly governed by the relative electronegativity of atoms and the resulting polarization of bonds (Tables 1-2 and 8-2). Resonance takes place through $\pi$ bonds, is therefore longer range, and is particularly strong in charged systems (Section 1-5, Chapter 14).

Let us look at both of these effects of typical groups introduced by electrophilic aromatic substitution, starting with inductive donors and acceptors. Thus, simple alkyl groups, such as methyl, are donating by virtue of their hyperconjugating $\sigma$ frame, a phenomenon that we encountered earlier (Sections 7-5 and 11-5). On the other hand, trifluoromethyl (by virtue of its electronegative fluorines) is electron withdrawing. Similarly, directly bound heteroatoms, such as N, O, and the halogens (by virtue of their relative electronegativity), as well as positively polarized atoms, such as those in carbonyl, cyano, nitro, and sulfonyl functions, are inductively electron withdrawing.
Inductive Effects of Some Substituents on the Benzene Ring

Now we turn to substituents that resonate with the aromatic $\pi$ system. Resonance donors bear at least one electron pair capable of delocalization into the benzene ring. Therefore, such groups as $-\text{NR}_2$, $-\text{OR}$, and the halogens belong in that category. You will note that, inductively, these groups are electron withdrawing; in other words, here the two phenomena, induction and resonance, are opposing each other. Which one wins out? The answer depends on the relative electronegativity of the heteroatoms (Table 1-2) and on the ability of their respective $p$ orbitals to overlap with the aromatic $\pi$ system. For amino and alkoxy groups, resonance overrides induction. For the halogens, induction outcompetes resonance, making them weak electron acceptors.

Finally, groups bearing a polarized double or triple bond, whose positive ($\delta^+$) end is attached to the benzene nucleus, such as carbonyl, cyano, nitro, and sulfonyl, are electron withdrawing through resonance.

Note that, here, resonance reinforces induction.

Electrostatic potential maps indicate the presence of electron-donating substituents by depicting the benzene ring as shaded relatively red; electron-withdrawing groups make the benzene ring appear shaded relatively blue (green).
Chapter 16
Electrophilic Attack on Derivatives of Benzene

**Exercise 16-1**

Explain the \(^1\)H NMR spectral assignments in Figures 15-11 and 15-12. (Hint: Draw resonance structures involving the substituents on the benzene ring.)

**Exercise 16-2**

The \(^1\)C NMR spectrum of phenol, C\(_6\)H\(_5\)OH, shows four lines at \(\delta = 116.1\) (C2), 120.8 (C4), 130.5 (C3), and 155.6 (C1) ppm. Explain these assignments. (Hint: The \(^1\)C chemical shift for benzene is \(\delta = 128.7\) ppm.)

How do we know whether a substituent functions as a donor or acceptor? In electrophilic aromatic substitution, the answer is simple. Because the attacking species is an electrophile, the more electron rich the arene, the faster the reaction. Conversely, the more electron poor the arene, the slower the reaction. Hence, electron donors activate the ring, whereas electron acceptors deactivate.

**Relative Rates of Nitration of C\(_6\)H\(_2\)X**

\[
\begin{array}{cccccc}
X & \text{NH(C}_2\text{H}_3) & \text{OH} & \text{CH}_3 & \text{H} & \text{Cl} & \text{CO}_2\text{CH}_2\text{CH}_3 & \text{CF}_3 & \text{NO}_2 \\
10^6 & 1000 & 25 & 1 & 0.033 & 0.0037 & 2.6 \times 10^{-5} & 6 \times 10^{-8}
\end{array}
\]

Increasing rate of nitration

**Exercise 16-3**

Specify whether the benzene rings in the compounds below are activated or deactivated.

(a) \[
\begin{array}{c}

\text{CF}_3
\end{array}
\]

(d) \[
\begin{array}{c}
\text{OCH}_3 \\
\text{N(C}_2\text{H}_3)_2
\end{array}
\]

**In Summary** When considering the effect of substituents on the reactivity of the benzene nucleus, we have to analyze the contributions that occur by induction and resonance. We can group these substituents into two classes: (1) electron donors, which accelerate electrophilic aromatic substitutions relative to benzene, and (2) electron acceptors, which retard them.

16-2 Directing Inductive Effects of Alkyl Groups

We are now ready to tackle the question of the regioselectivity (orientation) of electrophilic aromatic substitution of substituted benzenes. What controls the position along the benzene ring at which an electrophile will attack? We begin with the electrophilic substitution reactions of alkyl-substituted benzenes, such as methylbenzene (toluene), in which the methyl group is electron donating by induction.
Groups that donate electrons by induction are activating and
direct ortho and para

Electrophilic bromination of methylbenzene (toluene) is considerably faster than the bromi-
nation of benzene itself. The reaction is also regioselective: It results mainly in para (60%) and
ortho (40%) substitutions, with virtually no meta product.

Electrophilic Bromination of Methylbenzene (Toluene)
Gives Ortho and Para Substitution

1-Bromo-2-methylbenzene
(o-Bromotoluene)

1-Bromo-3-methylbenzene
(m-Bromotoluene)

1-Bromo-4-methylbenzene
(p-Bromotoluene)

60%
<1%
39%

Is bromination a special case? The answer is no; nitration, sulfonation, and Friedel-Crafts
reactions of the alkylbenzene give similar results—mainly ortho and para substitutions (see
also Table 16-2 in Section 16-3). Evidently, the nature of the attacking electrophile has little
influence on the observed orientation; it is the alkyl group that matters. Because there is virtually
no meta product, we say that the activating methyl substituent is ortho and para directing.

Can we explain this selectivity by a mechanism? Let us inspect the possible resonance
forms of the cations generated after the electrophile, \(E^+\), has attacked the ring in the first,
and rate-determining, step.

Ortho, Meta, and Para Attack on Methylbenzene (Toluene)

Ortho attack \((E^+ = \text{electrophile})\)

Meta attack
Para attack

The alkyl group is electron donating by induction (Section 16-1). Electrophilic attack at the ortho and para positions produces an intermediate carbocation in which one of the resonance forms places the positive charge next to the alkyl substituent, rendering it tertiary carbocationlike (Section 7-5). Because the alkyl group can donate electron density to stabilize the positive charge, that resonance form is a more important contributor to the resonance hybrid than the others, in which the positive charge is at an unsubstituted carbon. Meta attack, however, produces an intermediate in which none of the resonance forms benefits from such direct stabilization. Thus, electrophilic attack on a carbon located ortho or para to the methyl (or another alkyl group) leads to a cationic intermediate that is more stable than the one derived from attack at the meta carbon. The transition state leading to the more stable intermediate is of relatively low energy (Hammond postulate, Section 3-5) and is therefore reached relatively rapidly.

Why are the two favored products, ortho and para, not formed in equal amounts? Frequently, the answer is steric effects. Thus, attack ortho to an existing substituent, especially when it is bulky, by an electrophile (again, especially when bulky) is sterically more encumbered than para attack. Therefore, para products often predominate over their ortho isomers. In the bromination of methylbenzene (toluene), this predominance is small. However, similar halogenation of 1,1-dimethylethyl (tert-buty1) benzene results in a much larger para : ortho ratio (~10:1).

A particularly impressive “green” example (Chemical Highlight 3-1) of this effect is achieved in the Friedel-Crafts acetylation of (2-methylpropyl)benzene with acetic anhydride, in an industrial approach to an ibuprofen intermediate (Chapter Opening; see also Exercise 16-10). Here, a porous zeolite catalyst (see Section 3-3) provides not only the acidic surface sites necessary for the reaction to proceed, but also an environment that enhances para selectivity. This process avoids the use of the corrosive acetyl chloride and AlCl₃ reagents and with it the formation of the toxic HCl by-product of the classical Friedel-Crafts acetylation. Instead, the by-product is acetic acid, itself a valuable commodity.

**A Green Acetylation of an Alkylbenzene**

Groups that withdraw electrons inductively are deactivating and meta directing

The strongly electronegative fluorine atoms in (trifluoromethyl)benzene make the trifluoromethyl group inductively electron withdrawing (Section 16-1). In this case, the benzene ring becomes deactivated and reaction with electrophiles is very sluggish. Under stringent
conditions, such as heating, substitution does take place—but only at the meta positions: The trifluoromethyl group is deactivating and meta directing.

Electrophilic Nitration of (Trifluoromethyl)benzene Gives Mainly Meta Substitution

![Chemical Reaction Diagram]

Electrophilic Nitration of (Trifluoromethyl)benzene

\[
\begin{align*}
\text{HNO}_3, \text{H}_2\text{SO}_4 & \rightarrow \quad \begin{array}{c}
\text{CF}_3 \\

\end{array} & + & \quad \begin{array}{c}
\text{CF}_3 \\
\text{NO}_2 \\
\text{CF}_3
\end{array} \\
6\% & & 91\% & & 3\%
\end{align*}
\]

1-Nitro-2-(trifluoromethyl)benzene
[\text{o-Nitro(trifluoromethyl)benzene}]

1-Nitro-3-(trifluoromethyl)benzene
[\text{m-Nitro(trifluoromethyl)benzene}]

1-Nitro-4-(trifluoromethyl)benzene
[\text{p-Nitro(trifluoromethyl)benzene}]

Once again, the explanation lies in the various resonance forms for the cation produced by ortho, meta, and para attack.

Ortho, Meta, and Para Attack on (Trifluoromethyl)benzene

**Ortho attack**

![Ortho Cation Resonance Forms]

**Meta attack**

![Meta Cation Resonance Forms]

**Para attack**

![Para Cation Resonance Forms]

The presence of an inductively electron-withdrawing substituent destabilizes the carbocations resulting from electrophilic attack at all positions in the ring. However, ortho and para attack are even less favored than meta attack for the same reasons that they are relatively favored with methylbenzene (toluene): In each case, one of the resonance forms in the
intermediate cation places the positive charge next to the substituent. This structure is stabilized
by an electron-donating group, but it is destabilized by an electron-withdrawing substituent—
removing electron density from a positively charged center is energetically unfavored. Meta
attack avoids this situation. The destabilizing inductive effect is still felt in the meta
intermediate, but to a lesser extent. Therefore, the trifluoromethyl group slows substitution and
directs the electrophile meta, or, more accurately, away from the ortho and para carbons.

**Exercise 16-4**

Rank these compounds in order of decreasing activity in electrophilic substitution.

(a) \[
\begin{align*}
&\text{CF}_3 \\
&\text{CH}_3
\end{align*}
\]

(b) \[
\begin{align*}
&\text{CH}_3 \\
&\text{CH}_3
\end{align*}
\]

(c) \[
\begin{align*}
&\text{CF}_3 \\
&\text{CH}_3
\end{align*}
\]

(d) \[
\begin{align*}
&\text{CH}_3 \\
&\text{CH}_3
\end{align*}
\]

**Exercise 16-5**

Electrophilic bromination of an equimolar mixture of methylbenzene (toluene) and
(trifluoromethyl)benzene with one equivalent of bromine gives only 1-bromo-2-methylbenzene and
1-bromo-4-methylbenzene. Explain.

**In Summary** Electron-donating substituents inductively activate the benzene ring and direct
electrophiles ortho and para; their electron-accepting counterparts deactivate the benzene
ring and direct electrophiles to the meta positions.

**16-3 Directing Effects of Substituents in Conjugation with the
Benzene Ring**

What is the influence of substituents whose electrons are in conjugation with those of the
benzene ring? We can answer this question by again comparing the resonance forms of the
intermediates resulting from the various modes of electrophilic attack.

**Groups that donate electrons by resonance activate and direct
ortho and para**

Benzene rings bearing the groups –NH₂ and –OH are strongly activated. For example,
halogenations of benzenamine (aniline) and phenol not only take place in the absence of
catalysts but also are difficult to stop at single substitution. The reactions proceed very
rapidly and, as in inductive activation (Section 16-2), furnish exclusively ortho- and para-
substituted products.

**Electrophilic Brominations of Benzenamine (Aniline) and Phenol Give Ortho and Para Substitution**

\[
\begin{align*}
\text{NH}_2 & \quad 3 \text{Br} \rightarrow \text{Br}, \text{H}_2\text{O} \\
\text{Br} & \quad \text{Br} \\
& \quad \text{Br} \\
100\% \\
\text{Br} & \quad \text{Br} \\
\text{Br} & \quad \text{Br} \\
\text{Br} & \quad \text{Br} \\
\text{Br} & \quad \text{Br} \\
\text{Br} & \quad \text{Br} \\
\text{Br} & \quad \text{Br} \\
100\%
\end{align*}
\]

Benzenamine
(Aniline)            2,4,6-Tribromobenzenamine
(2,4,6-Tribromoaniline)           Phenol            2,4,6-Tribromophenol
Better control of monosubstitution is attained with modified amino and hydroxy substituents, such as in N-phenylacetamide (acetanilide) and methoxybenzene (anisole). These groups are ortho and para directing but less strongly activating (Section 16-5).

**Electrophilic Nitrations of N-Phenylacetamide (Acetanilide)**

\[
\begin{align*}
\text{HNCCH}_3 & \quad \text{HNCCH}_3 & \quad \text{HNCCH}_3 \\
\text{N-Phenylacetamide (Acetanilide)} & \quad \text{Nitration} & \quad \text{N-(2-Nitrophenyl)-acetamide} \\
& & \quad \text{N-(3-Nitrophenyl)-acetamide} \\
& & \quad \text{N-(4-Nitrophenyl)-acetamide} \\
\end{align*}
\]

Both the activated nature of these compounds and the observed regioselectivity on electrophilic substitution can be explained by writing resonance forms for the various intermediate cations.

**Ortho, Meta, and Para Attack on Benzenamine (Aniline)**

**Ortho attack**

\[
\begin{align*}
\text{NH}_2 & \quad \text{E}^+ & \quad \overset{\text{Strongly stabilized cation}}{\text{all-octet form}} \\
\end{align*}
\]

**Meta attack**

\[
\begin{align*}
\text{NH}_2 & \quad \text{E}^+ & \quad \overset{\text{Strongly stabilized cation}}{\text{all-octet form}} \\
\end{align*}
\]

**Para attack**

\[
\begin{align*}
\text{NH}_2 & \quad \text{E}^+ & \quad \overset{\text{Strongly stabilized cation}}{\text{all-octet form}} \\
\end{align*}
\]
Because nitrogen is more electronegative than carbon, the amino group in benzenamine (aniline) is inductively electron withdrawing (Section 16-1). However, the lone electron pair on the nitrogen atom may participate in resonance, thereby stabilizing the intermediate cations resulting from ortho and para (but not meta) substitutions. This resonance contribution outweighs the inductive effect. Compared to inductively directing alkyl groups (Section 16-2), the amino function provides not only an extra resonance contributor to the intermediate cation, but one that features an all-important Lewis octet. The result is a much reduced activation barrier for ortho or para attack. Consequently, benzenamine (aniline) is strongly activated toward electrophilic substitution relative to alkylbenzenes (and benzene), and the reaction is more highly regioselective as well, giving ortho and para substitution products almost exclusively.

Exercise 16-6

**Working with the Concepts: Predicting Regiochemistry in Electrophilic Aromatic Substitutions**

Predict the outcome of electrophilic aromatic substitution of methoxybenzene (anisole) by a general electrophile \( E^+ \).

**Strategy**
In all problems addressing the potential regioselectivity of electrophilic substitution on substituted benzenes, there is a golden rule: When in doubt, write down all intermediates from all possible modes of attack before attempting to formulate a solution.

**Solution**
- In the case of methoxybenzene, this procedure results in the following cations:

  **Ortho attack**
  
  ![Ortho Attack Diagram]
  
  **Meta attack**
  
  ![Meta Attack Diagram]
  
  **Para attack**
  
  ![Para Attack Diagram]

- How do they differ? You can immediately tell that ortho and para attacks give intermediates with four resonance forms, respectively, one of which in each case involves the lone electron pair on the methoxy group.
- In contrast, meta substitution proceeds through a cation described by only three resonance forms, none of which benefits from the participation of the oxygen lone pair of electrons.
- Thus, substitution will occur exclusively ortho and para to the directing methoxy substituent in the starting material.

Exercise 16-7

**Try It Yourself**

In strongly acidic solution, benzenamine (aniline) becomes less reactive to electrophilic attack, and, while ortho, para attack is still dominant, increased meta substitution is observed. Explain. 

(**Hint:** The nitrogen atom in benzenamine may behave as a base. How would you classify the resulting substituent within the framework of the discussion in Section 16-1?)
Explosive Nitroarenes: TNT and Picric Acid

Complete ortho, para nitration of methylbenzene (toluene) or phenol furnishes the corresponding trinitro derivatives, both of which are powerful explosives: *TNT* (discovered in 1863) and *picric acid* (1771). Both compounds have long histories as military and industrial explosives.

\[
\begin{align*}
\text{2-Methyl-1,3,5-trinitrobenzene (2,4,6-Trinitrotoluene, TNT)} & & \\
\text{2,4,6-Trinitrophenol (Picric acid)} & & \\
\end{align*}
\]

Explosives are generally high-energy-density compounds capable of extremely rapid decomposition. In contrast to propellants (such as rocket fuel), they do not burn, but detonate under their own power. They frequently generate high heat and a large quantity of gaseous products, producing a (usually destructive) shock wave: TNT has a detonation velocity of 6940 m s\(^{-1}\) (~4.3 mi s\(^{-1}\)). An explosion can be initiated by impact (including blasting caps), friction, heat and flame, electrical discharge (including static), and ultraviolet irradiation, depending on the compound. The nitro group features prominently in these materials, because it functions as an oxidizer to the surrounding carbon framework (producing the gases CO and CO\(_2\)) and as a precursor to N\(_2\).

TNT is the most widely used military explosive in history. The reasons for its popularity are its low cost and simplicity of preparation, safe handling (low sensitivity to impact and friction), relatively high explosive power (yet good chemical and thermal stability), low volatility and toxicity, compatibility with other explosives, and a low melting point, allowing for melt-cast formulations.

TNT has become such a standard, particularly in military uses, that the destructive power of other explosives, especially in bombs, is often compared to that of an equivalent of TNT. For example, the first atomic bomb—detonated on July 16, 1945, in New Mexico—had the equivalent power of 19,000 tons of TNT. The device exploded over Hiroshima, Japan, which killed more than 140,000 people, had the power of 13,000 tons of TNT. Although these numbers appear huge, comparison with the hydrogen bomb—with the destructive equivalent of 10 million tons of TNT—dwarfs them. For further calibration, all of the explosions of World War II combined amounted to the equivalent of “only” 2 million tons of TNT.

Picric acid has some commercial applications other than as an explosive—in matches, in the leather industry, in electric batteries, and in colored glass. It is called an acid because of the unusually high acidity of its hydroxy group (\(pK_a\) 0.38; Section 22-3), which is increased beyond that of acetic acid (\(pK_a\) 4.7) and even hydrogen fluoride (\(pK_a\) 3.2; Table 2-2) by the electron-withdrawing effect of the three nitro groups. This property was in part responsible for its replacement by TNT in military uses. For example, in artillery shells, it would corrode the casing and cause leakage, thus creating a hazard.

TNT is now rarely used pure, but more commonly in mixtures with other high-energy compounds, such as tetryl and RDX. In modern commercial applications, particularly mining and building demolition, TNT and picric acid have been replaced by nitroglycerine (Section 9-11). On the research front, chemists are continuing to explore novel structures. A case in point is octanitrocubane, synthesized in 2000, in which ring strain adds to the brisance of the compound. Its molecular formula, \(C_8N_8O_{16}\), indicates a composition conducive to gaseous product formation (e.g., \(8\ CO_2 + 4\ N_2\)) with an associated ~1150-fold volume expansion and an estimated energy release of 830 kcal mol\(^{-1}\) (3470 kJ mol\(^{-1}\)).
Groups that withdraw electrons by resonance deactivate and direct meta

Several groups deactivate the benzene ring by resonance (Section 16-1). An example is the carboxy group in benzoic acid, \( \text{C}_6\text{H}_5\text{CO}_2\text{H} \). Nitration of benzoic acid takes place at only about 1/1000th the rate of benzene nitration and gives predominantly meta substitution. The \( \text{CO}_2\text{H} \) group is deactivating and, as in inductive deactivation (Section 16-2), meta directing.

**Electrophilic Meta Nitration of Benzoic Acid**

\[
\begin{align*}
\text{CO}_2\text{H} & \quad \text{CO}_2\text{H} & \quad \text{CO}_2\text{H} \\
\text{HNO}_3, \text{H}_2\text{SO}_4, \Delta & \quad \text{HNO}_3, \text{H}_2\text{SO}_4, \Delta & \quad \text{H}_2\text{O} \\
-\text{H}_2\text{O} & \quad \text{NO}_2 & \quad \text{NO}_2 & \quad \text{NO}_2 \\
18.5\% & \quad 80\% & \quad 1.5\%
\end{align*}
\]

2-Nitrobenzoic acid (\( \alpha\)-Nitrobenzoic acid)  
3-Nitrobenzoic acid (\( \beta\)-Nitrobenzoic acid)  
4-Nitrobenzoic acid (\( \gamma\)-Nitrobenzoic acid)

Let us see how conjugation with the \( \text{CO}_2\text{H} \) function affects the resonance forms of the cations resulting from electrophilic attack on benzoic acid.

**Ortho, Meta, and Para Attack on Benzoic Acid**

**Ortho attack**

\[
\begin{align*}
\text{HO} & \quad \text{C} & \quad \text{O} \\
\text{E}^+ & \quad \text{H} & \quad \text{H} \\
\text{Poor} & \quad \text{Poor}
\end{align*}
\]

**Meta attack**

\[
\begin{align*}
\text{HO} & \quad \text{C} & \quad \text{O} \\
\text{E}^+ & \quad \text{H} & \quad \text{H} \\
\text{None is poor} & \quad \text{Less destabilized cation}
\end{align*}
\]

**Para attack**

\end{align*}
\]

Strongly destabilized cation
Attack at the meta position avoids placing the positive charge next to the electron-withdrawing carboxy group, whereas ortho and para attacks necessitate the formulation of poor resonance contributors. Thus, while the substituent deactivates all positions, it does so to a greater extent at the ortho and para positions than at the meta positions. One might say, meta “wins by default.”

**Exercise 16-8**

Electrophilic nitration of nitrobenzene gives almost exclusively 1,3-dinitrobenzene. Formulate the (poor) resonance forms of the intermediate cations resulting from attack by NO$_2^-$ at the ortho and para positions that explain this result.

**There is always an exception: halogen substituents, although deactivating, direct ortho and para**

Halogen substituents inductively withdraw electron density (Section 16-1); however, they are donors by resonance. On balance, the inductive effect wins out, rendering haloarenes deactivated. Nevertheless, the electrophilic substitution that does take place is mainly at the ortho and para positions.

**Electrophilic Bromination of Bromobenzene Results in ortho- and para-Dibromobenzene**

![Chemical structure of bromobenzene and dibromobenzene products](image)

The competition between resonance and inductive effects explains this seemingly contradictory reactivity. Again, we must examine the resonance forms for the various possible intermediates.

**Ortho, Meta, and Para Attack on a Halobenzene**

**Ortho attack**

![Resonance forms for ortho attack](image)

**Meta attack**

![Resonance forms for meta attack](image)
Para attack

Note that ortho and para attack lead to resonance forms in which the positive charge is placed next to the halogen substituent. Although this might be expected to be unfavorable, because the halogen is inductively electron withdrawing, resonance with the lone electron pairs allows the charge to be delocalized. Therefore, ortho and para substitutions become the preferred modes of reaction. The inductive effect of the halogen is still strong enough to make all three possible cations less stable than the one derived from benzene itself. Therefore, we have the unusual result that halogens are ortho and para directing, but deactivating.

This section completes the survey of the regioselectivity of electrophilic attack on mono-substituted benzenes, summarized in Table 16-1. Table 16-2 ranks various substituents by their activating power and lists the product distributions obtained on electrophilic nitration of the benzene ring.

**Exercise 16-9**

Explain why (a) –NO₂, (b) –NR₃, and (c) –SO₃H are meta directing. (d) Why should phenyl be activating and ortho and para directing (Table 16-1)? [Hint: Draw resonance forms for the appropriate cationic intermediates of electrophilic attack on phenylbenzene (biphenyl).]

In Summary

Activating groups, whether operating by induction or resonance, direct incoming electrophiles to the ortho and para positions, whereas deactivating groups direct to the meta carbons. This statement is true for all classes of substituents except one—the halogens. They are deactivating by induction, but they stabilize positive charges by resonance, therefore effecting ortho, para substitution.

### 16-4 Electrophilic Attack on Disubstituted Benzenes

Do the rules developed so far in this chapter predict the reactivity and regioselectivity of still higher substitution? We shall see that they do, provided we take into account the individual effect of each substituent. Let us investigate the reactions of disubstituted benzenes with electrophiles.

**The strongest activator wins out**

In trying to predict the regioselectivity of electrophilic substitution of disubstituted benzenes, we have to apply the same considerations that were necessary to understand the directing

**Exercise 16-10**

Compound A is an intermediate in one of the syntheses of ibuprofen (see Chapter Opening). Propose a synthetic route to compound A, starting with (2-methylpropyl)benzene. (Hint: You need to introduce the cyano group by nucleophilic substitution.)

---

**In Summary**

Activating groups, whether operating by induction or resonance, direct incoming electrophiles to the ortho and para positions, whereas deactivating groups direct to the meta carbons. This statement is true for all classes of substituents except one—the halogens. They are deactivating by induction, but they stabilize positive charges by resonance, therefore effecting ortho, para substitution.
effects of one substituent (Sections 16-1 through 16-3). This may seem rather difficult at first, because the two substituents may be ortho, para, or they may be meta directing, and they can be placed around the ring in three possible ways, 1,2, 1,3, or 1,4. However, the problem becomes much simpler when you remember that ortho, para directors are activators and therefore accelerate attack of the electrophile at the ortho, para positions relative to benzene. In contrast, meta directors are deactivators and exert regiocontrol by retarding ortho, para substitution more than meta substitution. Taking these electronic effects into account, in conjunction with steric considerations, allows us to formulate a set of simple guidelines that enable us to predict the outcome of most electrophilic aromatic substitution reactions.

**Guideline 1.** The most powerful activator controls the position of attack (indicated by yellow arrows).

Guideline 2. Experimentally, we can rank the directing power of substituents into three groups:

\[ NR_2, OR \quad > \quad X, R \quad > \quad \text{meta directors} \]

Members of the higher-ranking groups override the effect of members of lower rank (guideline 1). However, substituents within each group compete to give isomer mixtures (except when such substituents direct to the same position or when symmetry ensures the generation of a single product).

**Guideline 3.** In such cases where product mixtures are predicted on the basis of guidelines 1 and 2, you may typically discount those that constitute ortho attack to bulky groups or between two substituents (dashed black arrows).
Guideline 4. Guidelines 1 through 3 are applicable to more highly substituted benzenes for which the decreasing number of reactive positions reduces the number of possible products.

Exercise 16-11

Working with the Concepts: Predicting Regiochemistry in Electrophilic Aromatic Substitutions of Di- and More Highly Substituted Benzenes

Predict the result of mononitration of 1-bromo-2-methoxybenzene:

Strategy
Following the given guidelines, look at the overall electronic and directing effects of each substituent separately.
Solution

- Methoxy is a strong activator and directs ortho, para.
- Bromine is a weak deactivator but still directs ortho, para. Clearly, the two substituents conflict in the direction in which they send the incoming electrophile.

![Diagrams of directing effects of methoxy and bromine groups]

- Guidelines 1 and 2 allow for an unambiguous choice between the two with respect to their directing power: Methoxy wins.

Exercise 16-12

Try It Yourself

Predict the result of mononitration of

(a) \( \text{CHO} \)
(b) \( \text{Br} \) \( \text{N(CH}_3\text{)}_2 \)
(c) \( \text{H}_3\text{C} \) \( \text{CN} \)

Exercise 16-13

The German chemist Wilhelm Körner (1839–1925) observed in 1874 that each of the three dibromobenzenes A, B, and C furnished a different number of tribromobenzenes upon further bromination, allowing him to assign their respective structures. Try to do the same on the basis of the following results.

(i) A gives two tribromobenzenes in comparable amounts.
(ii) B gives three tribromobenzenes, one of them in minor quantities.
(iii) C gives only one tribromobenzene.

Exercise 16-14

The food preservative BHT (\( \text{tert-} \)butylated hydroxytoluene) has the structure shown here. Suggest a synthesis starting from 4-methylphenol (\( p\)-cresol).

![Structure of 4-Methyl-2,6-bis(1,1-dimethylethyl)phenol]

4-Methyl-2,6-bis(1,1-dimethylethyl)phenol
(2,6-Di-\( \text{tert-} \)butyl-4-methylphenol)
In Summary  Electrophilic aromatic substitution of multiply substituted benzenes is controlled by the strongest activator and, to a certain extent, by steric effects. The greatest product selectivity appears when there is only one dominant activator or when the substitution pattern minimizes the number of isomers that can be formed.

16-5 Synthetic Strategies Toward Substituted Benzenes

The synthesis of substituted benzenes requires planning to ensure that a specific substitution pattern is obtained. How do we approach the problem of targeting a product in which this pattern seems incompatible with the directing sense of the substituents? For example, how can we make a meta-substituted benzenamine (aniline) or an ortho, para–substituted nitrobenzene? To solve problems such as these, we need to know a couple of synthetic “tricks.” Among them are the chemical interconversions of ortho, para with meta directors, such as nitro ⇔ amino or carbonyl ⇔ methylene, some additional knowledge about the practicality of certain electrophilic substitutions, and the employment of reversible blocking strategies at certain positions with sulfonic acid groups (–SO₃H).

We can change the sense of the directing power of substituents

The easiest way to introduce a nitrogen substituent into an arene is by nitration. Yet many desired substituted benzenes have amino functions. Moreover, the nitro group is a meta director, poorly suited for preparing ortho, para–substituted systems. A solution to these problems is provided by the availability of simple reagents that reversibly convert –NO₂, a meta director, into –NH₂, an ortho, para director. Thus, the nitro group can be reduced to the amino function by either catalytic hydrogenation or exposure to acid in the presence of active metals such as iron or zinc amalgam. The reverse, oxidation of aniline to nitrobenzene, employs trifluoroperacetic acid.

Interconversion of Nitro (Meta Director) with Amino (Ortho, Para Director)

For an example of applying this capability in synthetic strategy, consider the preparation of 3-bromobenzenamine. Direct bromination of benzenamine (aniline) leads to complete ortho and para substitution (Section 16-3) and is therefore useless. However, bromination of nitrobenzene allows preparation of 3-bromonitrobenzene, which can be converted into the required target molecule by reduction. The outcome is a benzene derivative in which two ortho, para directors emerge positioned meta to each other.

Exercise 16-15
Would nitration of bromobenzene be a useful alternative way to begin a synthesis of 3-bromobenzenamine?
Chapter 16
Electrophilic Attack on Derivatives of Benzene

Exercise 16-16
Propose a synthesis from benzene of 3-aminobenzenesulfonic acid [metanilic acid, used in the synthesis of azo dyes (Section 22-11), such as “Metanil yellow,” and certain sulfa drugs (Section 15-10)].

Exercise 16-17
Use the methods just presented to devise a synthesis of 4-nitrobenzenesulfonic acid from benzene. [Hint: Sulfonation proceeds selectively para to activating groups, because the reagent is sterically hindered and the process reversible (Section 15-10).]

Another example of the interconversion of the directing ability of a substituent on a benzene ring is the redox reaction acyl = alkyl. Thus, the carbonyl group in acylarenes can be completely reduced by using palladium-catalyzed hydrogenation or treatment with zinc amalgam in concentrated HCl (Clemmensen* reduction). Conversely, the methylene group next to the aromatic ring in an alkylarene is susceptible to oxidation to the carbonyl function with the use of CrO₃, H₂SO₄ (Section 22-2).

Interconversion of Acyl (Meta Director) with Alkyl (Ortho, Para Director)

> \[ \text{O} \rightarrow \text{CH}_2 \rightarrow \text{R} \]

How is this useful? Consider the preparation of 1-chloro-3-ethylbenzene from benzene. Retrosynthetic analysis (Section 8-9) indicates that neither chlorobenzene nor ethylbenzene is suitable as the immediate precursor to product, because each substituent is ortho, para directing. However, we recognize that ethyl can be produced from acetyl, a meta director. Hence, acetylbenzene, readily prepared by Friedel-Crafts acylation, is a perfect relay point, because it can be chlorinated meta. After the carbonyl group has completed its directing job, it is reduced to the desired alkyl group.

Exercise 16-18
Propose a synthesis of 1-chloro-3-propylbenzene, starting from propylbenzene.

The ready reduction of acyl- to alkylarenes also provides a way to synthesize alkylbenzenes without the complication of alkyl group rearrangement and overalkylation.

---

*E. C. Clemmensen (1876–1941), president of Clemmensen Chemical Corporation, Newark, New Jersey.
For example, butylbenzene is best synthesized by the sequence of Friedel-Crafts acylation with butanoyl chloride, followed by Clemmensen reduction.

**Synthesis of Butylbenzene Without Rearrangement**

![Synthesis of Butylbenzene Without Rearrangement](image)

The more direct alternative, Friedel-Crafts butylation of benzene, fails because of the formation of the rearranged product (1-methylpropyl)benzene (sec-butylbenzene; Section 15-12) and di- and trialkylation.

**Exercise 16-19**

Give an efficient synthesis of (2-methylpropyl)benzene (isobutylbenzene, the starting material for the preparation of ibuprofen; see Exercise 16-10), starting from benzene. **[Hint: What would you expect as the major monosubstitution product of Friedel-Crafts alkylation of benzene with 1-chloro-2-methylpropane (isobutyl chloride)?]**

**Friedel-Crafts electrophiles do not attack strongly deactivated benzene rings**

Let us examine possible syntheses of 1-(3-nitrophenyl)ethanone (m-nitroacetophenone). Because both groups are meta directors, two possibilities appear available: nitration of 1-phenylethanone or Friedel-Crafts acetylation of nitrobenzene. However, in practice, only the first route succeeds.

**Successful and Unsuccessful Syntheses of 1-(3-Nitrophenyl)ethanone (m-Nitroacetophenone)**

![Successful and Unsuccessful Syntheses of 1-(3-Nitrophenyl)ethanone (m-Nitroacetophenone)](image)

The failure of the second route results from a combination of factors. One is the extreme deactivation of the nitrobenzene ring. Another is the relatively low electrophilicity of the acylium ion, at least compared with other electrophiles in aromatic substitution. As a general rule, neither Friedel-Crafts alkylations nor acylations take place with benzene derivatives strongly deactivated by meta-directing groups.

**Exercise 16-20**

Propose a synthesis of 5-propyl-1,3-benzenediamine, starting from benzene. **[Caution: Consider carefully the order in which you introduce the groups.]**
Reversible sulfonation allows the efficient synthesis of ortho-disubstituted benzenes

A problem of another sort arises in the attempt to prepare an o-disubstituted benzene, even when one of the groups is an ortho, para director. Although appreciable amounts of ortho isomers may form in electrophilic substitutions of benzenes containing such groups, the para isomer is the major product in most such cases (Sections 16-2 and 16-3). Suppose you required an efficient synthesis of 1-(1,1-dimethylethyl)-2-nitrobenzene \([o-(t\text{e}r\text{t}-b\text{u}t\text{l}y)\text{n}i\text{t}o\text{b}e\text{n}z\text{e}n\text{e}]}\). Direct nitration of (1,1-dimethylethyl)benzene (\(t\text{e}r\text{t}\)-butylbenzene) is unsatisfactory.

A Poor Synthesis of 1-(1,1-Dimethylethyl)-2-nitrobenzene
\([o-(t\text{e}r\text{t}-B\text{u}t\text{y})\text{n}i\text{t}o\text{b}e\text{n}z\text{e}n\text{e}]}\)

\[
\begin{align*}
1-(1,1-Dimethylethyl)-2-nitrobenzene & \quad 16\% \\
1-(1,1-Dimethylethyl)-2-nitrobenzene \ [o-(t\text{e}r\text{t}-B\text{u}t\text{y})\text{n}i\text{t}o\text{b}e\text{n}z\text{e}n\text{e}]} & \quad 11\% \\
1-(1,1-Dimethylethyl)-4-nitrobenzene \ [p-(t\text{e}r\text{t}-B\text{u}t\text{y})\text{n}i\text{t}o\text{b}e\text{n}z\text{e}n\text{e}]} & \quad 73\%
\end{align*}
\]

A clever solution makes use of reversible sulfonation (Section 15-10) as a blocking procedure. Both the substituent and the electrophile are sterically bulky; hence, (1,1-dimethylethyl)benzene is sulfonated almost entirely para, blocking this carbon from further electrophilic attack. Nitration now can occur only ortho to the alkyl group. Heating in aqueous acid removes the blocking group and completes the synthesis.

Reversible Sulfonation as a Blocking Procedure

Exercise 16-21
Suggest a synthetic route from benzene to 1,3-dibromo-2-nitrobenzene.

Protection strategies moderate the activating power of amine and hydroxy groups

We noted in Section 16-3 that electrophilic attack on benzenamine (aniline) and phenol are difficult to stop at the stage of monosubstitution because of the highly activating nature of the \(\text{NH}_2\) and \(\text{OH}\) groups. In addition, with these Lewis basic functions, complications can arise by direct attack on the heteroatom. To prevent these problems, protecting groups are used: acetyl for benzenamine, as in \(N\)-phenylacetamide (acetanilide; Sections 20-2 and 20-6), and methyl for phenol, as in methoxybenzene. Deprotection is achieved by basic or acidic hydrolyses, respectively.
In this way, selective halogenation, nitration, and Friedel-Crafts reactions are accomplished. For example, the synthesis of 2-nitrobenzenamine (o-nitroaniline) employs this strategy in conjunction with sulfonation to block the para position.

**A Synthesis of 2-Nitrobenzenamine (o-Nitroaniline)**

Through Protected Benzenamine (Aniline)

![Synthesis diagram](image)

**Exercise 16-22**

**Working with the Concepts: Synthetic Strategy in Electrophilic Aromatic Substitution**

What would be a good way of making the benzene derivative A, a synthetic intermediate in the construction of unnatural amino acid oligomers?

**Strategy**

On first sight, this target looks formidable. To simplify it, we need to apply the principles of retrosynthesis in conjunction with what we have learned in this section. This discussion will offer one solution, but you may come up with more! We can start by evaluating the directing power of the individual substituents.

**Solution**

- Proceeding clockwise, bromine is an ortho, para director, but a deactivator, and using it as a way to introduce the amino and carbonyl functions does not look promising.
- The amino group is better: Its powerful activating effect could be applied to nitrate para and brominate ortho.
- Guidelines 1 and 2 allow for an unambiguous choice between the two with respect to their directing power: Amino wins.
- Next, the ester carbonyl substituent is meta directing and might also be useful, as it could be employed to introduce the meta nitrogen in the form of a nitro group.
- Finally, the nitro function is useless (at least as such), as it is meta directing and sufficiently deactivating that substitutions would be very slow.
- By this analysis, most fruitful appears to be a retrosynthetic step that removes the bromine and leads to B. The amino function in B could be considered again, now as a way to add the nitro group, leading to C.
- At this stage, things have become more transparent, as the meta amino group can be envisaged to be readily attached via D, the product of nitration of methyl benzene carboxylate (methyl benzoate) E.

**Retrosynthesis of A**

![Retrosynthesis diagram](image)
By careful choice of the sequence in which new groups are introduced, it is possible to devise specific syntheses of multiply substituted benzenes. Such strategies may require changing the directing power of substituents, modifying their activating ability, and reversibly blocking positions on the ring.

In this section, we shall use resonance forms to predict the regioselectivity and reactivity of polycyclic aromatic molecules (Section 15-5), using naphthalene as an example. Some biological implications of the reactivity of these substances will be explored in Section 16-7.

Naphthalene is activated toward electrophilic substitution

The aromatic character of naphthalene is manifest in its reactivity: It undergoes electrophilic substitution rather than addition. For example, treatment with bromine, even in the absence of a catalyst, results in smooth conversion into 1-bromonaphthalene. The mild conditions required for this process reveal that naphthalene is activated with respect to electrophilic aromatic substitution.
Other electrophilic substitutions also are readily achieved and, again, are highly selective for reaction at C1. For example,

$$\text{HNO}_3, \text{CH}_3\text{COOH}, 20^\circ \text{C} \rightarrow$$

$$\text{NO}_2$$

$$\text{84\%} \quad \text{8\%}$$

1-Nitronaphthalene 2-Nitronaphthalene

The highly delocalized nature of the intermediate explains the ease of attack. The cation can be nicely pictured as a hybrid of five resonance forms.

**Electrophilic Reactivity of Naphthalene: Attack at C1**

However, attack of an electrophile at C2 also produces a cation that may be described by five contributing resonance forms.

**Electrophilic Attack on Naphthalene at C2**

Why, then, do electrophiles prefer to attack naphthalene at C1 rather than at C2? Closer inspection of the resonance contributors for the two cations reveals an important
difference: Attack at C1 allows two of the resonance forms of the intermediate to keep an intact benzene ring, with the full benefit of aromatic cyclic delocalization. Attack at C2 allows only one such structure, so the resulting carbocation is less stable and the transition state leading to it is less energetically favorable. Because the first step in electrophilic aromatic substitution is rate determining, attack is faster at C1 than at C2.

**Electrophiles attack substituted naphthalenes regioselectively**

The rules of orientation in electrophilic attack on monosubstituted benzenes extend easily to naphthalenes. The ring carrying the substituent is the one most affected: An activating group usually directs the incoming electrophile to the same ring, a deactivating group directs it away. For example, 1-methoxynaphthalene undergoes electrophilic nitration at C2 and C4.

![Nitration of 1-Methoxynaphthalene]

Deactivating groups in one ring usually direct electrophilic substitutions to the other ring and preferentially in the positions C5 and C8.
Resonance structures aid in predicting the regioselectivity of larger polycyclic aromatic hydrocarbons

The same principles of resonance, steric considerations, and directing power of substituents apply to larger polycyclic systems, derived from naphthalene by additional benzfusion, such as anthracene and phenanthrene (Section 15-5). For example, the site of preferred electrophilic attack on phenanthrene is C9 (or C10) because the dominant resonance contributor to the resulting cation retains two intact, delocalized benzene rings, whereas all the other forms require disruption of the aromaticity of either one or two of those rings.

Electrophilic Attack on Phenanthrene

Similar considerations pertain to anthracene and the higher polycyclic aromatic hydrocarbons in predicting the relative ease of electrophilic attack at various positions.

**Exercise 16-24**

**Working with the Concepts: Predicting Electrophilic Attack on Substituted Naphthalenes**

Predict the position of major electrophilic aromatic nitration in 1-(1-methylethyl)naphthalene.

**Strategy**

We apply the rules of orientation developed in this section: The more activated (or less deactivated) ring is subject to attack.

**Solution**

- The substituted ring bears an alkyl group, which is activating and ortho, para directing.
- 1-Methylethyl is moderately bulky, therefore ortho attack is hindered.
- Preferential nitration will occur at C4 to give:

![Electrophilic Attack on Phenanthrene](image)

**Exercise 16-25**

**Try It Yourself**

Predict the position of electrophilic aromatic nitration in (a) 2-nitronaphthalene; (b) 5-methoxy-1-nitronaphthalene; (c) 1,6-bis(1,1-dimethylethyl)naphthalene. (Caution: In problem (c), both rings are activated. Hint: Consider steric effects.)
Forest fires generate major environmental pollutants, including benzo[a]pyrene.

**Exercise 16-26**

Formulate a resonance form of the cation derived by electrophilic attack at C9 of phenanthrene in which the aromaticity of all benzene rings is disrupted.

**Exercise 16-27**

Electrophilic protonation of anthracene exhibits the following relative rates: $k(C9):k(C1):k(C2) = 11,000:7:1$. Explain. (For the numbering of the anthracene skeleton, see Section 15-5.)

**In Summary** Naphthalene is activated with respect to electrophilic aromatic substitution; favored attack takes place at C1. Electrophilic attack on a substituted naphthalene takes place on an activated ring and away from a deactivated ring, with regioselectivity in accordance with the general rules developed for electrophilic aromatic substitution of benzene derivatives. Similar considerations apply to the higher polycyclic aromatic hydrocarbons.

**16-7 Polycyclic Aromatic Hydrocarbons and Cancer**

Many polycyclic benzenoid hydrocarbons are carcinogenic. The first observation of human cancer caused by such compounds was made in 1775 by Sir Percival Pott, a surgeon at London’s St. Bartholomew’s hospital, who recognized that chimney sweeps were prone to scrotal cancer. Since then, a great deal of research has gone into identifying which polycyclic benzenoid hydrocarbons have this physiological property and how their structures correlate with activity. A particularly well studied molecule is benzo[a]pyrene, a widely distributed environmental pollutant. It is produced in the combustion of organic matter, such as automobile fuel and oil (for domestic heating and industrial power generation), in incineration of refuse, in forest fires, in burning cigarettes and cigars, and even in roasting meats. The annual release into the atmosphere in the United States alone has been estimated at 3000 tons.

**Carcinogenic Benzenoid Hydrocarbons**

What is the mechanism of carcinogenic action of benzo[a]pyrene? An oxidizing enzyme (an oxidase) of the liver converts the hydrocarbon into the oxacyclopropane at C7 and C8. Another enzyme (epoxide hydratase) catalyzes the hydration of the product to the trans diol. Rapid further oxidation then results in the ultimate carcinogen, a new oxacyclopropane at C9 and C10.
Enzymatic Conversion of Benzo[a]pyrene into the Ultimate Carcinogen

What makes the compound carcinogenic? It is believed that the amine nitrogen in guanine, one of the bases in DNA (see Chapter 26), attacks the oxacyclopropane as a nucleophile. The altered guanine disrupts the DNA double helix, leading to a mismatch in DNA replication.

The Carcinogenic Event

Polycyclic aromatic hydrocarbons are also prevalent in outer space. This photo shows the spiral galaxy NGC 7793, about 12.7 million light-years away from us, as observed with the Spitzer Infrared Space Telescope. The blue colors embody the $\nu = 2800 \text{ cm}^{-1}$ emission from stars. The green and red colors represent the $\nu = 1700$ and $1250 \text{ cm}^{-1}$ emissions from polycyclic aromatic hydrocarbons and possibly dust.
This change can lead to an alteration (mutation) of the genetic code, which may then generate a line of rapidly and indiscriminately proliferating cells typical of cancer. Not all mutations are carcinogenic; in fact, most of them lead to the destruction of only the one affected cell. Exposure to the carcinogen simply increases the likelihood of a carcinogenic event.

Notice that the carcinogen acts as an alkylating agent on DNA. This observation implies that other alkylating agents could also be carcinogenic, and indeed that is found to be the case. The Occupational Safety and Health Administration (OSHA) has published lists of likely carcinogens that include simple alkylating agents such as 1,2-dibromoethane and oxacyclopropane (see Problem 50 of Chapter 1).

The discovery of carcinogenicity in a number of organic compounds necessitated their replacement in synthetic applications. Both 1- and 2-naphthalenamines (naphthylamines) were once widely used in the synthesis of dyes because of the brilliant colors of many of their derivatives (azo dyes; see Section 22-11). These substances were discovered many years ago to be carcinogens, a finding that led to the development both of synthetic routes that avoided their use as intermediates and of new dyes with completely unrelated structures. A more recent example is chloro(methoxy) methane (ClCH2OCH3, chloromethyl methyl ether), once a commonly used reagent for the protection of alcohols by ether formation. The discovery of carcinogenicity in this alkylating agent in the 1970s resulted in the development of several less hazardous reagents.

**THE BIG PICTURE**

The directing effects of substituents on a benzene ring constitute another case of regioselectivity in organic chemistry. We encountered such selectivity previously in the nucleophilic ring opening of oxacyclopropanes (Section 9-9) and halonium ions (Section 12-6), where it could be controlled by steric or electronic factors (basic or acidic conditions, respectively). We also observed regioselectivity in the nucleophilic trapping of delocalized cations (for example, allylic cations; Section 14-6), where reversibility presented us with the options of kinetic versus thermodynamic regiocontrol. In electrophilic aromatic substitutions, the regiochemical outcome is (usually) kinetic in origin and results mainly from electronic effects. In cases for which several electronically favored sites of attack exist, steric factors often tip the balance. To predict the preferred product of a particular electrophilic aromatic substitution, we need to formulate all the possible cationic intermediates and assess the relative importance of all contributing stabilizing and destabilizing electronic and steric effects.

We have now completed our study of multiple bonds between carbon atoms, including alkenes and alkynes, conjugated dienes, and benzene and other aromatic compounds. Next we examine double bonds between carbon and oxygen atoms, which occur in the important classes of compounds that contain the carbonyl group. We shall see that some of the electronic effects that occur in carbon–carbon double bonds also occur in carbon–oxygen double bonds, but other effects are unique to the polar carbonyl group. As a result, carbonyl chemistry is a rich and very important area of organic chemistry. Understanding reactions involving the carbonyl group is essential to understanding many areas of biochemistry, from the action of pharmaceuticals to the details of molecular genetics. We start in Chapter 17 with a discussion of the carbonyl group in aldehydes and ketones.

**CHAPTER INTEGRATION PROBLEMS**

16-28. Specifically substituted, functionalized benzenamines (anilines) are important synthetic intermediates in medicinal chemistry and the dye industry. Propose a selective synthesis of 5-chloro-2-methoxy-1,3-benzenediamine, B, from methoxybenzene, A.
What are the feasible bond disconnections that lead to a simpler precursor to B directly—\(a\), \(b\), or \(c\)? Our retrosynthetic analysis below (Section 8-9) answers the question: None. Retrosynthetic step \(a\) proposes a transformation that is impossible to achieve with our present repertory of reactions and, in fact, is very difficult even with special reagents (requiring a source of “CH\(_3\)O’’). Quite apart from this problem, step \(a\) appears unwise because it cleaves a bond that is given in the starting material. Step \(c\) is a reverse electrophilic chlorination (Section 15-9), feasible in principle but not in practice because no selectivity for the desired position at C5 can be expected. Thus, while CH\(_3\)O directs para (and hence to C5) as wanted, the amino groups activate the other positions ortho, para (and hence to C4 and C6) even more (Section 16-3), ruling out step \(c\) as a good option, at least as such.

What about disconnection \(b\)? While direct electrophilic amination of arenes is (like alkoxylation or hydroxylation) not viable, we know that we can achieve it indirectly through a nitration–reduction sequence (Section 16-5). Thus, the problem reduces to a nitration of 1-chloro-4-methoxybenzene. Will it proceed with the desired regioselectivity? Guideline 2 in Section 16-4 answers in the affirmative. This analysis provides 1-chloro-4-methoxybenzene as a new relay point, available, in addition to its ortho isomer, by chlorination of methoxybenzene.

Therefore, a reasonable solution to our synthetic problem is that shown below as a proper synthetic scheme, with reagents, synthetic intermediates, and forward arrows in place.

**Solution Synthetic Scheme 1**
As a purist, you might not be satisfied with the lack of regiochemical control of the first step, which not only cuts down on yields but also requires a cumbersome separation. Consideration of a blocking strategy employing a sulfonation may help (Section 16-5). \( \text{SO}_3 \) is more bulky than chlorine and will furnish exclusively the para substitution product of electrophilic attack on methoxybenzene. Blocking the para position allows selective dinitration ortho to methoxy. After deblocking, the chlorine can be introduced, as shown below.

**Solution Synthetic Scheme 2**

\[ \begin{align*}
\text{A} & \xrightarrow{\text{SO}_3, \text{H}_2\text{SO}_4} \text{B} \\
\text{OCH}_3 & \xrightarrow{\text{HNO}_3, \text{H}_2\text{SO}_4} \text{OCH}_3 \\
\text{SO}_3 & \xrightarrow{\text{Cl}_2, \text{FeCl}_3} \text{Cl} \\
\text{H}_2 & \xrightarrow{\text{Ni}} \text{NH}_2
\end{align*} \]

This sequence requires two additional steps and, in practice, overall yields, ease of experimentation, including work-up, disposal cost of waste, and the value and availability of starting materials will determine which route to take, Scheme 1 or Scheme 2.

**16-29.** Acid-catalyzed cascade reactions are employed by nature and also by synthetic chemists in the construction of complex polycyclic molecules, including steroids (Section 4-7). Provide a mechanism for the following multiple cyclization.

**SOLUTION**

This is a mechanistic and not a synthetic problem, and therefore we can use only what is given above. Let us look at the general features of this transformation. A starting material with only two rings is converted into a product with four rings by the making of two new C–C bonds, and somewhere along the sequence, the hydroxy function is lost. The reagent \( \text{BF}_3 \) is a Lewis acid (Section 2-2), “hungry” for an electron pair, and the hydroxy oxygen is an obvious source for such. What are the exact changes in composition during the reaction? This question is answered by assessing the change in the respective molecular formulas: \( \text{C}_{19}\text{H}_{26}\text{O}_2 \) turns into \( \text{C}_{19}\text{H}_{24}\text{O} \). Thus, overall, the process constitutes a dehydration (\( -\text{H}_2\text{O} \)).

After this general analysis, we can go about addressing the details of the mechanism. What do we anticipate to happen when a secondary (and allylic) alcohol is treated with a Lewis acid?

**Answer:** (Allylic) carbocation (C) formation (Sections 9-2, 9-3, and 14-3):
What do we expect from a carbocation in the presence of a nearby double bond? *Answer:* electrophilic addition (Section 12-14) to form a new carbocation (D):

While this answer satisfies the structural requirements for proceeding on to the eventual final product, we can ponder several questions regarding the selectivity of the formation of D. First, C contains two electrophilic sites. Why is only one picked? *Answer:* The less hindered carbon should react faster. Second, conversion to D makes a six-membered ring. Why not attack the other end of the double bond to give a five-membered ring? *Answer:* The observed six-membered ring should be less strained (Section 4-3). And third, when going from C to D, a resonance-stabilized allylic carbocation is converted into an “ordinary” secondary cation. What is the driving force? *Answer:* A new carbon–carbon bond is formed. Having arrived at D, we can recognize the last step as a Friedel-Crafts alkylation of an activated benzene, para to the directing methoxy group.
New Reactions
Electrophilic Substitution of Substituted Benzenes

1. Ortho- and Para-Directing Groups (Sections 16-1 through 16-3)

\[
\begin{align*}
G & \quad \text{E}^+ & G & \quad \text{E}^+ & G \\
\text{Ortho isomer} & & \text{Para isomer} \\
(\text{Usually predominates})
\end{align*}
\]

\[G = \text{NH}_2, \text{OH}; \text{strongly activating}\]
\[= \text{NHCOR, OR}; \text{moderately activating}\]
\[= \text{alkyl, aryl}; \text{weakly activating}\]
\[= \text{halogen}; \text{weakly deactivating}\]

2. Meta-Directing Groups (Sections 16-1 through 16-3)

\[
\begin{align*}
G & \quad \text{E}^+ & G \\
\text{Meta isomer}
\end{align*}
\]

\[G = \text{N(CH}_3)_3, \text{NO}_2, \text{CF}_3, \text{C}≡\text{N}, \text{SO}_3\text{H}; \text{very strongly deactivating}\]
\[= \text{CHO, COR, COOH, COOR, CONH}_2; \text{strongly deactivating}\]

Synthetic Planning: Switching and Blocking of Directing Power

3. Interconversion of Nitro and Amino Groups (Section 16-5)

\[
\begin{align*}
\text{NO}_2 & \quad \text{HCl, Zn(Hg) or H}_2\text{, Ni or Fe, HCl} & \text{NH}_2 \\
\text{CF}_3\text{CO}_3\text{H}
\end{align*}
\]

Meta directing

Ortho, para directing

4. Interconversion of Acyl and Alkyl (Section 16-5)

\[
\begin{align*}
\text{RC}=\text{O} & \quad \text{H}_2, \text{Pd, CH}_3\text{CH}_2\text{OH or Zn(Hg), HCl} & \text{RCH}_2 \\
\text{CF}_3\text{CO}_3\text{H}, \text{H}_2\text{SO}_4, \text{H}_2\text{O}
\end{align*}
\]

Meta directing

Ortho, para directing
5. Blocking by Sulfonation (Section 16-5)

\[
\begin{align*}
\text{R} & \rightarrow \text{SO}_3, \text{H}_2\text{SO}_4, \text{Block} \quad \text{R} \quad \text{SO}_3\text{H} \\
\text{E} & \rightarrow \text{H}_2\text{O}, \Delta, \text{Deblock} \\
\text{R} & \quad \text{E}
\end{align*}
\]

6. Moderation of Strong Activators by Protection (Section 16-5)

\[
\begin{align*}
\text{NH}_2 & \quad \text{CH}_3\text{CCl}, \text{pyridine} \quad \text{O} \quad \text{OH}, \text{H}_2\text{O} \text{or} \quad \text{H} \quad \text{H}_2\text{O} \\
\text{O} & \quad \text{HNCCH}_3 \quad \text{OH} \quad \text{NaOH}, \text{CH}_3\text{I} \\
\quad & \quad \text{H}_2\text{O}, \text{H}_2\text{O} \\
\quad & \quad \text{Moderately} \quad \text{Strongly} \quad \text{Moderately} \quad \text{Moderately} \\
\quad & \quad \text{activated} \quad \text{activated} \text{ and protected} \quad \text{activated} \text{ and protected}
\end{align*}
\]

7. Electrophilic Aromatic Substitution of Naphthalene (Section 16-6)

\[
\begin{align*}
\text{E} & \rightarrow \text{E}^+ \\
\text{E} & \rightarrow \text{H}_2\text{O}, \Delta, \text{Deblock}
\end{align*}
\]

**Important Concepts**

1. Substituents on the benzene ring can be divided into two classes: those that activate the ring by electron donation and those that deactivate it by electron withdrawal. The mechanisms of donation and withdrawal are based on induction or resonance. These effects may operate simultaneously to either reinforce or oppose each other. Amino and alkoxy substituents are strongly activating, alkyl and phenyl groups weakly so; nitro, trifluoromethyl, sulfonyl, oxo, nitrile, and cationic groups are strongly deactivating, whereas halogens are weakly so.

2. Activators direct electrophiles ortho and para; deactivators direct meta, although at a much lower rate. The exceptions are the halogens, which deactivate but direct ortho and para.

3. When there are several substituents, the strongest activator (or weakest deactivator) controls the regioselectivity of attack, the extent of control decreasing in the following order:

   \[
   \text{NR}_2, \text{OR} > \text{X}_2, \text{R} > \text{meta directors}
   \]

4. Strategies for the synthesis of highly substituted benzenes rely on the directing power of the substituents, the synthetic ability to change the sense of direction of these substituents by chemical manipulation, and the use of blocking and protecting groups.

5. Naphthalene undergoes preferred electrophilic substitution at C1 because of the relative stability of the intermediate carbocation.

6. Electron-donating substituents on one of the naphthalene rings direct electrophiles to the same ring, ortho and para. Electron-withdrawing substituents direct electrophiles away from that ring; substitution is mainly at C5 and C8.

7. The actual carcinogen derived from benz[a]pyrene appears to be an oxacyclopropanediol in which C7 and C8 bear hydroxy groups and C9 and C10 are bridged by oxygen. This molecule alkylates one of the nitrogens of one of the DNA bases, thus causing mutations.
Problems

30. Rank the compounds in each of the following groups in order of decreasing reactivity toward electrophilic substitution. Explain your rankings.

(a) CCl₃ CH₃ CHCl₂ CH₂Cl CH₃ OCH₃ O⁻Na⁺ OCCH₃
(b) CH₂CH₃ CH₂CCl₃ CH₂CF₃ CF₂CH₃
(c) CH₂CH₃ CH₂CCl₃ CH₂CF₃ CF₂CH₃

31. The rate of nitration of (chloromethyl)benzene, \(-\text{CH₂Cl}\), is 0.71 relative to the rate of nitration of benzene (=1). The (chloromethyl)nitrobenzene product mixture that results contains 32% ortho, 15.5% meta, and 52.5% para isomers. Explain.

32. Specify whether you expect the benzene rings in the following compounds to be activated or deactivated.

(a) COOH (b) NO₂ (c) OH
(d) F (e) NH₂ (f) SO₃H (g) C(CH₃)₃

33. Rank the compounds in each of the following groups in order of decreasing reactivity toward electrophilic aromatic substitution. Explain your answers.

(a) CH₃ COOH COOH
(b) CH₃ COOH

34. Halogenation of 1,3-dimethylbenzene (m-xylene) takes place 100 times faster than halogenation of either its 1,2- or 1,4-isomers (o- or p-xylene). Suggest an explanation.
35. Write the structure(s) of the major product(s) that you expect from each of the following electrophilic aromatic substitutions. (a) Nitration of methylbenzene (toluene); (b) sulfonation of methylbenzene (toluene); (c) nitration of 1,1-dimethylethylbenzene (tert-butylbenzene); (d) sulfonation of 1,1-dimethylethylbenzene (tert-butylbenzene).

In what way does changing the substrate structures from methylbenzene (toluene) in (a) and (b) to 1,1-dimethylethylbenzene (tert-butylbenzene) in (c) and (d) affect the expected product distributions?

36. Write the structure(s) of the major product(s) that you expect from each of the following electrophilic aromatic substitutions. (a) Sulfonation of methoxybenzene (anisole); (b) bromination of nitrobenzene; (c) nitration of benzoic acid; (d) Friedel-Crafts acetylation of chlorobenzene.

37. Draw appropriate resonance forms to explain the deactivating meta-directing character of the SO$_3$H group in benzenesulfonic acid.

38. Do you agree with the following statement? “Strongly electron-withdrawing substituents on benzene rings are meta directing because they deactivate the meta positions less than they deactivate the ortho and para positions.” Explain your answer.

39. Draw appropriate resonance forms to explain the activating ortho, para-directing character of the phenyl substituent in biphenyl (margin).

40. Give the expected major product(s) of each of the following electrophilic substitution reactions.

41. Reaction review. Without consulting the Reaction Road Map on p. 721, suggest a combination of reagent and monosubstituted benzene that would give each of the following compounds. (Hint: Refer to Table 16-2 for guidance. Caution: Directing effects arise from the group already present on the benzene ring, not the group you are trying to attach.)
42. Reaction review. The preparation of the following compounds requires more than one step. As in Problem 41, suggest a monosubstituted benzene as starting material and the reagents for all the steps needed to complete their synthesis.

(a) \[
\text{CH}_3\text{NO}_2 \xrightarrow{\text{Cl}_2, \text{FeCl}_3}\]

(b) \[
\text{CH}_3\text{Cl} \xrightarrow{\text{SO}_3, \text{H}_2\text{SO}_4}\]

(c) \[
\text{CH}_2\text{CH}_3\text{COOH} \xrightarrow{\text{HNO}_3, \text{H}_2\text{SO}_4}\]

(d) \[
\text{CH}_3\text{NHCCH}_3\text{O} \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(e) \[
\text{SO}_3\text{H} \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(f) \[
\text{SO}_3\text{H} \xrightarrow{\text{O}_2\text{N}}\]

(g) \[
\text{CH}_3\text{Cl} \xrightarrow{\text{AlCl}_3}\]

43. Give the expected major product(s) of each of the following reactions.

(a) \[
\text{NO}_2 \xrightarrow{\text{Cl}_2, \text{FeCl}_3}\]

(b) \[
\text{Cl} \xrightarrow{\text{SO}_3, \text{H}_2\text{SO}_4}\]

(c) \[
\text{COOH} \xrightarrow{\text{HNO}_3, \text{H}_2\text{SO}_4}\]

(d) \[
\text{NH}_2\text{Br} \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(e) \[
\text{I} \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(f) \[
\text{OCH}_3 \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(g) \[
\text{NO}_2 \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(h) \[
\text{NO}_2 \xrightarrow{\text{Br}_2, \text{FeBr}_3}\]

(i) \[
\text{Cl} \xrightarrow{\text{Cl}_2, \text{FeCl}_3}\]

44. **Challenge** (a) When a mixture containing one mole each of the three dimethylbenzenes (\(\alpha\)-, \(m\)-, and \(p\)-xylene) is treated with one mole of chlorine in the presence of a Lewis acid catalyst, one of the three hydrocarbons is monochlorinated in 100% yield, whereas the other two remain completely unreacted. Which isomer reacts? Explain the differences in reactivity. (b) The same
experiment carried out on a mixture of the following three trimethylbenzenes gives a similar outcome. Answer the questions posed in (a) for this mixture of compounds.

1,2,3-Trimethylbenzene 1,2,4-Trimethylbenzene 1,3,5-Trimethylbenzene

45. Propose a reasonable synthesis of each of the following multiply substituted arenes from benzene.

46. (4-Methoxyphenyl)methanol (anisyl alcohol) (see margin) contributes both to the flavor of licorice and to the fragrance of lavender. Propose a synthesis of this compound from methoxybenzene (anisole). (Hint: Consider your range of options for alcohol synthesis. If necessary, refer to Problem 55 of Chapter 15.)

47. The science of pain control has evolved dramatically in the past several years. The body deals with pain by releasing anandamide (see Section 20-6). Anandamide binds to the cannabinoid receptor, the same site that recognizes the active ingredients in marijuana. Binding to this site suppresses the perception of pain. The effect is not long lasting, because another enzyme degrades anandamide over time. Thus, recent research has focused on finding therapeutic molecules capable of blocking this anandamide-destroying enzyme. The biphenyl derivative URB597 is an experimental substance that displays some of this desired enzyme-blocking ability, and it has been demonstrated to enhance pain suppression in rats.

Examine the structure of URB597 and address the following question: Would you expect URB597 to be an easy or a difficult target molecule to prepare, beginning with biphenyl (Problem 39)? If you chose easy, illustrate how the reactions of this chapter might be employed in a synthetic approach to this drug. If you chose difficult, explain why.
48. The NMR and IR spectra for four unknown compounds A through D are presented below and on the next two pages. Possible empirical formulas for them (not in any particular order) are \( \text{C}_6\text{H}_5\text{Br} \), \( \text{C}_6\text{H}_6\text{BrN} \), and \( \text{C}_6\text{H}_5\text{Br}_2\text{N} \) (one of these formulas is used twice—two of the unknowns are isomers). Propose a structure and suggest a synthesis of each unknown, starting from benzene.
49. Catalytic hydrogenation of naphthalene over Pd–C results in rapid addition of 2 moles of H₂. Propose a structure for this product.

50. Predict the major mononitration product of each of the following disubstituted naphthalenes.
(a) 1,3-Dimethylnaphthalene;
(b) 1-chloro-5-methoxynaphthalene;
(c) 1,7-dinitronaphthalene;
(d) 1,6-dichloronaphthalene.
51. Write the expected product(s) of each of the following reactions.

(a) \( \text{Cl}_2, \text{CCl}_4, \Delta \)

(b) \( \text{HNO}_3 \)

(c) \( \text{Conc. H}_2\text{SO}_4, \Delta \)

(d) \( \text{CH}_3\text{CCl}, \text{AlCl}_3, \text{CS}_2 \)

(e) \( \text{NO}_2, \text{Br}_2, \text{FeBr}_3 \)

52. [CHALLENGE] Sulfonation of naphthalene at 80°C gives almost entirely 1-naphthalenesulfonic acid, whereas the same reaction at 160°C gives 2-naphthalenesulfonic acid. Propose an explanation. (Hint: For the underlying principle, see Section 14-6.)
53. Electrophilic substitution on the benzene ring of benzenethiol (thiophenol, C₆H₅SH) is not possible. Why? What do you think happens when benzenethiol is allowed to react with an electrophile? (Hint: Review Section 9-10.)

54. Although methoxy is a strongly activating (and ortho, para–directing) group, the meta positions in methoxybenzene (anisole) are actually slightly deactivated toward electrophilic substitution relative to benzene. Explain.

55. Predict the result of mononitration of

(a) ![Structure](attachment:structure_a.png)
(b) ![Structure](attachment:structure_b.png)
(c) ![Structure](attachment:structure_c.png)
(d) ![Structure](attachment:structure_d.png)
(e) ![Structure](attachment:structure_e.png)

56. **Challenge** The nitroso group, –NO, as a substituent on a benzene ring acts as an ortho, para–directing group but is deactivating. Use the Lewis structure of the nitroso group and its inductive and resonance interactions with the benzene ring to explain this finding. (Hint: Consider possible similarities to another type of substituent that is ortho, para–directing but deactivating.)

57. Typical conditions for nitrosation are illustrated in the following equation. Propose a detailed mechanism for this reaction.

![Reaction](attachment:reaction.png)

**Team Problem**

58. Polystyrene (polyethenylbenzene) is a familiar polymer used in the manufacture of foam cups and packing beads. One could, in principle, synthesize polystyrene by cationic polymerization with acid. However, this approach is unsuccessful because of the formation of dimer A.

![Polymerization](attachment:polymerization.png)

Split your group into two teams. The first should formulate a mechanism for the cationic polymerization of styrene using acid; the second should do so for the formation of A. Reconvene and compare your notes. At which stage is the normal polymerization sequence diverted to generate A?
Preprofessional Problems

59. Which of the following reactions is an electrophilic aromatic substitution?

(a) $\text{C}_6\text{H}_{12} \xrightarrow{\text{Se, 300°}} \text{C}_6\text{H}_6$
(b) $\text{C}_6\text{H}_5\text{CH}_3 \xrightarrow{\text{Cl}_2, h\nu} \text{C}_6\text{H}_5\text{CH}_2\text{Cl}$
(c) $\text{C}_6\text{H}_6 + (\text{CH}_3)_2\text{CHOH} \xrightarrow{\text{BF}_3, 60°} \text{C}_6\text{H}_5\text{CH}(\text{CH}_3)_2$
(d) $\text{C}_6\text{H}_5\text{Br} \xrightarrow{\text{Mg}, \text{ether}} \text{C}_6\text{H}_5\text{MgBr}$

60. The intermediate cation A in the sequence $\text{C}_6\text{H}_6 + E^+ \rightarrow A \rightarrow \text{C}_6\text{H}_5E + H^+$ is best shown as

(a) $\text{(a)}$
(b) $\text{(b)}$
(c) $\text{(c)}$
(d) $\text{(d)}$

61. The $^1\text{H NMR}$ spectrum of an unknown compound shows absorptions at (no multiplicities given) $\delta = 7.3$ (5 H), 2.3 (1 H), and 0.9 (6 H) ppm. One of the following five structures satisfies these data. Which one? (Hint: The $^1\text{H NMR}$ signal for ethane is at $\delta = 0.9$ ppm, that for benzene at $\delta = 7.3$ ppm.)

(a) $\text{(a)}$ $\text{C}_6\text{H}_5\text{CH}_2\text{CH}_3$
(b) $\text{(b)}$ $\text{CH}_3$
(c) $\text{(c)}$ $\text{C}_6\text{H}_5\text{CH}(\text{CH}_3)_2$
(d) $\text{(d)}$ $\text{CH}_3$
(e) $\text{(e)}$ $\text{CH}_2\text{CH}_3$

62. A volume of 135 mL of benzene was treated with excess Cl$_2$ and AlCl$_3$ to yield 50 mL of chlorobenzene. Given the atomic weights of C = 12.0, H = 1.00, and Cl = 35.5, and the densities of benzene, 0.78 g mL$^{-1}$, and chlorobenzene, 1.10 g mL$^{-1}$, the percent yield is closest to (a) 15; (b) 26; (c) 35; (d) 46; (e) 55.

63. Among the following choices, the group that activates the benzene ring toward electrophilic aromatic substitution is (a) $-\text{NO}_2$; (b) $-\text{CF}_3$; (c) $-\text{CO}_2\text{H}$; (d) $-\text{OCH}_3$; (e) $-\text{Br}$.
Have you ever sensed an odor that suddenly brought back a long-forgotten memory? If so, you have experienced a phenomenon unique to our sense of smell—it is a primitive sense and the only one for which the related sensory nerves are part of the brain itself. These nerves respond to both the shape and the presence of polar functional groups in volatile molecules. Prominent among the organic compounds with the most potent and varied odors are those possessing the carbon–oxygen double bond, the carbonyl group.

In this chapter and the next, we focus on the two simplest classes of carbonyl compounds: aldehydes, in which the carbon atom of the carbonyl group is bound to at least one hydrogen atom, and ketones, in which it is bound to two other carbons. These compounds exist throughout nature, contributing to the flavors and aromas of many foods and assisting in the biological functions of many enzymes. Even individual cells, such as the sperm shown in the illustration above, display a sensing ability related to that of smell. The aldehyde bourgeonal mimics as yet unidentified molecules produced by the female reproductive system to attract the most sensitive sperm for fertilization. Understanding these processes may have valuable implications for reproductive medicine. In addition, industry makes considerable use of aldehydes and ketones, both as reagents and as solvents in synthesis. Indeed, the carbonyl group is frequently considered to be the most important functional group in organic chemistry.

After explaining how to name aldehydes and ketones, we look at their structures and physical properties. Like alcohols, the carbonyl group possesses an oxygen atom with two lone pairs, a structural feature that enables it to function as a weak Lewis base. Moreover, the carbon–oxygen double bond is also highly polarized, making the carbonyl carbon quite electrophilic. In the remainder of this chapter, we show how these properties shape the chemistry of this versatile functional group.
17-1 Naming the Aldehydes and Ketones

For the purposes of naming, the carbonyl function is the highest-ranking group we have encountered so far. The aldehyde function takes precedence over that of ketones. For historical reasons, the simpler aldehydes often retain their common names. These names are derived from the common name of the corresponding carboxylic acid, with the ending -ic or -oic acid replaced by -aldehyde, as shown in the examples below.

Formic acid  Formaldehyde  Acetic acid  Acetaldehyde  $\alpha$-Bromobenzoic acid  $\alpha$-Bromobenzaldehyde

Many ketones also have common names, which consist of the names of the substituent groups followed by the word ketone. Dimethyl ketone, the simplest example, is a common solvent best known as acetone. Phenyl ketones have common names ending in -phenone.

Dimethyl ketone (Acetone)  Ethyl methyl ketone  Diethyl ketone  Acetophenone  Benzophenone

IUPAC names treat aldehydes as derivatives of the alkanes, with the ending -e replaced by -al. An alkane thus becomes an alkanal. Methanal, the systematic name of the simplest aldehyde, is thus derived from methane, ethanal from ethane, propanal from propane, and so forth. However, Chemical Abstracts retains the common names for the first two, and so shall we. We number the substituent chain beginning with the carbonyl carbon.

Methanal (Formaldehyde)  Ethanal (Acetaldehyde)  Propanal  4-Chlorobutanal  4,6-Dimethylheptanal

Notice that the names parallel those of the 1-alkanols (Section 8-1), except that the position of the aldehyde carbonyl group does not have to be specified; its carbon is defined as C1. When the –CHO group is attached to a ring, the compound is called a carbaldehyde and the carbon atom bearing the –CHO group is C1. The parent aromatic aldehyde, for instance, is benzenecarbaldehyde, although its common name, benzaldehyde, is so widely used that it is accepted by Chemical Abstracts.
Ketones are called *alkanones*, the ending -e of the alkane replaced with -one. An exception is the smallest ketone, propanone, for which IUPAC has accepted the common name acetone. The carbonyl carbon is assigned the lowest possible number in the chain, regardless of the presence of other substituents or the OH, C=C, or C=C functional groups. Aromatic ketones are named as aryl-substituted alkanones. Ketones, unlike aldehydes, may also be part of a ring, an arrangement that gives compounds called *cycloalkanones*.

Notice that we assign the number 1 to the carbonyl carbon when it is in a ring. For purposes of numbering and naming, the carbonyl group of an aldehyde takes precedence over all other groups we have encountered so far. Both aldehydes and ketones take precedence over alcohols, but not over the carboxylic acid function, which we shall encounter in Chapter 19 when we present the entire order of precedence of all the common functional groups.

### Aldehydes and Ketones with Other Functional Groups

Systematic nomenclature accepts both *alkanoyl* and *acyl* as names for the fragment RC–. Acyl is more widely used and is the one we will employ (see also Section 15-13). Both the IUPAC and Chemical Abstracts retain the common names *formyl* for HC– and *acetyl* for CH₃C–. The term *oxo* denotes the location of a ketone carbonyl group when it is present together with an aldehyde function.

### Exercise 17-1

Name or draw the structures of the following compounds.

(a)  [Structure image]
(b)  [Structure image]

**In Summary** Aldehydes and ketones are named systematically as alkanals and alkanones. The carbonyl group takes precedence over the hydroxy function and carbon–carbon double and triple bonds in numbering. With these rules, the usual guidelines for numbering the stem and labeling the substituents are followed.

### 17-2 Structure of the Carbonyl Group

If we think of the carbonyl group as an oxygen analog of the alkene functional group, we can correctly predict its orbital description, the structures of aldehydes and ketones, and some of their physical properties. However, the alkene and carbonyl double bonds do differ considerably in reactivity because of the electronegativity of oxygen and its two lone pairs of electrons.

**The carbonyl group contains a short, strong, and very polar bond**

Both the carbon and the oxygen of the carbonyl group are sp² hybridized. They therefore lie in the same plane as the two additional groups on carbon, with bond angles approximating 120°. Perpendicular to the molecular frame are two p orbitals, one on carbon and one on oxygen, making up the π bond (Figure 17-1).

![Figure 17-1](image-url)  
**Figure 17-1** Orbital picture of the carbonyl group. The sp² hybridization and the orbital arrangement are similar to those of ethene (Figure 11-2). However, both the two lone electron pairs and the electronegativity of the oxygen atom modify the properties of the functional group.

Figure 17-2 shows some of the structural features of acetaldehyde. As expected, the molecule is planar, with a trigonal carbonyl carbon and a short carbon–oxygen bond, indicative of its double-bond character. Not surprisingly, this bond is also rather strong, ranging from 175 to 180 kcal mol⁻¹ (732 to 753 kJ mol⁻¹).

Comparison with the electronic structure of an alkene double bond reveals two important differences. First, the oxygen atom bears two lone electron pairs located in two sp² hybrid orbitals. Second, oxygen is more electronegative than carbon. This property causes an appreciable polarization of the carbon–oxygen double bond, with a partial positive
charge on carbon and an equal amount of negative charge on oxygen. Thus, the carbon is electrophilic, the oxygen nucleophilic and slightly basic. This polarization can be described either by a polar resonance form for the carbonyl moiety or by partial charges. It can also be seen in the electrostatic potential map of formaldehyde in the margin, where the area around the carbon atom appears blue (positive), and that around the oxygen red (negative). As we have seen (Section 16-1), the partial positive charge on the carbonyl carbon renders acyl groups electron withdrawing.

**Descriptions of a Carbonyl Group**

\[
\begin{align*}
\text{Electrophilic} & \quad \text{Nucleophilic and basic}
\end{align*}
\]

**Polarization alters the physical constants of aldehydes and ketones**

The polarization of the carbonyl functional group makes the boiling points of aldehydes and ketones higher than those of hydrocarbons of similar size and molecular weight (Table 17-1). Because of their polarity, the smaller carbonyl compounds such as acetaldehyde and acetone are completely miscible with water: An aqueous solution of formaldehyde (Section 17-6) has applications as a disinfectant and a fungicide. As the hydrophobic hydrocarbon part of the molecule increases in size, however, water solubility decreases. Carbonyl compounds with more than six carbons are rather insoluble in water.

**In Summary** The carbonyl group in aldehydes and ketones is an oxygen analog of the carbon–carbon double bond. However, the electronegativity of oxygen polarizes the \( \pi \) bond, thereby rendering the acyl substituent electron withdrawing. The arrangement of bonds around the carbon and oxygen is planar, a consequence of \( sp^2 \) hybridization.

### 17-3 Spectroscopic Properties of Aldehydes and Ketones

What are the spectral characteristics of carbonyl compounds? In \(^1\text{H NMR}\) spectroscopy, the formyl hydrogen of the aldehydes is very strongly deshielded, appearing between 9 and 10 ppm, a chemical shift that is unique for this class of compounds. The reason for this effect is twofold. First, the movement of the \( \pi \) electrons, like that in alkenes (Section 11-4), causes a local magnetic field, which strengthens the external field. Second, the charge on
the positively polarized carbon exerts an additional deshielding effect. Figure 17-3 shows the \(^1\)H NMR spectrum of propanal with the formyl hydrogen resonating at \(\delta = 9.79\) ppm, split into a triplet \((J = 2\) Hz) because of a small coupling to the neighboring (C2) hydrogens. These hydrogens are also slightly deshielded relative to alkane hydrogens because of the electron-withdrawing character of the carbonyl group. This effect is also seen in the \(^1\)H NMR spectra of ketones: The \(\alpha\)-hydrogens normally appear in the region \(\delta = 2.0 – 2.8\) ppm.

Carbon-13 NMR spectra are diagnostic of both aldehydes and ketones because of the characteristic chemical shift of the carbonyl carbon. Partly because of the electronegativity of the directly bound oxygen, the carbonyl carbons in aldehydes and ketones appear at even lower field (\(\sim 200\) ppm) than do the \(sp^2\)-hybridized carbon atoms of alkenes (Section 11-4). The carbons next to the carbonyl group also are deshielded relative to those located farther away. The \(^{13}\)C NMR spectrum of cyclohexanone is shown in Figure 17-4.
Infrared spectroscopy is a useful way of directly detecting the presence of a carbonyl group. The C=O stretching frequency gives rise to an intense band that typically appears in a relatively narrow range (1690–1750 cm\(^{-1}\), Figure 17-5). The carbonyl absorption for aldehydes appears at about 1735 cm\(^{-1}\); absorptions for acyclic alkanones and cyclohexanone are found at about 1715 cm\(^{-1}\). Conjugation with either alkene or benzene \(\pi\) systems reduces the carbonyl infrared frequency by about 30–40 cm\(^{-1}\); thus 1-phenylethanone (acetophenone) exhibits an IR band at 1680 cm\(^{-1}\). Conversely, the stretching frequency increases for carbonyl groups in rings with fewer than six atoms: Cyclopentanone absorbs at 1745 cm\(^{-1}\), cyclobutanone at 1780 cm\(^{-1}\).

Carbonyl groups also exhibit characteristic electronic (UV) spectra because the non-bonding lone electron pairs on the oxygen atom undergo low-energy \(n \rightarrow \pi^*\) transitions (Figure 17-6). For example, acetone shows an \(n \rightarrow \pi^*\) band at 280 nm (\(\epsilon = 15\)) in hexane. The corresponding \(\pi \rightarrow \pi^*\) transition appears at about 190 nm (\(\epsilon = 1100\)). Conjugation with a carbon–carbon double bond shifts absorptions to longer wavelengths. For example, the electronic spectrum of 3-buten-2-one, \(\text{CH}_2=\text{CHCOCH}_3\), has peaks at 324 nm (\(\epsilon = 24\), \(n \rightarrow \pi^*\)) and 219 nm (\(\epsilon = 3600\), \(\pi \rightarrow \pi^*\)).

**Electronic Transitions of Acetone and 3-Buten-2-one**

\[
\begin{align*}
\text{Acetone} & : & \lambda_{\text{max}}(\epsilon) = 280(15) & n \rightarrow \pi^* \\
& & 190(1100) & \pi \rightarrow \pi^* \\
3\text{-Buten-2-one} & : & \lambda_{\text{max}}(\epsilon) = 324(24) & n \rightarrow \pi^* \\
& & 219(3600) & \pi \rightarrow \pi^*
\end{align*}
\]
Mass spectral fragmentation of aldehydes and ketones provides structural information

The fragmentation patterns of carbonyl compounds are often useful in structural identifications. For example, the mass spectra of the isomeric ketones 2-pentanone, 3-pentanone, and 3-methyl-2-butanone (Figure 17-7) reveal very clean and distinct fragment ions. The predominant decomposition pathway is α cleavage, which severs an alkyl bond to the carbonyl function to give the corresponding acylium cation and an alkyl radical.

\[
\begin{align*}
\text{R–C} & \xrightarrow{\alpha \text{ Cleavage}} \text{R–C} \\
\text{R–C} & \xrightarrow{\alpha \text{ Cleavage}} \text{R–C}
\end{align*}
\]

Acylium cation
Figure 17-7  Mass spectra of (A) 2-pentanone, showing two peaks for \( \alpha \) cleavage and one for McLafferty rearrangement; (B) 3-pentanone, showing only a single \( \alpha \) cleavage peak because of symmetry; and (C) 3-methyl-2-butanone, showing two \( \alpha \) cleavages.
The acylium cation forms easily because of resonance stabilization. These fragment ions allow the gross composition of the two alkyl groups in a ketone to be read from the spectrum. In this way, 2-pentanone is readily differentiated from 3-pentanone: α Cleavage of 2-pentanone gives two acylium ions, at \( m/z = 43 \) and 71, but 3-pentanone gives only one, at \( m/z = 57 \). (The \( m/z = 29 \) peak in the mass spectrum of 3-pentanone is due partly to \( \text{CH}_3\text{CH}_2^+ \) and partly to \( \text{HC}==\text{O}^+ \), which arises by loss of \( \text{C}_2\text{H}_4 \) from \( \text{CH}_3\text{CH}_2\text{C}==\text{O}^+ \)).

**α Cleavage in 2-Pentanone**

\[
\begin{align*}
\text{C}==\text{O} &\quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \\
\text{m/z} = 71 &\quad \text{m/z} = 86 \\
\end{align*}
\]

**α Cleavage in 3-Pentanone**

\[
\begin{align*}
\text{C}==\text{O} &\quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \\
\text{m/z} = 86 &\quad \text{m/z} = 57 \\
\end{align*}
\]

Can 2-pentanone be distinguished from 3-methyl-2-butanone? Not by the observation of α cleavage—in both molecules, the substituent groups are \( \text{CH}_3 \) and \( \text{C}_3\text{H}_7 \). However, comparison of the mass spectra of the two compounds (Figure 17-7A and C) reveals an additional prominent peak for 2-pentanone at \( m/z = 58 \), signifying the loss of a molecular fragment of weight \( m/z = 28 \). This fragment is absent from the spectra of both other isomers and is characteristic of the presence of hydrogens located \( \gamma \) to the carbonyl group. Compounds with this structural feature and with sufficient flexibility to allow the \( \gamma \)-hydrogen to be close to the carbonyl oxygen decompose by the **McLafferty** rearrangement. In this reaction, the molecular ion of the starting ketone splits into two pieces (a neutral fragment and a radical cation) in a unimolecular process.

**McLafferty Rearrangement**

The McLafferty rearrangement yields an alkene and the enol form of a new ketone. In the case of 2-pentanone, ethene and the enol of acetone are produced; the radical cation of the acetone enol is observed with \( m/z = 58 \).

\[
\begin{align*}
\text{C}==\text{O} &\quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{C}==\text{O} \\
\text{m/z} = 86 &\quad \text{m/z} = 58 \\
\end{align*}
\]

Neither 3-pentanone nor 3-methyl-2-butanone possesses a \( \gamma \)-hydrogen; therefore, neither is able to undergo McLafferty rearrangement.

**Exercise 17-5**

How would you tell the difference between (a) 3-methyl-2-pentanone and 4-methyl-2-pentanone, and (b) 2-ethylcyclohexanone and 3-ethylcyclohexanone, using only mass spectrometry?

*Professor Fred W. McLafferty (b. 1923), Cornell University, Ithaca, New York.*
**In Summary** In the NMR spectra of aldehydes and ketones, the formyl hydrogens and the carbonyl carbons show strong deshielding. The carbon–oxygen double bond in ketones gives rise to a strong infrared band at about 1715 cm$^{-1}$, which is shifted to lower frequency by conjugation and to higher frequency in aldehydes and small rings. The ability of non-bonding electrons to be excited into the $\pi^*$ molecular orbitals causes the carbonyl group to exhibit characteristic, relatively long-wavelength UV absorptions. Finally, aldehydes and ketones fragment in the mass spectrometer by $\alpha$ cleavage and McLafferty rearrangement.

**17-4 Preparation of Aldehydes and Ketones**

Several ways to prepare aldehydes and ketones have already been described in connection with the chemistry of other functional groups (see the Reaction Summary Road Map on pp. 816–817). This section reviews the methods that we have studied, pointing out special features and additional examples. Other routes to aldehydes and ketones will be described in later chapters.

**Laboratory syntheses of aldehydes and ketones use four common methods**

Table 17-2 summarizes four approaches to synthesizing aldehydes and ketones. First, we have seen (Section 8-6) that oxidation of alcohols by chromium(VI) reagents gives carbonyl compounds. Secondary alcohols give ketones. Primary alcohols give aldehydes, but only in the absence of water, to prevent overoxidation to carboxylic acids. Chromium(VI) is selective and does not oxidize alkene and alkyne units.

### Selective Alcohol Oxidation

![Selective Alcohol Oxidation](image)

**Use of PCC (CrO$_3$ + Pyridine + HCl) to Oxidize a Primary Alcohol to an Aldehyde**

Air is the “greenest” oxidizing agent. There is currently much research effort aimed at achieving the oxidation of alcohols under mild aerobic conditions.

\text{RCH}_2\text{OH} \\
\text{RCH} \\
\text{RCHO} \\
\text{RCOH}
\end{array} 
\]

Another mild reagent that specifically oxidizes allylic alcohols (Section 14-3) is manganese dioxide. Ordinary alcohols are not attacked at room temperature, as shown below in the selective oxidation to form a steroid found in the adrenal gland.

**Selective Allylic Oxidations with Manganese Dioxide**

Exercise 17-6

Design a synthesis of 1-cyclohexyl-2-butyn-1-one starting from cyclohexane. You may use any other reagents.

The second method of preparation that we studied is the oxidative cleavage of carbon–carbon double bonds—**ozonolysis** (Section 12-12). Exposure to ozone followed by treatment with a mild reducing agent, such as zinc metal or dimethyl sulfide, cleaves alkenes to give aldehydes and ketones.

Third, **hydration** of the carbon–carbon triple bond yields enols that tautomerize to carbonyl compounds (Sections 13-7 and 13-8). In the presence of mercuric ion, addition of water follows Markovnikov’s rule to furnish ketones.

**Markovnikov Hydration of Alkynes**

\[
\text{RC≡CH} \quad \text{HOH, H}^+, \text{Hg}^{2+} \quad \text{RCHO} \quad \text{RCCH}_3
\]

Anti-Markovnikov addition is observed in hydroboration–oxidation.
Finally, Section 15-13 discussed the synthesis of aryl ketones by Friedel-Crafts acylation, a form of electrophilic aromatic substitution. The following example furnishes an industrially useful perfume additive.

**Friedel-Crafts Acylation**

\[ \text{CH}_3\text{COCH}_3, \text{AlCl}_3, \text{CS}_2 \rightarrow \text{CH}_3\text{OCCH}_3\text{H}_3\text{O} \]

Ortho, para–directing and activating

17-5 Reactivity of the Carbonyl Group: Mechanisms of Addition

How does the carbonyl group’s structure (Section 17-2) help us understand the way it functions chemically? We shall see that the carbon–oxygen double bond is prone to additions, just like the \( \pi \) bond in alkenes. Being highly polar, however, the C=O function is predisposed toward attack by nucleophiles at carbon and electrophiles at oxygen. This section begins the discussion of the chemistry of the carbonyl group in aldehydes and ketones.

There are three regions of reactivity in aldehydes and ketones

Aldehydes and ketones contain three regions at which most reactions take place: the Lewis basic oxygen, the electrophilic carbonyl carbon, and the adjacent “\( \alpha \)”-carbon.

The remainder of this chapter concerns the first two areas of reactivity, both of which lead to ionic addition to the carbonyl \( \pi \) bond. Other reactions, centered instead on the acidic hydrogen of the \( \alpha \)-carbon, will be the subject of Chapter 18.

The carbonyl group undergoes ionic additions

Polar reagents add to the dipolar carbonyl group according to Coulomb’s law (Section 1-2) and the fundamental principles of Lewis acid–Lewis base interactions (Section 2-2). Nucleophiles bond to the electrophilic carbonyl carbon and the Lewis basic carbonyl oxygen bonds to electrophiles. Sections 8-6 and 8-8 described several such additions of organometallic and hydride reagents to give alcohols (Table 17-3). These additions fall under the general mechanistic category 4(a), as introduced in Section 2-2.
The hydride reagents NaBH₄ and LiAlH₄ reduce carbonyl groups but not carbon–carbon double bonds. These reagents therefore convert unsaturated aldehydes and ketones into unsaturated alcohols.

Because the nucleophilic reagents illustrated in Table 17-3 are strong bases, their additions are irreversible. This section and Sections 17-6 through 17-9 consider ionic additions of less basic nucleophiles Nu–H, such as water, alcohols, thiols, and amines. These processes are not strongly exothermic but instead establish equilibria that can be pushed in either direction by the appropriate choice of reaction conditions. Table 17-4 summarizes these reactions.

What is the mechanism of the ionic addition of these milder reagents to the carbon–
oxigen double bond? Two pathways can be formulated: nucleophilic addition–protonation
and electrophilic protonation–addition. The first, which begins with nucleophilic attack,
takes place under neutral or, more commonly, basic conditions. As the nucleophile
approaches the electrophilic carbon, the carbon rehybridizes and the electron pair of the
π bond moves over to the oxygen, thereby producing an alkoxide ion. Subsequent protonation,
usually from a protic solvent such as water or alcohol, yields the final addition product.

### Nucleophilic Addition–Protonation (Basic Conditions)

Note that the new Nu–C bond is made up entirely of the electron pair of the nucleophile.
The entire transformation is reminiscent of an SN2 reaction. In that process, a leaving group
is displaced. Here, an electron pair is displaced from a shared position between carbon and
oxygen to a position solely on the oxygen atom. Additions of strongly basic nucleophiles
to carbonyl groups typically follow the nucleophilic addition–protonation pathway.

The second mechanism predominates under acidic conditions and begins with electrophilic attack.
In the first step, protonation of the carbonyl oxygen occurs, facilitated by the
polarization of the C=O bond and the presence of lone electron pairs on the oxygen atom.
The oxygen is only weakly basic, as shown by the pKₐ of the conjugate acid, which ranges
from about −7 to −8. Thus, in a dilute acidic medium, in which many carbonyl addition
reactions are carried out, most of the carbonyl compound will stay unprotonated. However,
the small amount of protonated material behaves like a very reactive carbon electrophile.
Nucleophilic attack by the nucleophile completes the addition process and shifts the first,
unfavorable equilibrium.

### Electrophilic Protonation–Addition (Acidic Conditions)

The electrophilic protonation–addition mechanism is best suited for reactions of relatively
weakly basic nucleophiles. The acidic conditions are incompatible with strongly basic nucleo-
philes, because protonation of the nucleophile occurs.

### In Summary

There are three regions of reactivity in aldehydes and ketones. The first two
are the two atoms of the carbonyl group and are the subject of the remainder of this chap-
ter. The third is the adjacent carbon. The reactivity of the carbonyl group is governed by
addition processes. Nucleophilic organometallic and hydride reagents result in irreversible
alcohol formation (after protonation). Ionic additions of NuH (Nu = OH, OR, SR, NR₂)
are reversible and may begin with nucleophilic attack at the carbonyl carbon, followed by
electrophilic trapping of the alkoxide anion so generated. Alternatively, in acidic media,
protonation precedes the addition of the nucleophile.

### 17-6 Addition of Water to Form Hydrates

This section and Sections 17-7 and 17-8 introduce the reactions of aldehydes and ketones
with water and alcohols. These compounds attack the carbonyl group through the mechanisms
just outlined, utilizing either acid or base catalysis.
Water hydrates the carbonyl group

Water is capable of attacking the carbonyl function of aldehydes and ketones. The transformation can be catalyzed by either acid or base and leads to equilibration with the corresponding geminal diols, \( \text{RC(OH)}_2\text{R} \), also called carbonyl hydrates.

![Reaction](image)

In the base-catalyzed mechanism, the hydroxide functions as the nucleophile. Water then protonates the intermediate adduct, a hydroxy alkoxide, to give the product diol and to regenerate the catalyst.

![Mechanism](image)

In the acid-catalyzed mechanism, the sequence of events is reversed. Here, initial protonation facilitates nucleophilic attack by the weak nucleophile water. Subsequently, the catalytic proton is lost to reenter the catalytic cycle.

![Mechanism](image)

Hydration is reversible

As these equations indicate, hydrations of aldehydes and ketones are reversible. The equilibrium lies to the left for ketones and to the right for formaldehyde and aldehydes bearing inductively electron-withdrawing substituents. For ordinary aldehydes, the equilibrium constant approaches unity.

How can these trends be explained? Look again at the resonance structures of the carbonyl group, as described in Section 17-2 and repeated here in the margin. In the dipolar resonance form, the carbon possesses carbocation character. Therefore, alkyl groups, which stabilize carbocations (Section 7-5), stabilize carbonyl compounds as well. Conversely, inductively electron-withdrawing substituents, such as \( \text{CCl}_3 \) and \( \text{CF}_3 \), increase positive charge at the carbonyl carbon and destabilize carbonyl compounds. The stabilities of the product diols are affected to a lesser extent by substituents. As a net result, therefore, relative to hydration of formaldehyde, the hydration reactions of aldehydes and ketones are progressively more endothermic, whereas hydrations of carbonyl compounds containing electron-withdrawing groups are more exothermic. These thermodynamic effects are paralleled by differences in kinetic reactivity: Carbonyl compounds containing electron-withdrawing groups are the most electrophilic and the most reactive, followed in turn by formaldehyde, other aldehydes, and finally ketones. We shall see that the same trends also govern other addition reactions.
Relative Reactivities of Carbonyl Groups:  
Aldehydes Are More Reactive than Ketones

Electron-withdrawing CCl₃ group  
generates additional positive 
charge at carbonyl carbon

Electron-donating CH₃ groups  
reduce positive charge at carbonyl carbon

Increasing reactivity

Exercise 17-7

(a) Rank in order of increasing favorability of hydration: Cl₃CCH, Cl₃CCCH₃, Cl₃CCCCl₃.

(b) Treatment of acetone with H₂¹⁸O results in the formation of labeled acetone, CH₃CCH₃. Explain.

Despite the fact that hydration is energetically favorable in some cases, it is usually not possible to isolate carbonyl hydrates as pure substances: They lose water too easily, regenerating the original carbonyl compound. However, they may participate as intermediates in subsequent chemistry, such as the oxidation of aldehydes to carboxylic acids under aqueous conditions (Sections 8-6 and 17-4).

In Summary  
The carbonyl group of aldehydes and ketones is hydrated by water. Aldehydes are more reactive than ketones. Electron-withdrawing substituents render the carbonyl group more electrophilic. Hydration is an equilibrium process that may be catalyzed by acids or bases.

17-7 Addition of Alcohols to Form Hemiacetals and Acetals

In this section we shall see that alcohols add to carbonyl groups in much the same manner as water does. Both acids and bases catalyze the process. In addition, acids catalyze the further transformation of the initial addition product to furnish acetals by replacement of the hydroxy group with an alkoxy substituent.

Aldehydes and ketones form hemiacetals reversibly

Not surprisingly, alcohols also undergo addition to aldehydes and ketones, by a mechanism virtually identical to that outlined for water. The adducts formed are called hemiacetals (hemi, Greek, half) because they are intermediates on the way to acetals.
Like hydration, these addition reactions are governed by equilibria that usually favor the starting carbonyl compound. Hemiacetals, like hydrates, are therefore usually not isolable. Exceptions are those formed from reactive carbonyl compounds such as formaldehyde or 2,2,2-trichloroacetaldehyde. Hemiacetals are also isolable from hydroxy aldehydes and ketones when cyclization leads to the formation of relatively strain-free five- and six-membered rings.

Intramolecular hemiacetal formation is common in sugar chemistry (Chapter 24). For example, glucose, the most common simple sugar in nature, exists as an equilibrium mixture of an acyclic pentahydroxyaldehyde and two stereoisomeric cyclic hemiacetals. The cyclic forms constitute more than 99% of the mixture in aqueous solution.

Acids catalyze acetal formation

In the presence of excess alcohol, the acid-catalyzed reaction of aldehydes and ketones proceeds beyond the hemiacetal stage. Under these conditions, the hydroxy function of the initial adduct is replaced by another alkoxy unit derived from the alcohol. The resulting compounds are called acetals. (Ketal is an older term for an acetal derived from a ketone.)
The net change is the replacement of the carbonyl oxygen by two alkoxy groups and the formation of one equivalent of water.

Let us examine the mechanism of this transformation for an aldehyde. The initial reaction is the ordinary acid-catalyzed addition of the first molecule of alcohol. The resulting hemiacetal can be protonated at the hydroxy group, changing this substituent into water, a good leaving group. Upon loss of water, the resulting carbocation is stabilized by resonance with a lone electron pair on oxygen. A second molecule of alcohol now adds to the electrophilic carbon, initially giving the protonated acetal, which is then deprotonated to the final product.

Mechanism of Acetal Formation

**Step 1.** Hemiacetal generation: acid-catalyzed addition of first molecule of alcohol

\[
\begin{align*}
\text{Hemiacetal} & \quad \text{Acetal} \\
RCH & \quad RCH \\
\text{OH} & \quad \text{OR'} \\
\text{R} & \quad \text{R'} \\
\text{H} & \quad \text{H}
\end{align*}
\]

**Step 2.** Acetal generation: acid-catalyzed S_N1 displacement of water by second molecule of alcohol

Each step is reversible; the entire sequence, starting from the carbonyl compound and ending with the acetal, is an equilibrium process. In the presence of the acid catalyst, the equilibrium may be shifted in either direction: toward acetal by using excess alcohol or removing water; toward starting aldehyde or ketone by adding excess water, a process called **acetal hydrolysis**. However, in contrast with hydrates and hemiacetals, acetals may be isolated as pure substances by neutralizing the acid catalyst used in their formation. Reversal of acetal formation cannot occur in the absence of acid. Therefore, acetals may be prepared and put to use synthetically, as described in the next section.

**In Summary** Alcohols react with aldehydes and ketones to form hemiacetals. This process, like hydration, is reversible and is catalyzed by both acids and bases. Hemiacetals are converted by acid and excess alcohol into acetals. Acetals are stable under neutral or basic conditions but are hydrolyzed by aqueous acid.

**17-8 Acetals as Protecting Groups**

In the conversion of an aldehyde or ketone to an acetal, the reactive carbonyl function is transformed into a relatively unreactive ether-like moiety. Because acetal formation is reversible, this process amounts to one of **masking**, or protecting, the carbonyl group. Such protection is necessary when selective reactions (for example, with nucleophiles) are required at one functional site of a molecule and the presence of an unprotected carbonyl group...
elsewhere in the same molecule might interfere. This section describes the execution of such protecting strategies.

**Cyclic acetal formation protects carbonyl groups from attack by nucleophiles**

Diols, such as 1,2-ethanediol, are particularly effective reagents compared to normal alcohols for forming acetals. Use of diols converts aldehydes and ketones into cyclic acetals, which are generally more stable than their acyclic counterparts. The reason lies in part in their relatively more favorable (or, better, less unfavorable) entropy of formation (Section 2-1). Thus, as shown below, two molecules of starting material (carbonyl compound and diol) are converted into two molecules of product (acetal and water) in this process. In contrast, acetal formation with a normal alcohol (Section 17-7) uses up three molecules (carbonyl compound and two equivalents of alcohol), resulting in the same number of product molecules.

Cyclic acetals are readily hydrolyzed in the presence of aqueous acid, but are not attacked by many basic, organometallic, and hydride reagents. These properties make them most useful as protecting groups for the carbonyl function in aldehydes and ketones. An example is the alkylation of an alkynyl anion with 3-iodopropanal 1,2-ethanediol acetal.

When the same alkylation is attempted with unprotected 3-iodopropanal, the alkynyl anion attacks the carbonyl group.
Thiols react with the carbonyl group to form thioacetals.

Thiols, the sulfur analogs of alcohols (see Section 9-10), react with aldehydes and ketones by a mechanism identical with the one described for alcohols. Instead of a proton catalyst, a Lewis acid, such as BF₃ or ZnCl₂, is often used in ether solvent. The reaction produces the sulfur analogs of acetals, thioacetals, again, especially well for cyclic systems.

**Exercise 17-8**

**Working with the Concepts: Using an Acetal Protecting Group in Synthesis**

Suggest a convenient way of converting compound A into compound B. (Caution: How many carbon atoms are present in A and B, respectively?)

![Chemical structure](image)

**Strategy**

Begin by identifying the structural change that the problem asks you to achieve. Notice that the target molecule B contains one more carbon atom in the chain than does the starting compound A. Therefore, the required transformation is RBr → RCH₂OH. We can prepare primary alcohols by addition of Grignard reagents to formaldehyde (Section 8-8):

1. H₂C=O, ether
2. H⁺, H₂O → RCH₂OH

The problem with substrate A is that it already contains a carbonyl group. This group is likely to be incompatible with the preparation and use of a Grignard function at the opposite end of the molecule. How can we prevent interference by this carbonyl group?

**Solution**

• Before doing anything else, protect the carbonyl group as an acetal. Being similar in function to ethers, acetals are inert to Grignard reagents.
• We follow acetal formation with the reactions needed to complete our synthesis: Convert the bromoalkane functional group to the Grignard reagent, react with formaldehyde to add the necessary carbon atom, and protonate the resulting alkoxide with aqueous acid.
• The final step, treatment with aqueous acid, conveniently also hydrolyzes the acetal group and restores the original ketone function. This is the deprotection step referred to in the example in the text above.

![Chemical reaction](image)

**Exercise 17-9**

**Try It Yourself**

Propose a synthetic scheme to convert bromobenzene into HOCH₂-CH₃.

(Hint: See Sections 15-13 and 16-3.)

![Chemical structure](image)
These sulfur derivatives are stable in aqueous acid, a medium that hydrolyzes ordinary acetics. The difference in reactivity may be useful in synthesis when it is necessary to differentiate two different carbonyl groups in the same molecule. Hydrolysis of thioacetals is carried out using mercuric chloride in aqueous acetonitrile. The driving force is the formation of insoluble mercuric sulfides.

**Thioacetal Hydrolysis**

\[ \text{Thioacetal} \xrightarrow{\text{H}_2\text{O}, \text{HgCl}_2, \text{CaCO}_3, \text{CH}_3\text{CN}} \text{Aldehyde} \]

**Exercise 17-10**

**Working with the Concepts: Differentiating Carbonyl Groups**

How would you accomplish the following transformation? (**Hint:** See Section 8-8.)

**Strategy**

Formation of a secondary alcohol may be achieved by addition of a Grignard reagent to an aldehyde. Choose a deprotection method that will release the aldehydic carbonyl function but will leave the thioacetal protected cyclic ketone part untouched.

**Solution**

- Hydrolyze the acetal with aqueous acid.
- React the resulting aldehyde with the appropriate Grignard reagent to give the desired alcohol.

Neither of these steps affects the thioacetal moiety.

**Exercise 17-11**

**Try It Yourself**

Show how the starting material for Exercise 17-10 may be converted into the alcohol in the margin.
In Summary  Acetals and thioacetals are useful protecting groups for aldehydes and ketones. Acetals are formed under acidic conditions and are stable toward bases and nucleophiles. They are hydrolyzed by aqueous acid. Thioacetals are usually prepared using Lewis acid catalysts and are stable to both aqueous base and acid. Mercuric salts are required for thioacetal hydrolysis. Thioacetals may also be desulfurized to hydrocarbons with Raney nickel.

17-9 Nucleophilic Addition of Ammonia and Its Derivatives

Ammonia and the amines may be regarded as nitrogen analogs of water and alcohols. Do they add to aldehydes and ketones? In fact, they do, giving products corresponding to those just studied. We shall see one important difference, however. The products of addition of amines and their derivatives lose water, furnishing either of two new derivatives of the original carbonyl compounds: imines and enamines.

Ammonia and primary amines form imines

Upon exposure to an amine, aldehydes and ketones initially form hemiaminals, the nitrogen analogs of hemiacetals. Hemiaminals of primary amines readily lose water to form a carbon–nitrogen double bond. This function is called an imine (an older name is Schiff* base) and is the nitrogen analog of a carbonyl group.

The mechanism of the elimination of water from the hemiaminal is the same as that for the decomposition of a hemiacetal to the carbonyl compound and alcohol. It begins with protonation of the hydroxy group. (Protonation of the more basic nitrogen just leads back to the original carbonyl compound.) Dehydration follows, and then deprotonation of the intermediate iminium ion.

Exercise 17-12

Suggest a possible synthesis of cyclodecane from .

(Caution: Simple hydrogenation will not do. Hint: See Section 12-12.)

Thioacetals are desulfurized to the corresponding hydrocarbon by treatment with Raney nickel (Section 12-2). Thioacetal generation followed by desulfurization is used to convert a carbonyl into a methylene group under neutral conditions.

Ammonia and primary amines form imines

Upon exposure to an amine, aldehydes and ketones initially form hemiaminals, the nitrogen analogs of hemiacetals. Hemiaminals of primary amines readily lose water to form a carbon–nitrogen double bond. This function is called an imine (an older name is Schiff* base) and is the nitrogen analog of a carbonyl group.

The mechanism of the elimination of water from the hemiaminal is the same as that for the decomposition of a hemiacetal to the carbonyl compound and alcohol. It begins with protonation of the hydroxy group. (Protonation of the more basic nitrogen just leads back to the original carbonyl compound.) Dehydration follows, and then deprotonation of the intermediate iminium ion.

*Professor Hugo Schiff (1834–1915), University of Florence, Italy.
Processes such as imine formation from a primary amine and an aldehyde or ketone, in which two molecules are joined with the elimination of water (or other small molecules such as alcohols), are called **condensations**.

**Condensation of a Ketone with a Primary Amine**

\[
RNH_2 + O=\text{C} \rightleftharpoons RN=\text{C} + H_2O
\]

Imines are useful compounds: For example, they are commonly employed in the synthesis of more complex amines (Section 21-6). However, the condensation reaction above is reversible, making imines very susceptible to hydrolysis and often difficult to isolate as pure substances. As a result, when a synthetic sequence requires an imine as an intermediate, the appropriate amine and carbonyl compound are usually mixed in the presence of the reagent that is needed to convert with the imine further. Thus, the imine reacts as soon as it is formed. In this way, the condensation equilibrium is constantly shifted to produce more imine, continuing the reaction until it finally goes to completion.

If care is taken to remove the water that is formed in the condensation process (for example, by continuous distillation from the reaction mixture), imines may be isolated, often in high yield. For example,

\[
\text{CH}_3\text{CCH}_3 + \text{NH}_2\text{C}\text{H}_3 \xrightarrow{\text{H}^+} \text{H}_3\text{C}\text{C} = \text{N} - \text{C} + \text{H}_2\text{O} \quad 95\%
\]

**Exercise 17-13**

Reagent A has been used with aldehydes to prepare crystalline imidazolidine derivatives, such as B, for the purpose of their isolation and structural identification. Write a mechanism for the formation of B. [**Hint:** Notice that the product is a nitrogen analog of an acetal. Develop a mechanism analogous to that for acetal formation (Section 17-7), using the two amine groups in the starting diamine in place of two alcohol molecules.]
Special imines aid in the identification of aldehydes and ketones

Several amine derivatives condense with aldehydes and ketones to form imine products that are highly crystalline and have sharp melting points. Among these are hydroxylamine, derivatives of hydrazine, H₂NNH₂, such as 2,4-dinitrophenylhydrazine, and semicarbazide. These imine products, called oximes, hydrazones, and semicarbazones, respectively, are more stable than the simple imines described above. As shown in the margin for oximes, each of these derivatives is stabilized by resonance delocalization of a lone pair on the oxygen or nitrogen that is attached to the imine nitrogen atom. Table 17-5 illustrates the structures of these substances.

Melting points have been tabulated for imine derivatives of thousands of aldehydes and ketones. Before spectroscopic methods became routinely available, chemists used comparisons...
of these melting points to determine whether an aldehyde or ketone of unknown structure was identical with a previously characterized compound. For example, the distillation of castor oil yields a compound with the formula C\textsubscript{7}H\textsubscript{14}O. Its boiling point of about 150°C is similar to those recorded for heptanal, 2-heptanone, and 4-heptanone. The unknown is readily identified as heptanal by preparing and determining the melting points of its semicarbazone (109°C) and 2,4-dinitrophenylhydrazone (108°C). These values match those tabulated for the derivatives of the aldehyde and are quite different from those recorded for the two ketones: The respective derivatives of 2-heptanone exhibit melting points of 127°C and 89°C, and those of 4-heptanone, 133°C and 75°C.

**Condensations with secondary amines give enamines**

The condensations of amines described so far are possible only for primary derivatives, because the nitrogen of the amine has to supply both of the hydrogens necessary to form water. Reaction with a secondary amine, such as azacyclopentane (pyrrolidine), therefore takes a different course. After the initial addition, water is eliminated by deprotonation at carbon to produce an enamine. This functional group incorporates both the ene function of an alkene and the amino group of an amine.

![Enamine Formation](image)

Enamine formation is reversible and hydrolysis occurs readily in the presence of aqueous acid. Enamines are useful substrates in alkylations (Section 18-4).
Exercise 17-14

Working with the Concepts: Enamine Formation

Formulate a detailed mechanism for the acid-catalyzed enamine formation shown above.

**Strategy**

Begin in a manner identical to the mechanisms of addition of ammonia and primary amines to give imines. As you proceed step by step, look for the point at which the structure of the secondary amine forces the mechanism to diverge from imine formation.

**Solution**

- Add the nucleophilic amine nitrogen as described earlier in this section. The negatively charged oxygen picks up a proton and the positively charged nitrogen loses one to give the usual hemiaminal intermediate.

- Using the catalytic acid, protonate the oxygen, converting it into a better leaving group (water). The water departs, leaving an iminium ion, just as in the case of imine formation.

- At this point, however, the nitrogen lacks another hydrogen to lose: Imine formation is impossible. Thus the system must take an alternative path.

- Examine the structure of the actual enamine product (above): One hydrogen is missing from the carbon adjacent to the one bearing the nitrogen (the α-carbon). This hydrogen can be lost as a proton from the iminium intermediate, giving the final product.

Exercise 17-15

Try It Yourself

Write the product, in addition to the mechanism of its formation, for the following acid-catalyzed reaction.

\[ \text{O} + \text{O} \xrightarrow{\text{H}^-} \text{H}_2\text{O} \]
In Summary Primary amines attack aldehydes and ketones to form imines by condensation. Hydroxylamine gives oximes, hydrazines lead to hydrazones, and semicarbazide results in semicarbazones. Secondary amines react with aldehydes and ketones to give enamines.

17-10 Deoxygenation of the Carbonyl Group

In Section 17-5 we reviewed methods by which carbonyl compounds can be reduced to alcohols. Reduction of the C\(\equiv\)O group to CH\(_2\) (deoxygenation) also is possible. Two ways in which this may be achieved are Clemmensen reduction (Section 16-5) and thioacetal formation followed by desulfurization (Section 17-8). This section presents a third method for deoxygenation—the Wolff-Kishner reduction.

Strong base converts simple hydrazones into hydrocarbons

Condensation of hydrazine itself with aldehydes and ketones produces simple hydrazones:

\[
\text{Hydrazine} + \text{Aldehyde or Ketone} \rightarrow \text{Hydrazone}
\]

Hydrazones undergo decomposition with evolution of nitrogen when treated with base at elevated temperatures. The product of this reaction, called the Wolff-Kishner* reduction, is the corresponding hydrocarbon.

The mechanism of nitrogen elimination includes a sequence of base-mediated hydrogen shifts. The base first removes a proton from the hydrazone to give the corresponding delocalized anion. Reprotonation may occur on nitrogen, regenerating starting material, or on carbon, thereby furnishing an intermediate azo compound (Section 22-11) leading on to the product. The base removes another proton from the azo nitrogen to generate a new anion.

*Professor Ludwig Wolff (1857–1919), University of Jena, Germany; Professor N. M. Kishner (1867–1935), University of Moscow.

Exercise 17-16

Write the products of the following reactions, under acid-catalyzed conditions.

(a) \(\text{O} + \text{H} \rightarrow \text{NH}_2\)  
(b) \(\text{CH}_3\text{CHCHCH}_3 + \text{NH}_2 \rightarrow \text{CH}_3\text{CH}_2\text{CC} = \text{CCH}_3\)

(c) \(\text{OH} + \text{C}_6\text{H}_5\text{NHNH}_2 \rightarrow \text{C}_6\text{H}_5\text{NHNH}_2\)

(Hint: See Section 17-7.)
which rapidly decomposes irreversibly, with the extrusion of nitrogen gas. The result is a strongly basic alkyl anion (carbanion), which is immediately protonated by the aqueous medium to give the final hydrocarbon product.

**Mechanism of Nitrogen Elimination in the Wolff-Kishner Reduction**

In practice, the Wolff-Kishner reduction is carried out without isolating the intermediate hydrazone. An 85% aqueous solution of hydrazine (hydrazine hydrate) is added to the carbonyl compound in a high-boiling alcohol solvent such as diethylene glycol (HOCH₂CH₂OCH₂CH₂OH, b.p. 245°C) or triethylene glycol (HOCH₂CH₂OCH₂CH₂OCH₂CH₂OH, b.p. 285°C) containing NaOH or KOH, and the mixture is heated. Aqueous work-up yields the pure hydrocarbon.

Wolff-Kishner reduction complements the Clemmensen and thioacetal desulfurization methods of deoxygenating aldehydes and ketones. Thus, the Clemmensen reduction is unsuitable for compounds containing acid-sensitive groups, and hydrogenation of multiple bonds can accompany desulfurization with hydrogen and Raney nickel. Such functional groups are generally not affected by Wolff-Kishner conditions.

**Wolff-Kishner reduction aids in alkylbenzene synthesis**

We have already seen that the products of Friedel-Crafts acylations may be converted into alkyl benzenes by using Clemmensen reduction. Wolff-Kishner deoxygenation also is frequently employed for this purpose and is particularly useful for acid-sensitive, base-stable substrates.

**Exercise 17-17**

Propose a synthesis of hexylbenzene from hexanoic acid.
**In Summary** The Wolff-Kishner reduction is the decomposition of a hydrazone by base, the second part of a method of deoxygenating aldehydes and ketones. It complements Clemmensen and thioacetal desulfurization procedures.

**17-11 Addition of Hydrogen Cyanide to Give Cyanohydrins**

Besides alcohols and amines, several other nucleophilic reagents may attack the carbonyl group. Particularly important are carbon nucleophiles, because new carbon–carbon bonds can be made in this way. Section 8-8 explained that organometallic compounds, such as Grignard and alkyl lithium reagents, add to aldehydes and ketones to produce alcohols. This section and Section 17-12 deal with the behavior of carbon nucleophiles that are not organometallic reagents—the additions of cyanide ion and of a new class of compounds called ylides.

Hydrogen cyanide adds reversibly to the carbonyl group to form hydroxyalkanenitrile adducts commonly called cyanohydrins. The equilibrium may be shifted toward the adduct by the use of liquid HCN as solvent. However, it is dangerous to use such large amounts of HCN, which is volatile and highly toxic. Therefore, slow addition of HCl to an excess of the strongly basic NaCN is typically employed to generate HCN in a moderately alkaline mixture.

**Cyanohydrin Formation**

\[
\begin{align*}
\text{HO} & \quad \text{CN} \\
\text{NC} & \quad \text{OH} \\
\text{C} & \quad \text{NC} \\
\end{align*}
\]

60%

1-Hydroxycyclohexanecarbonitrile
(Cyclohexanone cyanohydrin)

Cyanohydrin formation requires the presence of both free cyanide ion and unassociated HCN, a condition satisfied by maintaining a moderately basic pH. Cyanide adds to the carbonyl carbon in the slow, reversible first step of the mechanism. The HCN then protonates the negatively charged oxygen in the fast second step. This protonation is necessary to shift the overall equilibrium toward the product.

**Mechanism of Cyanohydrin Formation**

\[
\begin{align*}
\text{CN} & \quad \text{OH} \\
\text{C} & \quad \text{NC} \\
\end{align*}
\]

**Exercise 17-18**

Rank the following carbonyl compounds in order of thermodynamic favorability of HCN addition: acetone, formaldehyde, 3,3-dimethyl-2-butanone, acetaldehyde. (Hint: See Section 17-6.)

We shall see in subsequent chapters (Sections 19-6 and 26-2) that cyanohydrins are useful intermediates because the nitrile group can be modified by further reaction.

**In Summary** The carbonyl group in aldehydes and ketones can be attacked by carbon-based nucleophiles. Organometallic reagents give alcohols and cyanide gives cyanohydrins.

**17-12 Addition of Phosphorus Ylides: The Wittig Reaction**

Another useful reagent in nucleophilic additions contains a carbanion that is stabilized by an adjacent, positively charged phosphorus group. Such a species is called a phosphorus ylide, and its attack on aldehydes and ketones is called the *Wittig* reaction. The Wittig reaction is a powerful method for the selective synthesis of alkenes from aldehydes and ketones.

*Professor Georg Wittig (1897–1987), University of Heidelberg, Germany, Nobel Prize 1979 (chemistry).*
Deprotonation of phosphonium salts gives phosphorus ylides

Phosphorus ylides are most conveniently prepared from haloalkanes by a two-step sequence; the first step is the nucleophilic displacement of halide by triphenylphosphine to furnish an alkyltriphenylphosphonium salt.

\[
\text{Phosphonium Salt Synthesis} \\
(C_6H_5)_3P + CH_2RCH_2P(C_6H_5)_3 X \rightarrow RCH_2P(C_6H_5)_3 + X^{-}
\]

The positively charged phosphorus atom renders any neighboring proton acidic. In the second step, deprotonation by bases, such as alkoxides, sodium hydride, or butyllithium, gives the ylide. Ylides can be isolated, although they are usually only generated in solutions that are subsequently treated with other reagents.

\[
\text{Ylide Formation} \quad \text{RC} \quad \text{P(C}_6\text{H}_5)_3 \quad X^{-} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2 \quad \text{Li} \quad \text{THF} \quad \text{RCH} \quad \text{P(C}_6\text{H}_5)_3 \quad \text{Ylide}
\]

Notice that we may formulate a second resonance structure for the ylide by delocalizing the negative charge onto the phosphorus. In this form, the valence shell on phosphorus has been expanded and a carbon–phosphorus double bond is present.

The Wittig reaction forms carbon–carbon double bonds

When an ylide is exposed to an aldehyde or ketone, their reaction ultimately furnishes an alkene by coupling the ylide carbon with that of the carbonyl. The other product of this transformation is triphenylphosphine oxide.

\[
\text{The Wittig Reaction} \quad \text{Aldehyde or ketone} \quad \text{Ylide} \quad \text{Alkene} \quad \text{Triphenylphosphine oxide}
\]

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH} \quad \text{CH}_3\text{CH}_2\text{C} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \quad 66\%
\]

3-Methyl-3-heptene

The Wittig reaction is a valuable addition to our synthetic arsenal because it forms carbon–carbon double bonds. In contrast with eliminations (Sections 11-6 and 11-7), it gives rise to alkenes in which the position of the newly formed double bond is unambiguous. Compare, for example, two syntheses of 2-ethyl-1-butene, one by the Wittig reaction, the other by elimination.
Comparison of Two Syntheses of 2-Ethyl-1-butene

By Wittig reaction

\[
\text{CH}_3\text{CH}_2\text{CCH}_2\text{CH}_3 + \text{CH}_2\text{--P(C}_6\text{H}_5\text{)}_3 \rightarrow \text{CH}_3\text{CH}_2\text{CCH}_2\text{CH}_3 + (\text{C}_6\text{H}_5\text{)}_3\text{P--O}
\]

(Only one isomer)

By elimination

\[
\text{CH}_3\text{CH}_2\text{CCH}_2\text{CH}_3 \xrightarrow{\text{Base}} \text{CH}_3\text{CH}_2\text{CCH}_2\text{CH}_3 + \text{CH}_3\text{CH}_2\text{C--CHCH}_3
\]

(Mixture of isomers)

What is the mechanism of the Wittig reaction? The negatively polarized carbon in the ylide is nucleophilic and can attack the carbonyl group. The result is a phosphorus betaine, a dipolar species of the kind called a zwitterion (Zwitter, German, hybrid). The betaine is short lived and rapidly forms a neutral oxaphosphacyclobutane (oxaphosphetane), characterized by a four-membered ring containing phosphorus and oxygen. This substance then decomposes to the product alkene containing phosphorus and oxygen. The driving force for the last step is the formation of the very strong phosphorus-oxygen double bond.

Mechanism of the Wittig Reaction

Wittig reaction can be carried out in the presence of ether, ester, halogen, alkene, and alkyne functions. Many display useful stereoselectivity. For example, reactions between non-conjugated ylides and aldehydes typically result in cis (or Z) alkenes with good selectivity.

A Stereoselective Wittig Reaction Giving Mostly cis Product

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}--\text{P(C}_6\text{H}_5\text{)}_3 \xrightarrow{\text{CH}_3(\text{CH})_3\text{CHO, THF}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}--\text{(CH)}_2\text{CH}_3
\]

(70% cis : trans ratio = 6:1)

*Betaine is the name of an amino acid, (CH_3)_3NCH2COO^-, which is found in beet sugar (beta, Latin, beet) and exists as a zwitterion.
In contrast, the presence of conjugation in the ylide frequently results in trans products, as shown in the example below, taken from the commercial synthesis of vitamin A₁ (Section 14-7) by the German chemical company BASF (Badische Anilin and Soda Fabriken).

**A Highly trans-Selective Wittig Reaction: BASF Vitamin A₁ Synthesis**

In Summary Phosphorus ylides add to aldehydes and ketones to give betaines that decompose by forming carbon–carbon double bonds. The Wittig reaction affords a means of synthesizing alkenes from carbonyl compounds and haloalkanes by way of the corresponding phosphonium salts.
17-13 Oxidation by Peroxycarboxylic Acids: The Baeyer-Villiger Oxidation

When ketones are treated with peroxycarboxylic acids (Section 12-10), the result is an oxidation of the carbonyl function to an ester, a transformation called **Baeyer-Villiger** oxidation. The mechanism of this reaction starts by nucleophilic addition of the hydroperoxy end of the peracid to the carbonyl group to generate a reactive peroxide analog of a hemiacetal. This unstable adduct decomposes through a cyclic transition state in which an alkyl group shifts from the original carbonyl carbon to oxygen to give an ester.

**Baeyer-Villiger Oxidation**

\[
\text{CH}_3\text{CCH}_2\text{CH}_3 \xrightarrow{\text{CF}_3\text{COOH}, \text{CH}_2\text{Cl}_2} \text{CH}_3\text{COCH}_2\text{CH}_3
\]

2-Butanone \( \rightarrow \) Ethyl acetate

72%

Cyclic ketones are converted into cyclic esters. Attack is at the carbonyl rather than at the carbon–carbon double bond (Section 12-10). Unsymmetric ketones, such as that in the following reaction, can in principle lead to two different esters. Why is only one observed? The answer is that some substituents migrate more easily than others. Experiments have established their relative ease of migration, or **migratory aptitude**.

\[
\text{CH}_3\text{CCH}_2\text{CH}_3 \xrightarrow{\text{CH}_3\text{COOH}, \text{CHCl}_3} \text{CH}_3\text{COCH}_2\text{CH}_3
\]

56%

The ordering suggests that the migrating carbon possesses carbocationic character in the transition state for rearrangement.

**Migratory Aptitudes in the Baeyer-Villiger Reaction**

Methyl < primary < phenyl ~ secondary < tertiary

**Exercise 17-22**

Predict the outcome of the following oxidations with a peroxycarboxylic acid.

(a)  
(b)  
(c)  

*Professor Johann Friedrich Wilhelm Adolf von Baeyer (1835–1917), University of Munich, Nobel Prize 1905 (chemistry); Victor Villiger (1868–1934), BASF, Ludwigshafen, Germany.*
In Summary  Ketones can be oxidized with peroxyacarboxylic acids to give esters; with unsymmetric ketones, the esters can be formed selectively by migration of only one of the substituents.

17-14 Oxidative Chemical Tests for Aldehydes

Although the advent of NMR and other spectroscopy has made chemical tests for functional groups a rarity, they are still used in special cases in which other analytical tests may fail. Two characteristic simple tests for aldehydes will again turn up in the discussion of sugar chemistry in Chapter 24; they make use of the ready oxidation of aldehydes to carboxylic acids. The first is Fehling’s* test, in which copper(II) ion (such as in CuSO$_4$) is the oxidant. In a basic medium, the precipitation of red copper(I) oxide indicates the presence of an aldehyde function.

Fehling’s Test

\[
\text{RCH} + \text{Cu}^{2+} \xrightarrow{\text{NaOH, tartrate (see Chemical Highlight 5-3),} \text{H}_2\text{O}} \text{Cu}_2\text{O} + \text{RCOH} \quad \text{Brick-red}
\]

The second is Tollens’s† test, in which a solution of silver ion (such as in AgNO$_3$) precipitates a silver mirror on exposure to an aldehyde.

Tollens’s Test

\[
\text{RCH} + \text{Ag}^+ \xrightarrow{\text{NH}_3, \text{H}_2\text{O}} \text{Ag} + \text{RCOH} \quad \text{Mirror}
\]

The Fehling and Tollens tests are not commonly used in large-scale syntheses. However, the Tollens reaction is employed industrially to produce shiny silver mirrors on glass surfaces, such as the insides of Thermos bottles.

THE BIG PICTURE

We have begun an extended, systematic study of compounds containing the carbonyl group. Nine chapters remain in this book; carbonyl chemistry will be a significant presence in every one of them and will be a main focus of six of the nine. Why do these compounds play such a prominent role in organic chemistry? Recall that in Chapter 2 we introduced the properties of electrophilicity and nucleophilicity and discussed how they underlie almost all of the chemical reactivity of organic compounds. In the chapter just completed, we explored the carbonyl group as an electrophilic function, illustrating a number of processes that involve the addition of nucleophiles to the carbonyl carbon. In the next chapter, we shall see the other side of the picture of carbonyl chemistry: The carbon atom adjacent to the carbonyl group—the $\alpha$-carbon—is a potential site of nucleophilic reactivity. It is this capacity for both electrophilic and nucleophilic behavior at adjacent sites in the same molecule that sets carbonyl compounds apart from almost any other class of organic substances. It is no wonder that the formation of carbon–carbon bonds in nature is in large measure based on carbonyl chemistry.

*Professor Hermann C. von Fehling (1812–1885), Polytechnic School of Stuttgart, Germany.
†Professor Bernhard C. G. Tollens (1841–1918), University of Göttingen, Germany.
In the next chapter, we shall find out how to generate nucleophilic reactivity at the \( \alpha \) carbons of aldehydes and ketones and how to use that reactivity in the formation of bonds with a variety of electrophiles, including the carbon atoms of other molecules.

**CHAPTER INTEGRATION PROBLEMS**

17-23. Oxidation of 4-hydroxybutanal with PCC (pyH\(^+\) CrO\(_3\)Cl\(^-\), Section 8-6) does not produce the dialdehyde that one might expect. Instead a cyclic compound called a lactone is formed:

\[
\begin{align*}
\text{HO-} & \quad \text{O} \quad \text{H} \quad \xrightarrow{\text{PCC, CH}_{2}\text{Cl}_{2}} \quad \text{O} \quad \text{O} \\
\text{H} & \quad \text{H}
\end{align*}
\]

(No \( \text{H} \quad \text{H} \))

Explain this result.

**SOLUTION**

Let us first examine the type of compound with which we are dealing. It contains both alcohol and aldehyde functions. Section 17-7 described the reversible addition of alcohols to aldehydes and ketones to give hemiacetals; furthermore, it showed that the equilibrium of the process lies strongly on the product side when it leads to a five- or six-membered ring. For example:

\[
\begin{align*}
\text{HO} \quad & \quad \text{O} \quad \text{O} \\
\text{H} & \quad \text{H}
\end{align*}
\]

If we compare this hemiacetal with the product of the actual oxidation reaction shown earlier, we see that it is the *hemiacetal* whose oxidation produces the observed product. Notice that, in general, aldehyde hemiacetals possess the same structural feature that is present in ordinary alcohols that can be oxidized to carbonyl compounds: \( \text{C} \quad \text{O} \quad \text{H} \).

17-24. a. Propose a synthesis of norethynodrel, the major component in one common oral contraceptive preparation (Enovid, compare Chemical Highlight 4-3). Use as your starting compound the following nortestosterone derivative (left-hand structure).

**SOLUTION**

Analyze the problem retrosynthetically (Section 8-9). The target molecule is identical with the starting compound in all but one respect: the additional substituent on the cyclopentane ring (at C17). We know that we cannot add groups directly to secondary alcohols to make tertiary alcohols. However, addition reactions of organometallic reagents to *ketones* afford tertiary alcohols (Section 8-8). The necessary organometallic reagent for our purpose is Li\(^{+}\)C\(_3\)H\(_2\), an alkynyl anion (Section 13-5). Let us see if we can devise a plan based on this chemistry.

The final step in the synthesis would appear to be addition of LiC\(_3\)H\(_2\) to a C17 ketone, but, as the following reaction shows, there is a major problem: The precursor molecule contains a *second carbonyl group* in the six-membered ring at the lower left (at C3). In such a process, it would be impossible to prevent the alkynyl anion from adding indiscriminately to C3 as well as C17.
What to do? A similar problem arose in the synthesis of testosterone described in Chemical Highlight 9-2. It was solved by the use of protecting groups. We can do something similar here. The underlying conceptual problem is that we need to avoid having both C3 and C17 exist as carbonyls at the same time in any molecule in our synthesis. Failure to do so will doom a synthetic plan. With this concept in mind, we can imagine a modified ending to our synthesis, in which the carbon–oxygen double bond at C3 is protected in a form unreactive toward organometallic reagents during the previously shown step. After the addition reaction has been completed, the protecting group may be removed. An acetal derived from 1,2-ethanediol should do nicely (Section 17-8):

In this scheme, the aqueous acid does double duty: It protonates the alkoxide that results from alkynyllithium addition, and it hydrolyzes the acetal to a ketone.

How does the synthesis begin? The C17 hydroxy group in the original starting material must be oxidized to a carbonyl. However, we cannot perform that oxidation in the presence of the carbonyl function at C3, because we would then violate the aforedescribed principle: We would create a molecule with both carbonyls present at the same time and the need to later react one and not the other with a reagent that cannot discriminate between them. With these considerations in mind, it becomes clear that protection of C3 must come first, before oxidation at C17:

b. Why is pyridinium chlorochromate (PCC) in CH₂Cl₂ a better choice than K₂Cr₂O₇ for an oxidant in the second step?

**SOLUTION**
What could go wrong with K₂Cr₂O₇? Consider the conditions under which it is used: typically in aqueous sulfuric acid (Section 8-6). Therefore, this reagent carries the risk of hydrolysis of the acetal group under the acidic conditions. PCC is a neutral, nonaqueous reagent, ideal for substrates containing acid-sensitive functions.

c. Addition of alkynyllithium to the carbonyl at C17 is stereoselective to give the tertiary alcohol shown. Why? Would addition to a carbonyl at C3 also be stereoselective?

**SOLUTION**
What is the usual origin of stereoselectivity in reactions such as this? Steric hindrance in the immediate vicinity of the reacting center is the most common cause. The methyl substituent at the position adjacent to C17 is axial with respect to the six-membered ring and sterically hinders approach of the alkynyl reagent to the top face of the C17 carbonyl carbon (see Section 4-7). Addition from below is therefore strongly favored. There is no comparable steric hindrance in the vicinity of C3 to give rise to any preference for addition from either side.
New Reactions

Synthesis of Aldehydes and Ketones

1. Oxidation of Alcohols (Section 17-4)

\[
\text{R}^\prime \text{CHOH} \xrightarrow{\text{CrO}_3, \text{H}_2\text{SO}_4} \text{RCH}_2\text{OH} \xrightarrow{\text{PCC, CH}_2\text{Cl}_2} \text{RCH} = \text{CHO} \\
\text{Stable to oxidizing agent}
\]

Allylic oxidation

2. Ozonolysis of Alkenes (Section 17-4)

\[
\text{C} = \text{C} \xrightarrow{1. \text{O}_3, \text{CH}_2\text{Cl}_2, 2. \text{Zn, CH}_3\text{CO}_2\text{H}} \xrightarrow{\text{MnO}_2, \text{CHCl}_3} \text{C} = \text{O} + \text{O} = \text{C}
\]

3. Hydration of Alkynes (Section 17-4)

\[
\text{RC} = \text{CH} \xrightarrow{\text{H}_2\text{O, Hg}^{2+}, \text{H}_2\text{SO}_4} \text{RCCH}_3
\]

4. Friedel-Crafts Acylation (Section 17-4)

\[
\text{C}_6\text{H}_6 + \text{RCCL} \xrightarrow{1. \text{AlCl}_3} \xrightarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{C}_6\text{H}_5\text{CR}
\]

Reactions of Aldehydes and Ketones

5. Reduction by Hydrides (Section 17-5)

\[
\text{RCH} \xrightarrow{\text{NaBH}_4, \text{CH}_3\text{CH}_2\text{OH}} \text{RCH}_2\text{OH} \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)\text{O}, 2. \text{H}^+, \text{H}_2\text{O}} \text{RCH} = \text{CHOH}
\]

Selectivity

\[
\text{RCH} = \text{CHCR}^\prime \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)\text{O}, 2. \text{H}^+, \text{H}_2\text{O}} \text{RCH} = \text{CHCR}^\prime
\]

6. Addition of Organometallic Compounds (Section 17-5)

\[
\text{RLi or RMgX} + \text{CH}_2\text{==O} \xrightarrow{\text{THF}} \text{RCH}_2\text{OH} \quad \text{Primary alcohol}
\]

\[
\text{RLi or RMgX} + \text{R}^\prime\text{CH} \xrightarrow{\text{THF}} \text{RCH} = \text{CHCR}^\prime \quad \text{Aldehyde}
\]

\[
\text{RLi or RMgX} + \text{R}^\prime\text{CR}^\prime\text{R}^\prime \xrightarrow{\text{THF}} \text{RCH} = \text{CHCR}^\prime \quad \text{Ketone}
\]

\[
\text{RLi or RMgX} + \text{R}^\prime\text{CR}^\prime\text{R}^\prime \xrightarrow{\text{THF}} \text{RCH} = \text{CHCR}^\prime \quad \text{Tertiary alcohol}
\]
7. Addition of Water and Alcohols—Hemiacetals (Sections 17-6 and 17-7)

Intramolecular addition

8. Acid-Catalyzed Addition of Alcohols—Acetals (Sections 17-7 and 17-8)

Cyclic acetals

9. Thioacetals (Section 17-8)

Formation

Hydrolysis

10. Raney Nickel Desulfurization (Section 17-8)
11. Addition of Amine Derivatives (Section 17-9)

\[
\text{RCR'} + R''\text{NH}_2, \text{H}^+ \rightarrow \text{RCR'} + \text{N} \equiv \text{R''} + \text{H}_2\text{O}
\]

**Imine**

12. Enamines (Section 17-9)

\[
\text{RCH}_2\text{CR'} + R''\text{NH} \rightleftharpoons \text{RCH} = \text{C} \equiv \text{R''} \rightleftharpoons \text{RCH}_2\text{R'} + \text{H}_2\text{O}
\]

Secondary amine

**Enamine**

13. Wolff-Kishner Reduction (Section 17-10)

\[
\text{RCR'} + \text{H}_2\text{NNH}_2, \text{H}_2\text{O}, \text{HO}^-, \Delta \rightarrow \text{RCH}_2\text{R'}
\]

14. Cyanohydrins (Section 17-11)

\[
\text{RCR'} + \text{HCN} \rightleftharpoons \text{C} \equiv \text{CN} \equiv \text{R} \equiv \text{R'}
\]

**Cyanohydrin**

15. Wittig Reaction (Section 17-12)

\[
\text{R''CH}_2\text{X} + \text{P(C}_6\text{H}_5)_3 \xrightarrow{\text{C}_6\text{H}_6} \text{R''CH}_2\text{P(C}_6\text{H}_5)_3\text{X}^-
\]

Triphenylphosphine

Works with primary or secondary haloalkanes

\[
\text{R''CH}_2\text{P(C}_6\text{H}_5)_3\text{X}^- + \text{R''CH} = \text{P(C}_6\text{H}_5)_3 \xrightarrow{\text{Base}} \text{R''CH} = \text{P(C}_6\text{H}_5)_3
\]

**Ylide**

\[
\text{RCR'} + \text{R''CH} = \text{P(C}_6\text{H}_5)_3 \xrightarrow{\text{THF}} \text{R'} \equiv \text{C} \equiv \text{CHR''} + \text{P(C}_6\text{H}_5)_3\text{P} \equiv \text{O}
\]

(Not always stereoselective)

16. Baeyer-Villiger Oxidation (Section 17-13)

\[
\text{RCR'} + \text{R''COOH} \xrightarrow{\text{CH}_2\text{Cl}_2} \text{RCOR'} + \text{RCO}_2\text{H}
\]

Migratory aptitudes in Baeyer-Villiger oxidation

Methyl < primary < phenyl ~ secondary < cyclohexyl < tertiary
Important Concepts

1. The carbonyl group is the functional group of the aldehydes (alkanals) and ketones (alkanones). It has precedence over the hydroxy, alkenyl, and alkynyl groups in the naming of molecules.

2. The carbon–oxygen double bond and its two attached nuclei in aldehydes and ketones form a plane. The C=O unit is polarized, with a partial negative charge on oxygen and a partial positive charge on carbon.

3. The 1H NMR spectra of aldehydes exhibit a peak at δ ≈ 9.8 ppm. In 13C NMR, the carbonyl carbon absorbs at ~200 ppm. Aldehydes and ketones have strong infrared bands in the region 1690–1750 cm⁻¹; this absorption is due to the stretching of the C=O bond. Because of the availability of low-energy n→π* transitions, the electronic spectra of aldehydes and ketones have relatively long wavelength bands. This class of compounds displays characteristic mass spectral fragmentations around the carbonyl function.

4. The carbon–oxygen double bond undergoes ionic additions. The catalysts for these processes are acids and bases.

5. The reactivity of the carbonyl group increases with increasing electrophilic character of the carbonyl carbon. Therefore, aldehydes are more reactive than ketones.

6. Primary amines undergo condensation reactions with aldehydes and ketones to imines; secondary amines condense to enamines.

7. The combination of Friedel-Crafts acylation and Wolff-Kishner or Clemmensen reduction allows synthesis of alkylbenzenes free of the limitations of Friedel-Crafts alkylation.

8. The Wittig reaction is an important carbon–carbon bond-forming reaction that produces alkenes directly from aldehydes and ketones.

9. The reaction of peroxycarboxylic acids with the carbonyl group of ketones produces esters.

Problems

25. Draw structures and provide IUPAC names for each of the following compounds.

   (a) Methyl ethyl ketone; (b) ethyl isobutyl ketone; (c) methyl tert-butyl ketone; (d) diisopropyl ketone; (e) acetophenone; (f) m-nitroacetophenone.

26. Name or draw the structure of each of the following compounds.

   (a) (CH₃)₂CHCCH(CH₃)₂  
   (b)  
   (c)  
   (d)  
   (e)  
   (f)  
   (g) (Z)-2-Acetyl-2-butenal  
   (h) trans-3-Chlorocyclobutanecarbaldehyde
Chapter 17

Problems

Chapter 17

Problems
27. The following spectroscopic data are for two carbonyl compounds with the formula C₈H₁₂O. Suggest a structure for each compound. The letter “m” stands for the appearance of this particular part of the spectrum as an uninterpretable multiplet. (a) \(^1\)H NMR: \(\delta = 1.60 (m, 4 \text{ H}), 2.15 (s, 3 \text{ H}), 2.19 (m, 4 \text{ H}), \) and \(6.78 (t, 1 \text{ H}) \text{ ppm.} \ 13\text{C NMR:} \ \delta = 21.8, 22.2, 23.2, 25.0, 26.2, 139.8, 140.7, \) and \(198.6 \text{ ppm.} \) (b) \(^1\)H NMR: \(\delta = 0.94 (t, 3 \text{ H}), 1.48 (\text{sex, } 2 \text{ H}), 2.21 (q, 2 \text{ H}), 5.8–7.1 \) (m, 4 H), and \(9.56 (d, 1 \text{ H}) \text{ ppm.} \ 13\text{C NMR:} \ \delta = 13.6, 21.9, 35.2, 129.0, 135.2, 146.7, 152.5, \) and \(193.2 \text{ ppm.} \)

28. The compounds described in Problem 27 have very different ultraviolet spectra. One has \(\lambda_{\text{max}}(\varepsilon) = 232(13,000) \) and \(308(1450) \text{ nm, whereas the other has} \ \lambda_{\text{max}}(\varepsilon) = 272(35,000) \text{ nm and a weaker absorption near 320 nm (this value is hard to determine accurately because of the intensity of the stronger absorption). Match the structures that you determined in Problem 27 to these UV spectral data. Explain the spectra in terms of the structures.}

29. Following are spectroscopic and analytical characteristics for an unknown compound. Propose a structure. Empirical formula: C₈H₁₆O. \(^1\)H NMR: \(\delta = 0.90 (t, 3 \text{ H}), 1.0–1.6 (m, 8 \text{ H}), 2.05 (s, 3 \text{ H}), \) and \(2.25 (t, 2 \text{ H}) \text{ ppm.} \) IR: 1715 cm\(^{-1}\). UV: \(\lambda_{\text{max}}(\varepsilon) = 280(15) \text{ nm.} \) MS: \(m/z = 128 \text{ (M}^+\text{); intensity of (M} + 1\text{)}^+ \text{ peak is 9% of M}^+ \text{ peak; important fragments are at m/z = 113 (M} - 15\text{)}^+ \text{, m/z = 85 (M} - 43\text{)}^+ \text{, m/z = 71 (M} - 57\text{)}^+ \text{, m/z = 58 (M} - 70\text{)}^+ \text{ (the second largest peak), and m/z = 43 (M} - 85\text{)}^+ \text{ (the base peak).}

30. Reaction review. Without consulting the Reaction Road Map on pp. 816–817, suggest reagents to convert each of the starting materials below into 3-hexanone.

31. Indicate which reagent or combination of reagents is best suited for each of the following reactions.

32. Write the expected products of ozonolysis (followed by mild reduction—e.g., by Zn) of each of the following molecules.
33. For each of the following groups, rank the molecules in decreasing order of reactivity toward addition of a nucleophile to the most electrophilic $sp^2$-hybridized carbon.

(a) (CH$_3$)$_2$C=O, (CH$_3$)$_2$C=NH, (CH$_3$)$_2$C=OH
(b) CH$_3$CCCH$_3$, CH$_3$CCCH$_3$, CH$_3$CCCH$_3$
(c) BrCH$_2$COCH$_3$, CH$_3$COCH$_3$, CH$_3$CHO, BrCH$_2$CHO

34. Give the expected products of reaction of butanal with each of the following reagents.

(a) LiAlH$_4$, (CH$_3$CH$_2$)$_2$O, then H$^+$, H$_2$O
(b) CH$_3$CH$_2$MgBr, (CH$_3$CH$_2$)$_2$O, then H$^+$, H$_2$O
(c) HOCH$_2$CH$_2$OH, H$^+$

35. Give the expected products of reaction of 2-pentanone with each of the reagents in Problem 34.

36. Give the expected products of reaction of 4-acetylcyclohexene with each of the reagents in Problem 34.

37. Give the expected product(s) of each of the following reactions.

(a) 
\[ \text{cyclohexane} + \text{excess CH}_3\text{OH} \xrightarrow{\text{OH}} \text{products} \]

(b) 
\[ \text{cyclohexane} + \text{excess CH}_3\text{OH} \xrightarrow{H^+} \text{products} \]

(c) 
\[ \text{cyclohexane} + \text{H}_3\text{C} + \text{S-NNH}_2 \xrightarrow{H^+} \text{products} \]

(d) 
\[ \text{CH}_3\text{CH}_3 + \text{HOCH}_2\text{CHCH}_2\text{CH}_2\text{CH}_3 \xrightarrow{H^+} \text{products} \]

(e) 
\[ \text{cyclohexane} + 2\text{CH}_3\text{CH}_2\text{SH} \xrightarrow{\text{BF}_3, (\text{CH}_3\text{CH}_2)_3\text{O}} \text{products} \]

(f) 
\[ \text{cyclohexane} + (\text{CH}_3\text{CH}_2)_2\text{NH} \xrightarrow{} \text{products} \]

38. Formulate detailed mechanisms for (a) the formation of the hemiacetal of acetaldehyde and methanol under both acid- and base-catalyzed conditions and (b) the formation of the intramolecular hemiacetal of 5-hydroxypentanal (Section 17-7), again under both acid- and base-catalyzed conditions.

39. Formulate the mechanism of the BF$_3$-catalyzed reaction of CH$_3$SH with butanal (Section 17-8).

40. **CHALLENGE** Overoxidation of primary alcohols to carboxylic acids is caused by the water present in the usual aqueous acidic Cr(VI) reagents. The water adds to the initial aldehyde product to form a hydrate, which is further oxidized (Section 17-6). In view of these facts, explain the following two observations. (a) Water adds to ketones to form hydrates, but no overoxidation follows the conversion of a secondary alcohol into a ketone. (b) Successful oxidation of primary alcohols to aldehydes by the water-free PCC reagent requires that the alcohol be added slowly to the Cr(VI) reagent. If, instead, the PCC is added to the alcohol, a new side reaction forms an ester. This is illustrated for 1-butanol.

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3\text{OH} \xrightarrow{\text{PCC, CH}_2\text{Cl}_2} \text{CH}_3\text{CH}_2\text{CH}_2\text{COCH}_2\text{CH}_2\text{CH}_3 \]

(c) Give the products expected from reaction of 3-phenyl-1-propanol and water-free CrO$_3$ (1) when the alcohol is added to the oxidizing agent and (2) when the oxidant is added to the alcohol.
41. Explain the results of the following reactions by means of mechanisms.

(a) \[ \text{HO} \rightarrow \text{H}^+ \rightarrow \text{OH} \]

(b) \[ \text{HO} \rightarrow \text{H}^+ \rightarrow \text{OH} \]

(c) Explain why hemiacetal formation may be catalyzed by either acid or base, but acetal formation is catalyzed only by acid, not by base.

42. The two isomeric compounds below are naturally occurring insect pheromones. The isomer on the left attracts the male olive fruit fly; the one on the right, the female. (a) What kind of isomeric relationship exists between these two structures? (b) What functional group is contained in these molecules? (c) Both of these compounds are hydrolyzed under aqueous acidic conditions. Draw the products. Are the product molecules from the two starting isomers the same or different?

43. Formulate a plausible mechanism for the following reaction. The product is a precursor of mediquox (shown in the margin), an agent used to treat respiratory infections in chickens (no, we are not making this up).

Benzene-1,2-diamine + H₂C₃C₆H₃O → 2,3-Dimethylquinoxaline

44. The formation of imines, oximes, hydrazones, and related derivatives from carbonyl compounds is reversible. Write a detailed mechanism for the acid-catalyzed hydrolysis of cyclohexanone semicarbazone to cyclohexanone and semicarbazide.

45. Reaction review II. Without consulting the Reaction Road Map on p. 818, suggest reagents to convert cyclohexanone into each of the compounds below.
46. Propose reasonable syntheses of each of the following molecules, beginning with the indicated starting material.

(a) \[ \text{HO} \quad \text{OH} \quad \text{O} \quad \text{OH} \] from BB

(b) \( \text{C}_6\text{H}_5\text{N} \equiv \text{C}(\text{CH}_2\text{CH}_3)_2 \) from 3-pentanol

(c) \( \text{O} \quad \text{OH} \quad \text{O} \quad \text{OH} \) from 1,5-pentanediol

(d) \( \text{O} \quad \text{OH} \) from

47. The UV absorptions and colors of 2,4-dinitrophenylhydrazone derivatives of aldehydes and ketones depend sensitively on the structure of the carbonyl compound. Suppose that you are asked to identify the contents of three bottles whose labels have fallen off. The labels indicate that one bottle contained butanal, one contained trans-2-butenal, and one contained trans-3-phenyl-2-propenal. The 2,4-dinitrophenylhydrazones prepared from the contents of the bottles have the following characteristics.

Bottle 1: m.p. 187–188°C; \( \lambda_{\text{max}} = 377 \) nm; orange color
Bottle 2: m.p. 121–122°C; \( \lambda_{\text{max}} = 358 \) nm; yellow color
Bottle 3: m.p. 252–253°C, \( \lambda_{\text{max}} = 394 \) nm; red color

Match up the hydrazones with the aldehydes \( \text{without} \) first looking up the melting points of these derivatives, and explain your choices. \( \text{Hint: } \text{See Section 14-11.} \)

48. Indicate the reagent(s) best suited to effect these transformations.

(a) \[ \text{O} \quad \text{O} \quad \rightarrow \quad \text{O} \quad \text{O} \]

(b) \( \text{CH}_3\text{CH} \equiv \text{CHCH}_2\text{CH}_2\text{CH} \quad \rightarrow \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH} \)

(c) \( \text{CH}_3\text{CH} \equiv \text{CHCH}_2\text{CH}_2\text{CH} \quad \rightarrow \quad \text{CH}_3\text{CH} \equiv \text{CHCH}_2\text{CH}_2\text{CH}_2\text{OH} \)

(d) \[ \text{OH} \quad \text{OH} \quad \rightarrow \quad \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \]

49. The molecule bombykol, whose structure is shown below, is a powerful insect pheromone, the sex attractant of the female silk moth \( \text{see Section 12-17.} \) It was initially isolated in the amount of 12 mg from extraction of 2 tons of moth pupae. Propose a synthesis of bombykol from two simpler molecules based on the Wittig reaction.

\[ \text{CH}_3\text{CH}_2\text{CH}_2\text{C} \equiv \text{CCH} \equiv \text{CH} \text{(CH}_2)_n\text{CO}_2\text{CH}_2\text{CH}_3 \]

Bombykol
50. For each of the following molecules, propose two methods of synthesis from the different precursor molecules indicated.

(a) CH₃CH=CHCH₂CH(CH₃)₂ from (1) an aldehyde and (2) a different aldehyde

(b) CH₃CH=CH₂ from (1) a dialdehyde and (2) a diketone

51. Three isomeric ketones with the molecular formula C₇H₁₄O are converted into heptane by Clemmensen reduction. Compound A gives a single product upon Baeyer-Villiger oxidation; compound B gives two different products in very different yields; compound C gives two different products in virtually a 1:1 ratio. Identify A, B, and C.

52. Give the product(s) of reaction of hexanal with each of the following reagents.

(a) HOCH₂CH₂OH, H⁺
(b) LiAlH₄, then H⁺, H₂O
(c) NH₂OH, H⁺
(d) NH₂NH₂, KOH, heat
(e) (CH₃)₂CHCH₂CH=P(C₆H₅)₃
(f) \( \text{H}^- \text{N} \text{H} \)
(g) Ag⁺, NH₃, H₂O
(h) CrO₃, H₂SO₄, H₂O
(i) HCN

53. Give the product(s) of reaction of cycloheptanone with each of the reagents in Problem 52.

54. Formulate in full detail the mechanism for the Wolff-Kishner reduction of 1-phenylethanone (acetophenone) to ethylbenzene (see p. 803).

55. The general equation for the Baeyer-Villiger oxidation (see p. 808) begins with a reaction between a ketone and a peroxycarboxylic acid to form a peroxo analog of a hemiacetal. Formulate a detailed mechanism for this process.

56. Formulate a detailed mechanism for the Baeyer-Villiger oxidation of the ketone shown in the margin (refer to Exercise 17-22).

57. Give the two theoretically possible Baeyer-Villiger products from each of the following compounds. Indicate which one is formed preferentially.

(a) \( \text{O} \text{C} \text{CH₃} \text{H} \)
(b) \( \text{O} \text{C} \text{CH₃} \)
(c) \( \text{O} \text{C} \text{CH₃} \)
(d) \( \text{O} \text{C} \text{CH₃} \)
(e) \( \text{C}_₆\text{H}_₅\text{CCH₃} \)

58. Propose efficient syntheses of each of the following molecules, beginning with the indicated starting materials.

(a) \( \text{CHO} \text{H₃C} \text{OH} \)
(b) \( \text{CHO} \text{H₃C} \text{OH} \)
(c) \( \text{CHO} \text{ClCH₂CH₂CH₂OH} \)
59. **CHALLENGE**  Explain the fact that, although hemiacetal formation between methanol and cyclohexanone is thermodynamically disfavored, addition of methanol to cyclopropanone goes essentially to completion:

\[
\text{CH}_3\text{OH} + \text{C}_7\text{H}_8\text{O} \rightleftharpoons \text{C}_7\text{H}_8\text{OCH}_3
\]

60. The rate of the reaction of \(\text{NH}_2\text{OH}\) with aldehydes and ketones is very sensitive to pH. It is very low in solutions more acidic than pH 2 or more basic than pH 7. It is highest in moderately acidic solution (pH \(\sim\) 4). Suggest explanations for these observations.

61. Compound D, formula \(\text{C}_8\text{H}_{14}\text{O}\), is converted by \(\text{CH}_2\left\langle\text{P(C}_6\text{H}_5\right\rangle_3\) into compound E, \(\text{C}_9\text{H}_{16}\). Treatment of compound D with \(\text{LiAlH}_4\) yields two isomeric products F and G, both \(\text{C}_8\text{H}_{16}\text{O}\), in unequal yield. Heating either F or G with concentrated \(\text{H}_2\text{SO}_4\) produces H, with the formula \(\text{C}_8\text{H}_{16}\). Ozonolysis of H produces a ketoaldehyde after \(\text{Zn}--\text{H}^+\), \(\text{H}_2\text{O}\) treatment. Oxidation of this ketoaldehyde with aqueous \(\text{Cr(VI)}\) produces

\[
\text{CO}_2\text{H}
\]

Identify compounds D through H. Pay particular attention to the stereochemistry of D.

62. In 1862, it was discovered that cholesterol (for structure, see Section 4-7) is converted into a new substance named coprostanol by the action of bacteria in the human digestive tract. Make use of the following information to deduce the structure of coprostanol. Identify the structures of unknowns J through M as well. (i) Coprostanol, upon treatment with \(\text{Cr(VI)}\) reagents, gives compound J, \(\text{UV} \lambda_{\text{max}}(\epsilon) = 281(22)\) nm and \(\text{IR} = 1710\) cm\(^{-1}\). (ii) Exposure of cholesterol to \(\text{H}_2\) over \(\text{Pt}\) results in compound K, a stereoisomer of coprostanol. Treatment of K with the \(\text{Cr(VI)}\) reagent furnishes compound L, which has a UV peak very similar to that of compound J, \(\lambda_{\text{max}}(\epsilon) = 258(23)\) nm, and turns out to be a stereoisomer of J. (iii) Careful addition of \(\text{Cr(VI)}\) reagent to cholesterol produces M: \(\text{UV} \lambda_{\text{max}}(\epsilon) = 286(109)\) nm. Catalytic hydrogenation of M over \(\text{Pt}\) also gives L.

63. **CHALLENGE**  Three reactions that include compound M (see Problem 62) are described here. Answer the questions that follow. (a) Treatment of M with catalytic amounts of acid in ethanol solvent causes isomerization to compound N: \(\text{UV} \lambda_{\text{max}}(\epsilon) = 241(17,500)\) and \(310(72)\) nm. Propose a structure for N. (b) Hydrogenation of compound N (\(\text{H}_2--\text{Pd}\), ether solvent) produces compound J (Problem 62). Is this the result that you would have predicted, or is there something unusual about it? (c) Wolff-Kishner reduction of compound N (\(\text{H}_2\text{NNH}_2\), \(\text{H}_2\text{O}, \text{HO}^+\), \(\Delta\)) leads to 3-cholestene. Propose a mechanism for this transformation.

![3-Cholestene](image)

As a group, analyze the following \(^1\text{H}\) NMR and IR spectral data: \(^1\text{H}\) NMR (\(\text{CCl}_4\)): \(\delta = 2.19\) (s, 3 H), 2.75 (d, 2 H), 3.38 (s, 6 H), 4.89 (t, 1 H) ppm; IR: 1715 cm\(^{-1}\).
Consider the chemical shifts, the splitting patterns, and the integrations of the signals in the NMR spectrum and discuss possible fragments that could give rise to the observed multiplicities. Use the IR information to assign the functional group that exists in the new molecule. Present an explanation for your structural determination, including reference to the spectral data, and suggest a detailed mechanism for the formation of the new compound.

Preprofessional Problems

65. In the transformation shown here, which of the following compounds is most likely to be compound A (use IUPAC name)? (a) 5-Octyn-7-one; (b) 5-octyn-2-one; (c) 3-octyn-2-one; (d) 2-octyn-3-one.

\[
\text{3-Octyn-2-ol } \xrightarrow{\text{CrO}_3, \text{H}_2\text{SO}_4, \text{acetone}} \text{ A}
\]

66. The reaction

\[
\text{H}_3\text{C} \quad \text{C} \quad \text{H}_2\text{C} \equiv \text{C} \quad \text{H}
\]

\[
\text{CH}_2\equiv\text{C} \quad \text{O} \quad \text{OH}
\]

demonstrates (a) resonance; (b) tautomerism; (c) conjugation; (d) deshielding.

67. Which of the following reagents converts benzenecarbaldehyde (benzaldehyde) into an oxime? (a) \(\text{H}_2\text{NNHC}_6\text{H}_5\); (b) \(\text{H}_2\text{NNH}_2\); (c) \(\text{O}_3\); (d) \(\text{H}_2\text{NOH}\); (e) \(\text{CH}_3\text{CH(OH)}_2\).

68. Which of the following statements is correct? In the IR spectrum of 3-methyl-2-butanone, the most intense absorption is at (a) 3400 cm\(^{-1}\), owing to an OH stretching mode; (b) 1700 cm\(^{-1}\), owing to a C\(\equiv\)O stretching mode; (c) 2000 cm\(^{-1}\), owing to a CH stretching mode; (d) 1500 cm\(^{-1}\), owing to the rocking of an isopropyl group.
H ave another look at the Chapter Opening above. The very fact that you can see it is made possible by the chemistry alluded to in the caption: Photons impinge on the $\pi$ system (Section 14-11) of cis-retinal bound to a protein to cause cis-trans isomerization. The associated conformational changes result, within picoseconds, in a nerve impulse that is translated by your brain into “vision” (Chemical Highlight 18-3). The crucial chemical feature of retinal that makes this process possible is the (in this case extended) conjugative communication between the carbonyl group and the adjacent $\pi$ system. This chapter will show you that the carbonyl group (much like an ordinary carbon–carbon double bond; Section 14-1) activates adjacent C–H and C=C bonds even in much simpler systems, because of resonance. After you have absorbed the material that follows, you will be able to “look” at this page with quite a different perspective!

In the last chapter, we saw how the structure of the carbonyl group—a multiple bond that is also highly polar—gives rise to a characteristic combination of functional behaviors: addition reactions mediated by electrophilic attack (usually by protons) on the Lewis basic oxygen and attack by nucleophiles on the carbon. We turn now to a third site of reactivity in aldehydes and ketones, the carbon next to the carbonyl group, known as the $\alpha$-carbon. The carbonyl group induces enhanced acidity of hydrogens on the $\alpha$-carbon. Moving these $\alpha$-hydrogens may lead to either of two electron-rich species: unsaturated alcohols called enols or their corresponding conjugate bases, known as enolate ions. Both enols and enolate ions are important nucleophiles, capable of attacking electrophiles such as protons, halogens, haloalkanes, and even other carbonyl compounds.

$\alpha$-Unsaturated Aldehydes and Ketones
We begin by introducing the chemistry of enolates and enols. Especially important is a reaction between enolate ions and carbonyl compounds, called the aldol condensation. This process is widely used to form carbon–carbon bonds both in the laboratory and in nature. Among the possible products of aldol condensation are \(\alpha,\beta\)-unsaturated aldehydes and ketones, which contain conjugated carbon–carbon and carbon–oxygen \(\pi\) bonds. As expected, electrophilic additions may take place at either \(\pi\) bond. However, more significantly, \(\alpha,\beta\)-unsaturated carbonyl compounds are also subject to nucleophilic attack, a reaction that may involve the entire conjugated system.

### 18-1 Acidity of Aldehydes and Ketones: Enolate Ions

The \(pK_a\) values of aldehyde and ketone \(\alpha\)-hydrogens range from 16 to 21, much lower than the \(pK_a\) values of ethene (44) or ethyne (25), but comparable with those of alcohols (15–18). Strong bases can therefore remove an \(\alpha\)-hydrogen. The anions that result are known as enolate ions or simply enolates.

![Acetone enolate](image)

Why are aldehydes and ketones relatively acidic? We know that acid strength is enhanced by stabilization of the conjugate base (Section 2-2). In the enolate ion, the inductive effect of the positively polarized carbonyl carbon strongly stabilizes the negative charge at the \(\alpha\)-position. Aldehydes are stronger acids than ketones because their carbonyl carbon bears a larger partial positive charge (Section 17-6). Further strong stabilization is provided by delocalization of charge onto the electronegative oxygen, as described by the resonance forms just pictured. The effect of delocalization is also reflected in the electrostatic potential map of the acetone enolate shown in the margin (on an attenuated scale), which exhibits negative charge (red) on the \(\alpha\)-carbon as well as on the oxygen. An example of enolate formation is the deprotonation of cyclohexanone by lithium diisopropylamide (LDA; Section 7-8).

![Enolate Preparation](image)

**Exercise 18-1**

Identify the most acidic hydrogens in each of the following molecules. Give the structure of the enolate ion arising from deprotonation. (a) Acetaldehyde; (b) propanal; (c) acetone; (d) 4-heptanone; (e) cyclopentanone.

![Resonance hybrid](image)

Each resonance form contributes to the characteristics of the enolate ion and thus to the chemistry of carbonyl compounds. The resonance hybrid possesses partial negative charges on both carbon and oxygen; as a result, it is nucleophilic and may attack electrophiles at
either position. A species that can react at two different sites to give two different products is called **ambident** ("two fanged": from ambi, Latin, both; dens, Latin, tooth). The enolate ion is thus an ambident anion. Its carbon atom is normally the site of reaction, undergoing nucleophilic substitution with \( S_N^2 \) substrates such as suitable haloalkanes. Because this reaction attaches an alkyl group to the reactive carbon, it is called **alkylation** (more specifically, C-alkylation). As we shall see in Section 18-4, alkylation is a powerful method for carbon–carbon bond formation of ketones. For example, alkylation of cyclohexanone enolate with 3-chloropropene takes place at carbon. Alkylation at oxygen (O-alkylation) is uncommon, although oxygen is typically the site of protonation. The product of protonation is an unsaturated alcohol, called an **alkenol** (or **enol** for short). Enols are unstable and rapidly isomerize back to the original ketones (recall Section 13-7).

### Ambident Behavior of Cyclohexanone Enolate Ion

![Cyclohexanone enolate ion](image)

#### Exercise 18-2

Give the products of reaction of cyclohexanone enolate with (a) iodoethane (reacts by C-alkylation) and (b) chlorotrimethylsilane, \((CH_3)_3Si\–Cl\ (reacts by O-silylation)\).

### In Summary

The hydrogens on the carbon next to the carbonyl group in aldehydes and ketones are acidic, with \( pK_a \) values ranging from 16 to 21. Deprotonation leads to the corresponding enolate ions, which may attack electrophilic reagents at either oxygen or carbon. Protonation at oxygen gives enols.

### 18-2 Keto–Enol Equilibria

We have seen that protonation of an enolate at oxygen leads to an enol. The enol, an unstable isomer of an aldehyde or ketone, rapidly converts into the carbonyl system: It **tautomizes** (Section 13-7). These isomers are called **enol** and **keto tautomers**. We begin by discussing factors affecting their equilibria, in which the keto form usually predominates. We then describe the mechanism of tautomerism and its chemical consequences.

### An enol equilibrates with its keto form in acidic or basic solution

Enol–keto tautomerism proceeds by either acid or base catalysis. Base simply removes the proton from the enol oxygen, reversing the initial protonation. Subsequent (and slower) C-protonation furnishes the thermodynamically more stable keto form.

![Base-Catalyzed Enol–Keto Equilibration](image)
In the acid-catalyzed process, the enol form is protonated at the double-bonded carbon away from the hydroxy-bearing neighbor. The electrostatic potential map of ethenol (margin) shows that this carbon bears more negative charge (red). Moreover, the resulting cation is resonance-stabilized by the attached hydroxy group, and inspection of the corresponding resonance form reveals it to be simply the protonated carbonyl compound. Deprotonation then gives the product.

\[ \text{Enol form} + H^+ \rightleftharpoons \text{Protonated carbonyl system} \rightleftharpoons \text{Keto form} \]

Both the acid- and base-catalyzed enol–keto interconversions occur rapidly in solution whenever there are traces of the required catalysts. Remember that although the keto form (usually) predominates, the enol-to-keto conversion is reversible and the mechanisms by which the keto form equilibrates with its enol counterpart are the exact reverse of the above two schemes.

**Substituents can shift the keto–enol equilibrium**

The equilibrium constants for the conversion of the keto into the enol forms are very small for ordinary aldehydes and ketones, only traces of enol (which is less stable by ca. 8–12 kcal mol\(^{-1}\)) being present. However, relative to its keto form, the enol of acetaldehyde is about a hundred times more stable than the enol of acetone, because the less substituted aldehyde carbonyl is less stable than the more substituted ketone carbonyl.

**Enol formation leads to deuterium exchange and stereoisomerization**

What are some consequences of enol formation by tautomerism? One is that treatment of a ketone with traces of acid or base in D\(_2\)O solvent leads to the complete exchange of all the \(\alpha\)-hydrogens.
Hydrogen–Deuterium Exchange of Enolizable Hydrogens

This reaction can be conveniently followed by $^1$H NMR, because the signal for these hydrogens slowly disappears as each one is sequentially replaced by deuterium. In this way, the number of $\alpha$-hydrogens present in a molecule can be readily determined.

**Exercise 18-3**

Formulate mechanisms for the base- and acid-catalyzed replacement of a single $\alpha$-hydrogen in acetone by deuterium from $D_2O$.

**Exercise 18-4**

Write the products (if any) of deuterium incorporation by the treatment of the following compounds with $D_2O$–$NaOD$.

(a) Cycloheptanone  
(b) 2,2-Dimethylpropanal  
(c) 3,3-Dimethyl-2-butanone  
(d) $O$ \[ \begin{array}{c} \text{CHO} \end{array} \]

**Exercise 18-5**

**Working with the Concepts: Assigning NMR Signals of a Cyclic Ketone**

The $^1$H NMR spectrum of cyclobutanone consists of a quintet at $\delta = 2.00$ ppm and a triplet at $\delta = 3.13$ ppm. Assign the signals in this spectrum to the appropriate hydrogens in the molecule.

**Strategy**

Using the information in Section 17-3 regarding chemical shifts of hydrogens in ketones, apply the tools of NMR analysis that you acquired in Chapter 10.

**Solution**

- The structure of cyclobutanone implies an $^1$H NMR spectrum displaying two signals: One for the four $\alpha$-hydrogens (on C2 and C4) and another for the two $\beta$-hydrogens (on C3).
- We learned in Section 17-3 that $\alpha$-hydrogens in carbonyl compounds are more deshielded than $\beta$-hydrogens. Furthermore, in accordance with the $(N + 1)$ rule for spin–spin splitting (Section 10-7), the signal for the $\alpha$-hydrogens should appear as a triplet as a result of splitting by the two $\beta$-hydrogen neighbors; thus we may assign the triplet signal at $\delta = 3.13$ ppm to the four $\alpha$-hydrogens.
- Conversely, splitting by four neighboring $\alpha$-hydrogens should cause the signal for the $\beta$-hydrogens to appear as a quintet, consistent with the signal at $\delta = 2.00$ ppm.

**Exercise 18-6**

**Try It Yourself**

What would you expect to observe to change in the $^1$H NMR spectrum of cyclobutanone upon treatment with $D_2O$–$NaOD$? (**Hint:** Deuterium atoms do not display signals in an $^1$H NMR spectrum.)
Another consequence of enol formation, or enolization, is the ease with which stereo-isomers at α-carbons interconvert. For example, treatment of cis-2,3-disubstituted cyclopentanones with mild base furnishes the corresponding trans isomers. The trans isomers are more stable for steric reasons.

**Base-Catalyzed Isomerism of an α-Substituted Ketone**

The reaction proceeds through the enolate ion, in which the α-carbon is planar and, hence, no longer a stereocenter. Reprotonation from the side cis to the 3-methyl group results in the trans diastereomer (Sections 4-1 and 5-5).

Another consequence of enolization is the difficulty of maintaining optical activity in a compound whose only stereocenter is an α-carbon. Why? As the (achiral) enol converts back into the keto form, a racemic mixture of R and S enantiomers is produced. For example, at room temperature, optically active 3-phenyl-2-butanone racemizes with a half-life of minutes in basic ethanol.

**Racemization of Optically Active 3-Phenyl-2-butanone**

In Summary Aldehydes and ketones are in equilibrium with their enol forms, which are roughly 10 kcal mol⁻¹ less stable. Keto–enol equilibration is catalyzed by acid or base. Enolization allows for easy H–D exchange in D₂O and causes isomerization at stereocenters next to the carbonyl group.

### 18-3 Halogenation of Aldehydes and Ketones

This section examines a reaction of the carbonyl group that can proceed through the intermediacy of either enols or enolate ions—halogenation. Aldehydes and ketones react with halogens at the α-carbon. In contrast with deuteration, which proceeds to completion with either acid or base, the extent of halogenation depends on whether acid or base catalysis has been used.
In the presence of acid, halogenation usually stops after the first halogen has been introduced, as shown in the following example.

**Acid-Catalyzed α-Halogenation of Ketones**

![REACTION](image)

The rate of the acid-catalyzed halogenation is *independent of the halogen concentration*, an observation suggesting a rate-determining first step involving the carbonyl substrate. This step is enolization. The halogen then rapidly attacks the double bond to give an intermediate oxygen-stabilized halocarbocation. Subsequent deprotonation of this species furnishes the product.

**Mechanism of the Acid-Catalyzed Bromination of Acetone**

**Step 1.** Enolization (*rate determining*)

![MECHANISM](image)

**Step 2.** Halogen attack

![MECHANISM](image)

**Step 3.** Deprotonation

![MECHANISM](image)

Why is further halogenation retarded? The answer lies in the requirement for enolization. To repeat halogenation, the halo carbonyl compound must enolize again by the usual acid-catalyzed mechanism. However, the electron-withdrawing power of the halogen makes protonation, the initial step in enolization, *more difficult* than in the original carbonyl compound.

**Halogenation Slows Down Enolization Because Protonation Is Disfavored**

![MECHANISM](image)
Chapter 18
Enols, Enolates, and the Aldol Condensation

Therefore, the singly halogenated product is not attacked by additional halogen until the starting aldehyde or ketone has been used up.

Base-mediated halogenation is entirely different. It proceeds instead by the formation of an enolate ion, which then attacks the halogen. Here the reaction continues until it completely halogenates the same \( \alpha \)-carbon, leaving unreacted starting material (when insufficient halogen is employed). Why is base-catalyzed halogenation so difficult to stop at the stage of monohalogenation? The electron-withdrawing power of the halogen increases the acidity of the remaining \( \alpha \)-hydrogens, accelerating further enolate formation and hence further halogenation.

**Exercise 18-8**

Write the products of the acid- and base-catalyzed bromination of cyclohexanone.

**In Summary** Halogenation of aldehydes and ketones in acid can proceed selectively to the monohalocarbonyl compounds. In base, all \( \alpha \)-hydrogens are replaced before another molecule of starting material is attacked.

### 18-4 Alkylation of Aldehydes and Ketones

We have seen that enolates may be generated from ketones and aldehydes by treatment with bases, such as LDA (Sections 7-8 and 18-1). The nucleophilic \( \alpha \)-carbon of the enolate may participate in \( S_N2 \) alkylation reactions with suitable haloalkanes, forming a new carbon–carbon bond in the process. This section presents some features of enolate alkylation and compares it with a related process, alkylation of a species called an *enamine*.

**Alkylation of enolates can be difficult to control**

In principle, the alkylation of an aldehyde or a ketone enolate is nothing more than a nucleophilic substitution.

In practice, however, the reaction may be complicated by several factors. The enolate ion is a fairly strong base. Therefore, alkylation is normally feasible using only halomethanes or primary haloalkanes; otherwise, E2 elimination converting the haloalkane into an alkene (Section 7-8) becomes a significant process. Other side reactions can present additional difficulties. Alkylation of aldehydes usually fails because their enolates undergo a highly favorable condensation reaction, which is described in the next section. Even alkylation of ketones may be problematic, because the product of monoalkylation may lose another \( \alpha \)-hydrogen under the reaction conditions and become alkylated a second time. Furthermore, if the starting ketone is unsymmetrical, alkylation may occur at either of the two \( \alpha \)-carbons, leading to two regioisomeric products. The reaction of 2-methylcyclohexanone with iodo-methane illustrates both of these problems.
Under some circumstances, ketones may be alkylated successfully. In the virtually ideal example below, the ketone possesses only one \( \alpha \)-hydrogen and the primary allylic halide is an excellent \( S_N2 \) substrate (Section 14-3). The base in this example is sodium hydride, NaH (Section 8-6).

Successful Alkylation of a Ketone

Exercise 18-9

The reaction with base of the compound shown in the margin gives three isomeric products \( C_6H_{12}O \). What are they? (Hint: Try intramolecular alkylations. Caution: As stated in Section 18-1, enolate alkylation “normally” proceeds only at carbon. Is the present case “normal”?)

Exercise 18-10

C-alkylation of cyclohexanone enolate with 3-chloropropene (Section 18-1) is much faster than the corresponding reaction with 1-chloropropane. Explain. (Hint: See Section 14-3.) What product(s) would you expect from reaction of cyclohexanone enolate with (a) 2-bromopropane and (b) 2-bromo-2-methylpropane? (Hint: See Chapter 7.)

Enamines afford an alternative route for the alkylation of aldehydes and ketones

Section 17-9 showed that the reaction of secondary amines such as azacyclopentane (pyrrolidine) with aldehydes or ketones produces enamines. As the following resonance forms indicate, the nitrogen substituent renders the enamine carbon–carbon double bond electron rich. Furthermore, the dipolar resonance contribution gives rise to significant nucleophilicity at the remote carbon, even though the enamine is neutral. As a result, electrophiles may attack at this position. Let us see how this attack may be used to synthesize alkylated aldehydes and ketones.
Resonance in Enamines

Exposure of enamines to haloalkanes results in alkylation at the nucleophilic carbon to produce an iminium salt. Upon aqueous work-up, iminium salts hydrolyze by a mechanism that is the reverse of the one formulated for imine formation in Section 17-9. The results are a new alkylated aldehyde or ketone and the original secondary amine.

Alkylation of an Enamine

Exercise 18-11

Formulate the mechanism for the final step of the sequence just shown: hydrolysis of the iminium salt.

How does the alkylation of an enamine compare with the alkylation of an enolate? Enamine alkylation is far superior, because it minimizes double or multiple alkylation: Under the conditions of the process, the iminium salt formed after the first alkylation is relatively stable and unable to react with additional haloalkane. Enamines can also be used to prepare alkylated aldehydes, as shown here. (We shall see in the next section that aldehyde enolates undergo a new reaction called the aldol condensation and, therefore, cannot be alkylated readily.)

Exercise 18-12

Alkylations of the enolate of ketone A are very difficult to stop before dialkylation occurs, as illustrated here. Show how you would use an enamine to prepare monoalkylated ketone B.
In Summary  Enolates give rise to alkylated derivatives upon exposure to haloalkanes. In these reactions, control of the extent and the position of alkylation, when there is a choice, may be a problem. Enamines derived from aldehydes and ketones undergo alkylation to the corresponding iminium salts, which can hydrolyze to the alkylated carbonyl compounds.

18-5 Attack by Enolates on the Carbonyl Function:
Aldol Condensation

We have seen the dual functional capability of carbonyl compounds: electrophilic at the carbonyl carbon, potentially nucleophilic at the adjacent α-carbon. In this section we introduce one of the most frequently employed carbon–carbon bond-forming strategies: attack of an enolate ion at a carbonyl carbon. The product of this process is a β-hydroxy carbonyl compound. Subsequent elimination of water may occur, leading to α,β-unsaturated aldehydes and ketones. The next three sections describe these reactions in detail, and Chemical Highlights 18-1 and 18-2 illustrate them in a biological context.

Aldehydes undergo base-catalyzed condensations

Addition of a small amount of dilute aqueous sodium hydroxide to acetaldehyde at low temperature initiates the conversion of the aldehyde into a dimer, 3-hydroxybutanal, with the common name aldol (from aldehyde alcohol). Upon heating, this hydroxyaldehyde dehydrates to give the final product, the α,β-unsaturated aldehyde trans-2-butenal. This reaction is an example of the aldol condensation. The aldol condensation is general for aldehydes and, as we shall see, sometimes succeeds with ketones as well. We first describe its mechanism before turning to its uses in synthesis.

Aldol Condensation Between Two Molecules of Acetaldehyde

The aldol condensation highlights the two most important facets of carbonyl group reactivity: enolate formation and attack of nucleophiles at a carbonyl carbon. The base (hydroxide) is not strong enough to convert all of the starting aldehyde into the corresponding enolate ion, but it does bring about an equilibrium between the aldehyde and a small amount of enolate. Because the ion is formed in the presence of a large excess of aldehyde, its nucleophilic α-carbon can attack the carbonyl group of another acetaldehyde molecule. Protonation of the resulting alkoxide furnishes 3-hydroxybutanal.

Mechanism of Aldol Formation

Step 1. Enolate generation
Step 2. Nucleophilic attack

\[
\begin{align*}
\text{Electrophilic carbonyl carbon} & \quad \text{Nucleophilic } \alpha\text{-carbon} \\
\text{CH}_3\text{CH} & \quad \text{CH}_2=\text{C} \\
\text{O} & \quad \text{O} \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

\[\text{CH}_3\text{C} \equiv \text{CH} \quad \rightleftharpoons \quad \text{CH}_2=\text{CH} \quad \text{New carbon–carbon bond}\]

Step 3. Protonation

\[
\begin{align*}
\text{CH}_3\text{C} \equiv \text{CH} & \quad \text{H} \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

\[\rightleftharpoons \]

\[
\begin{align*}
\text{CH}_3\text{C} & \equiv \text{CH} + \text{HO}^- \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

50–60%

\[3\text{-Hydroxybutanal} \quad \text{(Aldol)}\]

Note that hydroxide ion functions as a catalyst in this reaction. The last two steps of the sequence drive the initially unfavorable equilibrium toward product, but the overall reaction is not very exothermic. The aldol is formed in 50–60% yield and does not react further when its preparation is carried out at low temperature (5°C).

Exercise 18-13

Give the structure of the hydroxyaldehyde product of aldol condensation at 5°C of each of the following aldehydes: (a) propanal; (b) butanal; (c) 2-phenylacetaldehyde; (d) 3-phenylpropanal.

Exercise 18-14

Can benzaldehyde undergo aldol condensation? Why or why not?

At elevated temperature, the aldol is converted into its enolate ion. Elimination of hydroxide ion, normally a poor leaving group, is driven thermodynamically by the formation of the conjugated, relatively stable final product. The net result of this transformation is a hydroxide-catalyzed dehydration of the aldol. We describe the overall process of aldol reaction followed by dehydration as aldol condensation. Recall (Section 17-9) that a condensation is a reaction that combines two molecules into one with the elimination of (typically) a molecule of water.

Mechanism of Aldol Dehydration

\[
\begin{align*}
\text{CH}_3\text{C} \equiv \text{C} & \quad \text{H} \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

\[\rightleftharpoons \]

\[\text{CH}_3\text{C} \equiv \text{C} \quad \text{H} \\
\text{H} \quad \text{H} \]

Enolate

\[\text{HO}^- \quad \text{as a leaving group is unusual}\]

\[\text{CH}_3\text{C} \equiv \text{C} \quad \text{H} \]

\[\rightarrow \quad \text{CH}_3\text{CH} \equiv \text{CHCH} \quad \text{HO}^- \]

What makes the aldol condensation synthetically useful? It couples two carbonyl compounds, with carbon–carbon bond formation, to furnish a product with a carbonyl group
and either an alcohol or an alkene function. Thus, at low temperatures, its outcome is a 
$\beta$-hydroxycarbonyl compound:

![Chemical structure of 2-Methylpropanal and 3-Hydroxy-2,2,4-trimethylpentanal](image)

At higher temperatures, however, it furnishes an $\alpha,\beta$-unsaturated carbonyl compound, which has considerable synthetic utility (Sections 18-9 through 18-11):

![Chemical structure of Heptanal and (Z)-2-Pentyl-2-nonenal](image)

**Exercise 18-15**

Give the structure of the $\alpha,\beta$-unsaturated aldehyde product of aldol condensation of each of the aldehydes in Exercise 18-13.

**Ketones can undergo aldol condensation**

So far, we have discussed only aldehydes as substrates in the aldol condensation. What about ketones? Treatment of acetone with base does indeed lead to some 4-hydroxy-4-methyl-2-pentanone, but the conversion is poor because of an unfavorable equilibrium with starting material.

![Chemical structures of Aldol Formation from Acetone](image)

The lesser driving force of the aldol reaction of ketones is due to the greater stability of a ketone than an aldehyde [about 3 kcal mol$^{-1}$ (12.5 kJ mol$^{-1}$)]. As a result, the aldol addition of ketones is endothermic. To drive the reaction forward, we can extract the product alcohol continuously from the reaction mixture as it is formed. Alternatively, under more vigorous conditions, dehydration and removal of water move the equilibrium toward the $\alpha,\beta$-unsaturated ketone (see margin).
In Summary

Treatment of enolizable aldehydes with catalytic base leads to $\beta$-hydroxy aldehydes at low temperature and to $\alpha,\beta$-unsaturated aldehydes upon heating. The reaction proceeds by enolate attack on the carbonyl function. Aldol addition to a ketone carbonyl group is energetically unfavorable. To drive the aldol condensation of ketones to product, special conditions have to be used, such as removal of the water or the aldol formed in the reaction.

18-6 Crossed Aldol Condensation

What happens if we try to carry out an aldol condensation between the enolate of one aldehyde and the carbonyl carbon of another? In such a situation, called crossed aldol condensation, mixtures ensue, because enolates of both aldehydes are present and may react with the carbonyl groups of either starting compound. For example, a 1:1 mixture of acetaldehyde and propanal gives the four possible aldol addition products in comparable amounts.
**CHEMICAL HIGHLIGHT 18-1**

**Enzyme-Catalyzed Stereoselective Aldol Condensations in Nature**

Glucose ($\text{C}_6\text{H}_{12}\text{O}_6$, Section 24-1), the most common sugar in nature, is absolutely essential to all life on Earth. In many species it is the sole energy source for the major organs, including the entire central nervous system. All species synthesize glucose from smaller molecules. The process is called *gluconeogenesis*, and it employs a crossed aldo condensation (catalyzed by enzymes appropriately named *aldolases*) to construct a carbon–carbon bond between two three-carbon precursors.

A primary amine in the enzyme (specifically, a substituent in the amino acid lysine, Section 26-1) condenses with the carbonyl group of the monophosphate ester of 1,3-dihydroxyacetone to form an iminium salt. Enzyme-catalyzed deprotonation gives an enamine (Section 17-9), whose nucleophilic carbon (red) attacks the aldehyde carbonyl carbon (blue) of 2,3-dihydroxypropanal (glyceraldehyde) 3-phosphate. This nitrogen analog of a crossed aldol condensation proceeds with 100% stereoselectivity: The enzyme causes the two substrate molecules to approach one another in a single, highly ordered geometry. Bond formation occurs exclusively to link the bottom faces of both the (red) enamine carbon and the carbonyl carbon (blue) to each other, resulting in the illustrated stereochemistry in the product. Hydrolysis of the resulting iminium salt gives the phosphate ester of the six-carbon sugar fructose, which is converted to glucose in a subsequent step.

**Result of Nonselective Crossed Aldol Reaction Between Acetaldehyde and Propanal**

*(All four reactions occur simultaneously)*

1. **Propanal enolate adds to acetaldehyde.**

   ![Propanal enolate adds to acetaldehyde](image)

CHEMICAL HIGHLIGHT 18-2

Enzymes in Synthesis: Stereoselective Crossed Aldol Condensations

The same enzymes that catalyze aldol condensations in nature may also be employed in the synthetic laboratory. In nature, the enzyme 2-deoxyribose-5-phosphate aldolase (DERA) catalyzes the condensation of acetaldehyde with glyceraldehyde 3-phosphate to produce the phosphate ester of 2-deoxyribose, the sugar component of the deoxyribonucleic acid (DNA) present in all living things (Chapter 26).

![Chemical Reaction Diagram]

DERA is employed to carry out laboratory syntheses of crossed aldol products in which both 100% stereoselectivity and 100% selectivity in the roles of the components are observed. An example is its catalysis of the condensation of propanal with (2R)-3-azido-2-hydroxypropanal. The condensation proceeds in only one of the four possible ways, via reaction of the α-carbon of propanal with the carbonyl carbon of the substituted aldehyde. In addition, the two new stereocenters are formed in single configurations: R at the new C2, and S at C3. This particular application is significant, because the azido group is readily reduced to an amino (NH₂) group, and the resulting compound is a member of a class of highly biologically active compounds called amino sugars. This class includes both antibiotics and anticancer agents (Section 24-12), as well as drugs with antihypertensive activity.

![Chemical Reaction Diagram]

3. Acetaldehyde enolate adds to acetaldehyde.

![Chemical Reaction Diagram]

4. Propanal enolate adds to propanal.

![Chemical Reaction Diagram]

Can we ever efficiently synthesize a single aldol product from the reaction of two different aldehydes? We can, when one of the aldehydes has no enolizable hydrogens, because two of the four possible condensation products cannot form. We add the enolizable aldehyde slowly to an excess of the nonenolizable reactant in the presence of base. As soon as the enolate of the addend is generated, it is trapped by the other aldehyde.
Exercise 18-18

Show the likely products of the following aldol condensations.

(a) \( \text{CHO} + \text{CH}_3\text{CHO} \)  
(b) 2 \( \text{CHO} \) (reacts with itself)  
(c) \( \text{CH}_2=\text{CHCHO} + \text{CH}_3\text{CHO} \)

In Summary

Crossed aldol condensations furnish product mixtures unless one of the reaction partners cannot enolize.

18-7 Intramolecular Aldol Condensation

It is possible to carry out aldol condensations between two carbonyl groups located in the same molecule. Such a reaction is called an intramolecular aldol condensation and is important in the synthesis of cyclic compounds, especially five- and six-membered rings.

For example, heating a dilute solution of hexanedial with aqueous base results in the formation of the cyclic product 1-cyclopentene carbaldehyde. Here, one end of the molecule functions as the nucleophilic enolate component (after deprotonation), the other as the electrophilic carbonyl partner. After the initial aldol addition, subsequent dehydration furnishes the product.

Why does the intramolecular aldol condensation take place in preference to the intermolecular alternative? For one, attack at the carbonyl carbon of a different molecule is minimized by high dilution of the dialdehyde in the reaction mixture. More important, however, intermolecular reactions must overcome the loss of entropy arising from the conversion of two molecules into one as the initial hydroxyaldehyde product forms. In contrast, their intramolecular variant merely converts the acyclic substrate into a cyclic one, a process that costs much less in entropic terms and therefore is more favorable both kinetically (Section 9-6) and thermodynamically (Section 17-8).

The entropic advantages of intramolecularity are particularly noticeable in intramolecular ketone condensations, transformations that provide a ready source of cyclic and bicyclic \( \alpha,\beta \)-unsaturated ketones. Since ketones can have two enolizable \( \alpha \)-carbons, in principle,
several aldol products may be possible. However, the reversibility of the reaction ensures that usually the least strained ring is generated, typically one that is five or six membered. Thus, reaction of 2,5-hexanone results in condensation between an enolate at C1 and the C5 carbonyl group. An alternative pathway, attack of a C3 enolate on C5 to give a strained three-membered ring, is not observed.

Intramolecular Aldol Condensation of a Dione

Vitamin A (retinol, see Section 14-7 and the Chapter Opening) is an important nutritional factor in vision. Enzyme-catalyzed oxidation converts it into trans-retinal. Trans-retinal is present in the light-receptor cells of the human eye, but before it can fulfill its biological function, it has to be isomerized by an enzyme, retinal isomerase, to give cis-retinal. Cis-retinal behaves like a “loaded spring” by virtue of the steric hindrance associated with the cis double bond (Section 11-5). The molecule fits well into the active site of a protein called opsins (approximate molecular weight 38,000). As shown on the facing page, cis-retinal reacts with one of the amine substituents of opsin to form the imine, rhodopsin, the light-sensitive chemical unit in the eye. The electronic spectrum of rhodopsin, with a $\lambda_{\text{max}}$ at 506 nm ($\epsilon = 40,000$), indicates the presence of a protonated imine group.

When a photon strikes rhodopsin, the cis-retinal part isomerizes extremely rapidly, in only picoseconds ($10^{-12}$ s), to the trans isomer. This isomerization induces a geometric change, which appears to severely disrupt the snug fit of the original molecule in the protein cavity. Within nanoseconds ($10^{-9}$ s), a series of new intermediates form from this photo-product, accompanied by conformational changes in the protein structure, followed by eventual hydrolysis of the ill-fitting retinal unit. This sequence initiates a nerve impulse perceived by us as light. The trans-retinal is then reisomerized to the cis form by retinal isomerase and re-forms rhodopsin, ready for another photon. What is extraordinary about this mechanism is its sensitivity, which allows the eye to register as little as one photon impinging on the retina.

Studies using nerve cells have shown that the geometric change brought about by isomerization of rhodopsin-bound retinal physically opens a “pore” in a special kind of protein called an ion channel, which is located in the cell membrane. Positively charged ions flow through the open pore into the cell, constituting an electrical current. The difference between this process and that of vision is that the geometric change in rhodopsin does not directly open the ion-channel pore in visual system cells. Rather, the dissociation of trans-retinal from rhodopsin causes the activation of a substance called G protein, discovered by Gilman* and Rodbell.† G protein is bound to the inner surface of the cell membrane and, upon activation, opens the ion channel to initiate the electrical signal of a nerve impulse.

*Professor Alfred G. Gilman (b. 1941), University of Texas Southwestern Medical School, Nobel Prize 1994 (physiology or medicine).† Dr. Martin Rodbell (1925–1998), National Institutes of Health, Nobel Prize 1994 (physiology or medicine).
Exercise 18-19

Predict the outcome of intramolecular aldol condensations of the following compounds.

(a) Cyclodecane-1,5-dione
(b) C₆H₅C(CH₂)₂CCH₃
(c) CH₂C(CH₂)₃CH₃
(d) 2,7-Octanediione

Exercise 18-20

The intramolecular aldol condensation of 2-(3-oxobutyl)cyclohexanone (margin) can, in principle, lead to four different compounds (ignoring stereochemistry). Draw them and suggest which one would be the most likely to form. (Hint: Build models!)
In Summary Intramolecular aldol condensation succeeds with both aldehydes and ketones. It can be highly regioselective and gives the least strained cycloalkenones.

18-8 Properties of \( \alpha,\beta \)-Unsaturated Aldehydes and Ketones

We have seen that the products of aldol condensation are \( \alpha,\beta \)-unsaturated aldehydes and ketones. How do the properties of \( \alpha,\beta \)-unsaturated aldehydes and ketones compare with the individual characteristics of their two types of double bonds? We shall find that their chemistry in some situations is a simple composite of the two and under other circumstances involves the \( \alpha,\beta \)-unsaturated carbonyl, or enone, functional group as a whole. As later chapters will indicate, this complex reactivity is quite typical of molecules with two functional groups, or difunctional compounds.

Conjugated unsaturated aldehydes and ketones are more stable than their unconjugated isomers

Like conjugated dienes (Section 14-5), \( \alpha,\beta \)-unsaturated aldehydes and ketones are stabilized by resonance, resulting in the delocalization of the partial positive charge on the carbonyl carbon. As a consequence, and as shown in the electrostatic potential map of 2-butenal in the margin, the double bond is relatively electron poor (green, not red; compare Section 12-3), and the \( \beta \)-carbon is electrophilic (blue).

Resonance Forms of 2-Butenal

Thus, unconjugated \( \beta,\gamma \)-unsaturated carbonyl compounds rearrange readily to their conjugated isomers. The carbon–carbon double bond is said to “move into conjugation” with the carbonyl group, as the following example shows.

Isomerization of a \( \beta,\gamma \)-Unsaturated Carbonyl Compound to a Conjugated System

The isomerization can be acid or base catalyzed. In the base-catalyzed reaction, the intermediate is the conjugated dienolate ion, which is reprotonated at the carbon terminus.
**α,β-Unsaturated aldehydes and ketones undergo the reactions typical of their component functional groups**

α,β-Unsaturated aldehydes and ketones undergo many reactions that are perfectly predictable from the known chemistry of the carbon–carbon and carbon–oxygen double bonds. For example, hydrogenation by palladium on carbon gives the saturated carbonyl compound.

\[ \text{H}_2, \text{Pd–C}, \text{CH}_3\text{CO}_2\text{CH}_2\text{CH}_3 \text{ (ethyl acetate solvent)} \rightarrow \text{95%} \]

The carbon–carbon \( \pi \) system also undergoes electrophilic additions. For example, bromination furnishes a dibromocarbonyl compound (compare Section 12-5).

\[ \text{O} \text{CH}_3\text{CH=CHCCH}_3 \rightarrow \text{Br} \text{CH}_3\text{CHCHCHCH}_3 \text{ (Br–Br, CCl}_4 \text{, 60%)} \]

**Exercise 18-22**

Propose a mechanism for the acid-catalyzed isomerization of 3-butenal to 2-butenal. (**Hint:** An intermediate is 1,3-butadien-1-ol.)

**Exercise 18-23**

Propose a synthesis of 3-phenyl-2-methyl-1-propanol starting from propanal.
In Summary $\alpha,\beta$-unsaturated aldehydes and ketones are more stable than their nonconjugated counterparts. Either base or acid catalyzes interconversion of the isomeric systems. Reactions typical of alkenes and carbonyl compounds are also characteristic of $\alpha,\beta$-unsaturated aldehydes and ketones.

18-9 Conjugate Additions to $\alpha,\beta$-Unsaturated Aldehydes and Ketones

We now show how the conjugated carbonyl group of $\alpha,\beta$-unsaturated aldehydes and ketones can enter into reactions that involve the entire functional system. These reactions are 1,4-additions of the type encountered with conjugated dienes, such as 1,3-butadiene (Section 14-6). The reactions proceed by acid-catalyzed, radical, or nucleophilic addition mechanisms, depending on the reagents.

The entire conjugated system takes part in 1,4-additions

Addition reactions in which only one of the $\pi$ bonds of a conjugated system takes part are classified as 1,2-additions (compare Section 14-6). Examples are the additions of Br$_2$ to the carbon–carbon double bond and NH$_2$OH to the carbon–oxygen double bond of $\alpha,\beta$-unsaturated aldehydes and ketones (Section 18-8).

However, several reagents add to the conjugated $\pi$ system in a 1,4-manner, a result also called conjugate addition. In these transformations, the nucleophilic part of a reagent attaches itself to the $\beta$-carbon, and the electrophilic part (most commonly, a proton) binds to the carbonyl oxygen. As the resonance forms and the resonance hybrid below illustrate, the $\beta$-carbon in an $\alpha,\beta$-unsaturated carbonyl compound possesses a partial positive charge and is therefore a second electrophilic site in these molecules, in addition to the carbonyl carbon itself (recall Section 17-2). Addition of nucleophiles to the $\beta$-carbon is therefore not a surprising process.

The initial product of conjugate addition to an $\alpha,\beta$-unsaturated carbonyl compound is an enol, which subsequently rapidly tautomerizes to its keto form. Thus the end result appears to be that of 1,2-addition of Nu–H to the carbon–carbon double bond.
Oxygen and nitrogen nucleophiles undergo conjugate additions

Water, alcohols, amines, and similar nucleophiles undergo 1,4-additions, as the following examples (hydration and amination) show. Although these reactions can be catalyzed by acid or base, the products are usually formed faster and in higher yields with base. These processes are readily reversed at elevated temperatures.

What determines whether 1,2- or 1,4-additions will take place? With the nucleophiles shown, both processes are reversible. Usually the 1,4-products form because they are carbonyl compounds and are more stable than the species arising from 1,2-addition (hydrates, hemiacetals, and hemiaminals, Sections 17-6, 17-7, and 17-9). Exceptions include amine derivatives such as hydroxylamine, semicarbazide, or the hydrazines, for which 1,2-addition eventually leads to an imine product whose precipitation out of solution drives the equilibrium.

The mechanism of the base-catalyzed addition to conjugated aldehydes and ketones is direct nucleophilic attack at the β-carbon to give the enolate ion, which is subsequently protonated.

**Mechanism of Base-Catalyzed Hydration of α,β-Unsaturated Aldehydes and Ketones**

Exercise 18-24

Treatment of 3-chloro-2-cyclohexenone with sodium methoxide in methanol gives 3-methoxy-2-cyclohexenone. Write the mechanism of this reaction. (Hint: Start with a conjugate addition.)

The ability to form new bonds with nucleophiles at the β carbon makes α,β-unsaturated aldehydes and ketones extremely useful in synthesis. This ability extends to carbon nucleophiles, permitting the construction of new carbon–carbon bonds. The remainder of the chapter illustrates processes of this type.
Hydrogen cyanide also undergoes conjugate addition

Treatment of a conjugated aldehyde or ketone with cyanide in the presence of acid may result in attack by cyanide at the $\beta$-carbon, in contrast with cyanohydrin formation (Section 17-11). This transformation proceeds through a 1,4-addition pathway. The reaction includes protonation of the oxygen, then nucleophilic $\beta$-attack, and finally enol–keto tautomerization.

**Exercise 18-25**

Formulate the mechanism of the acid-catalyzed 1,4-addition of cyanide to 1-phenylpropenone (see margin).

In Summary $\alpha,\beta$-Unsaturated aldehydes and ketones are synthetically useful building blocks in organic synthesis because of their ability to undergo 1,4-additions. Hydrogen cyanide addition leads to $\beta$-cyano carbonyl compounds; oxygen and nitrogen nucleophiles also can add to the $\beta$-carbon.

**18-10 1,2- and 1,4-Additions of Organometallic Reagents**

Organometallic reagents may add to the $\alpha,\beta$-unsaturated carbonyl function in either 1,2- or 1,4-fashion. Organolithium reagents, for example, react almost exclusively by direct nucleophilic attack at the carbonyl carbon.

**Exclusive 1,2-Addition of an Organolithium**

Reactions of Grignard reagents with $\alpha,\beta$-unsaturated aldehydes and ketones are not generally very useful, because Grignards may give 1,2-addition, 1,4-addition, or both, depending on the structures of the reacting species and conditions. Fortunately, another type of organometallic reagent, an organocuprate, is very effective in giving rise only to products of conjugate addition. *Organocuprates* have the empirical formula $R_2CuLi$, and they may be prepared by adding two equivalents of an organolithium reagent to one of copper(I) iodide, CuI.

**Example of Preparation of an Organocuprate**

$$2 \text{CH}_3\text{Li} + \text{CuI} \rightarrow (\text{CH}_3)\text{CuLi} + \text{LiI}$$

*Lithium dimethylcuprate*

(An organocuprate reagent)

Organocuprates are highly selective in undergoing 1,4-addition reactions:

**Exclusive 1,4-Addition of a Lithium Organocuprate**

The copper-mediated 1,4-addition reactions are thought to proceed through complex electron-transfer mechanisms. The first isolable intermediate is an enolate ion, which can be
trapped by alkylating species, as shown in Section 18-4. Conjugate addition followed by alkylation constitutes a useful sequence for $\alpha,\beta$-dialkylation of unsaturated aldehydes and ketones.

### $\alpha,\beta$-Dialkylation of Unsaturated Carbonyl Compounds

The following example illustrates this reaction.

### Exercise 18-26

**Working with the Concepts: Conjugate Addition in Synthesis**

Show how you might synthesize \( CH_3O \) from 3-methyl-2-cyclohexenone.

**Strategy**

The fact that your starting material is an $\alpha,\beta$-unsaturated ketone and your product has an additional bond to its $\beta$-carbon makes conjugate addition a reasonable place to start. However, for this problem, retrosynthetic analysis (working backward) is especially useful. The presence of an additional ring should suggest an intramolecular aldol condensation as a synthetic possibility. Analyze retrosynthetically first; then proceed in the forward direction.

**Solution**

- In the target molecule (below, left), consider the $C=\!\!C$ double bond of the $\alpha,\beta$-unsaturated ketone (arrow) to be the result of an intramolecular aldol condensation between the $\alpha$-carbon of a cyclohexanone and a side-chain aldehyde function (center structure).
- Consider the bond connecting this side chain to the $\beta$-carbon of the cyclohexanone (center, arrow) as deriving from a conjugate addition to 3-methyl-2-cyclohexenone, the specified starting material:

\[
\begin{align*}
\text{Target molecule} & \quad \Rightarrow \quad \text{Ketoaldehyde} & \quad \Rightarrow \quad \text{3-Methyl-2-cyclohexenone} \\
\text{CH}_3 & \quad \Rightarrow \quad \text{CH}_3 & \quad \Rightarrow \quad \text{CH}_3
\end{align*}
\]

- Before translating this retrosynthetic analysis into a synthesis in the forward direction, notice that the side chain, which we intend to use as a nucleophile for 1,4-addition, will have to be introduced as an organocuprate reagent, which in turn has to come from a halide via an organolithium species. However, it also contains a carbonyl function, which will need to be protected, so that the organolithium reagent can be prepared successfully (recall Section 17-8):
The synthesis is completed by addition of the cuprate to the cyclohexenone, hydrolysis of the acetal to free the aldehyde group, and intramolecular aldol condensation:

\[
\text{CH}_3\text{O} + \text{LiCu(O)}\text{H}_2 \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{CH}_3\text{O} + \text{H}_2\text{O} \xrightarrow{\text{OH}, \text{H}_2\text{O}, \Delta} \text{CH}_3
\]

**Exercise 18-27**

**Try It Yourself**

Design a synthesis of \(\text{CH}_3\text{O}\) from 3-methyl-2-cyclohexenone.

**In Summary** Organolithium reagents add 1,2 and organocuprate reagents add 1,4 to \(\alpha,\beta\)-unsaturated carbonyl systems. The 1,4-addition process initially gives rise to a \(\beta\)-substituted enolate, which upon exposure to haloalkanes furnishes \(\alpha,\beta\)-dialkylated aldehydes and ketones.

**18-11 Conjugate Additions of Enolate Ions: Michael Addition and Robinson Annulation**

Like other nucleophiles, enolate ions undergo conjugate additions to \(\alpha,\beta\)-unsaturated aldehydes and ketones, in a reaction known as the **Michael** addition.

**Michael Addition**

\[
\text{CH}_3\text{O} + \text{CH}_2=\text{CHCC}_6\text{H}_5 \xrightarrow{\text{CH}_3\text{CH}_2\text{O} \cdot \text{K}^-, \text{CH}_3\text{CH}_2\text{OH}, \text{(CH}_3\text{CH}_2)_2\text{O}} \text{CH}_2\text{CH}_2\text{CC}_6\text{H}_5
\]

64%

The mechanism of the Michael addition includes nucleophilic attack by the enolate ion on the \(\beta\)-carbon of the unsaturated carbonyl compound (the Michael “acceptor”), followed by protonation of the resulting enolate.

**Mechanism of the Michael Addition: 1,4-Addition of an Enolate**

*Professor Arthur Michael (1853–1942), Harvard University, Cambridge, MA.*
As the mechanism indicates, the reaction works because of the nucleophilic potential of the α-carbon of an enolate and the electrophilic reactivity of the β-carbon of an α,β-unsaturated carbonyl compound.

With some Michael acceptors, such as 3-buten-2-one, the products of the initial addition are capable of a subsequent intramolecular aldol condensation, which creates a new ring.

Tomb of the composer and chemist Alexander Borodin in St. Petersburg, Russia.
The synthetic sequence of a Michael addition followed by an intramolecular aldol condensation is also called a **Robinson® annulation**.

The Robinson annulation has found extensive use in the synthesis of polycyclic ring systems, including steroids and other natural products containing six-membered rings.

**Exercise 18-28**

**Working with the Concepts: Using Michael and Robinson Reactions in Synthesis**

Propose a synthesis of \( \text{C}_6\text{H}_5\text{O} \) using Michael or Robinson reactions.

**Strategy**

Use retrosynthetic analysis to identify reasonable starting materials. **(Hint: Always make your first “disconnection” at the C=C double bond in the \( \alpha,\beta \)-unsaturated ketone. Then proceed in a forward direction, following the steps presented in this section.)**

**Solution**

- The C=C double bond in an \( \alpha,\beta \)-unsaturated ketone may be formed from an aldol condensation. Therefore, we begin with its “disconnection” to identify a compound that can be converted to the desired final product. Break the bond, and place a carbonyl group ("\( \equiv\text{O} \)") at the former \( \beta \)-carbon. Why? In the forward direction, aldol condensation converts the carbonyl group in the starting compound into the \( \beta \)-carbon of the product. The result of this disconnection is the ketoaldehyde below:

- This compound is an example of a “1,5-dicarbonyl” compound: If you begin counting at either one of the two carbonyl carbons, the other one is the fifth atom away. This type of structure may be prepared by Michael addition of an enolate to an \( \alpha,\beta \)-unsaturated compound. We identify possible starting materials retrosynthetically, by “disconnecting” at either \( \alpha-\beta \) bond between the carbonyl carbons. There are two possible disconnections:

---

• We have two options from which to choose: Michael addition of the enolate of acetone to 2-
phenylpropenal (above, left), and Michael addition of the enolate of 2-phenylacetaldehyde to 3-
buten-2-one (above, right). Which is better? Michael additions are normally carried out under basic
conditions, and we know (Section 18-5) that aldehydes undergo aldol condensation with base much
more readily than do simple ketones. Thus, the second option above risks interference from the
aldol reaction between two molecules of 2-phenylacetaldehyde. The first option is better because
the enolate of acetone will undergo Michael addition to the aldehyde much more easily than aldol
condensation with itself. Thus, we have all the pieces we need to put the synthesis together in the
forward direction—it is a Robinson annulation:

\[
\begin{align*}
\text{First Possible Disconnection} & \quad \text{Second Possible Disconnection} \\
\text{C}_6\text{H}_5\text{CH}_3 & \quad \text{O} \\
\text{H}_3\text{C} & \quad \text{H}_3\text{C} \\
\text{O} & \quad \text{H} \\
\text{H}_3\text{C} & \quad \text{H}_2\text{C} \\
\text{O} & \quad \text{H}_2\text{C} \\
\text{O} & \quad \text{H}_2\text{C} \\
\text{C}_6\text{H}_5 & \quad \text{C}_6\text{H}_5 \\
\end{align*}
\]

In Summary The Michael addition results in the conjugate addition of an enolate ion to
give dicarbonyl compounds. The Robinson annulation reaction combines a Michael addition
with a subsequent intramolecular aldol condensation to produce new cyclic enones.

THE BIG PICTURE

The aldol condensation and the synthetic sequences that can be built around it provide us with
powerful methods for synthesizing complex organic molecules. These reactions provide ways
to form carbon–carbon bonds at three sites: the α-, the β-, and the carbonyl carbons. We can
construct elaborate acyclic compounds using these processes, and we can also close rings. In
the problems that follow, take note of the remarkable variety of compounds that can be formed
just using the chemical properties of the carbonyl group and its adjacent atoms.

Continuing our survey of carbonyl chemistry, we turn next to the carboxylic acids, to
see how these more highly oxidized systems compare. The principle of enhanced acidity
for hydrogens attached to atoms adjacent to a carbonyl carbon is illustrated by the acidity

Exercise 18-29

Try It Yourself

Propose syntheses of the following compounds by Michael or Robinson reactions.

(a)  
(b)  

In Summary The Michael addition results in the conjugate addition of an enolate ion to
give dicarbonyl compounds. The Robinson annulation reaction combines a Michael addition
with a subsequent intramolecular aldol condensation to produce new cyclic enones.
of the O–H hydrogen in these compounds. In addition, the OH portion of the carboxylic acid function is a potential leaving group. The next chapter presents a new method by which substitution reactions can occur, one that is central to the chemistry of all compounds in the carboxylic acid family: the addition–elimination pathway.

CHAPTER INTEGRATION PROBLEMS

18-30. Propose as many syntheses as you can of the bicyclic ketone in the margin, using at least one aldol condensation in each. You may use any starting materials you like.

SOLUTION

To approach this problem, it is useful to evaluate the information we have been given. The target compound is a saturated ketone, but aldol condensations give rise to \(\alpha,\beta\)-unsaturated carbonyl compounds. Therefore, we can infer that any synthesis we develop must finish with hydrogenation of a C=C double bond in conjugation with the carbonyl group. Based on the target structure, three \(\alpha,\beta\)-unsaturated ketones can be identified as possible precursors.

Having identified these three structures, we can proceed to formulate the compounds that, upon undergoing intramolecular aldol condensation, will produce each one. Retrosynthetically, disconnect each C=C double bond; each disconnected \(\beta\)-carbon derives from a carbonyl group. That gives the following structures, shown in the same left-to-right order as their corresponding aldol enone products above.

All that remains is to complete the syntheses in the forward direction, including necessary reagents. We do so below for the first of these three starting compounds; the other two can be completed in exactly the same way.

18-31. The Robinson annulation sequence is a powerful method for the construction of six-membered rings. It is therefore no surprise that this sequence has been widely applied in steroid synthesis. Beginning with the bicyclic ketone shown in the margin, propose a synthesis that makes use of one or more Robinson annihilations for the steroid shown here.
SOLUTION

The Robinson annulation combines Michael addition to an $\alpha,\beta$-unsaturated ketone with intramolecular aldol condensation (Section 18-11) to afford a cyclohexenone. Retrosynthetic analysis (Section 8-9) of the target molecule leads to the disconnection of two bonds in ring A: the carbon–carbon double bond, by a retro-aldol condensation, and a single bond by a retro-Michael addition. The Robinson annulation for the construction of ring A is closely related to the example in Section 18-11, which condenses 2-methylcyclohexanone with 3-buten-2-one.

At this stage, we have simplified the target from a tetracyclic to a tricyclic molecule. However, the latter is a $\beta,\gamma$-unsaturated ketone, not an obvious product of Robinson annulation for the formation of ring B. Postponing consideration of this problem for the moment, can we formulate a Robinson annulation that transforms the initial ketone into a tricyclic product with the same molecular skeleton as that of the product of the last reaction? Yes we can: In fact, we can construct a double-bond isomer:

We are quite close to a complete solution. All that remains is to connect the tricyclic ketone that we have just prepared with the necessary second Robinson sequence. To do so, we think mechanistically, asking ourselves, “What is the structure of the enolate needed to initiate the annulation?” It is shown at the right in the following reaction, and we note that it is an allylic enolate ion (Section 14-4), for which we can write a second resonance contributor. It therefore may be derived by deprotonation of the tricyclic ketone in the preceding reaction at the allylic ($\gamma$) position.

What does this realization mean in practical terms? We can carry out the needed second Robinson annulation starting directly from the preceding $\alpha,\beta$-unsaturated ketone; it is not necessary to first prepare the $\beta,\gamma$-unsaturated ketone revealed in our initial retrosynthetic disconnection, because they give the same enolate upon deprotonation. The complete synthesis is shown on the following page.
A final note: You may have recognized that the allylic anion discussed above is also benzylic and hence enjoys additional resonance stabilization by conjugation with the benzene ring. Benzylic resonance will be discussed in detail in Section 22-1. For more practice with Robinson annulations, go to Problems 59, 63, and 64.

**New Reactions**

**Synthesis and Reactions of Enolates and Enols**

1. Enolate Ions (Section 18-1)

   $$\text{RCH}_2\text{CR}' \xrightarrow{\text{LDA or KH or (CH}_3\text{)CO}^+\text{K}^-\text{ or other strong base, } -78^\circ\text{C}} \text{RCH}==\text{C}^-\text{R}'$$

   Enolate ion

2. Keto–Enol Equilibria (Section 18-2)

   $$\text{RCH}_2\text{CR}' \xrightarrow{\text{Catalytic H}^-\text{ or HO}^-\text{}} \text{Tautomerism} \text{RCH}==\text{C}^-\text{OH}$$

3. Hydrogen–Deuterium Exchange (Section 18-2)

   $$\text{RCH}_2\text{CR}' \xrightarrow{\text{D}_2\text{O, DO}^-\text{ or D}^-} \text{RCD}_2\text{CR}'$$

4. Stereoisomerization (Section 18-2)

   $$\text{RCH}_2\text{CR}' \xrightarrow{\text{H}^-\text{ or HO}^-} \text{RCH}==\text{C}^-\text{R}'$$

5. Halogenation (Section 18-3)

   $$\text{RCH}_2\text{CR}' \xrightarrow{\text{X}_2, \text{H}^-} \text{RCHCR}'$$
6. Enolate Alkylation (Section 18-4)

\[
\begin{align*}
RCH = C & \xrightarrow{\text{O}^-} RCHCR' \\
& \xrightarrow{R'X} RCHCR' \\
& \xrightarrow{-X^\text{R}} \\
& \xrightarrow{R^\text{R'}} R''
\end{align*}
\]

S$_2$2 reaction: R’X must be methyl or primary halide

7. Enamine Alkylation (Section 18-4)

\[
\begin{align*}
\text{SN2 reaction: } R'X & \text{ must be methyl, primary, or secondary halide}
\end{align*}
\]

8. Aldol Condensations (Sections 18-5 through 18-7)

\[
\begin{align*}
\text{condensation product: } RCHCHCH \xrightarrow{\text{H}^+, \text{H}_2\text{O}} & \text{RCH} \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{RCHCHCH}
\end{align*}
\]

Crossed aldol condensation (one aldehyde not enolizable)

\[
\begin{align*}
\text{condensation product: } RCH & \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{RCHCHCH}
\end{align*}
\]

Ketones

\[
\begin{align*}
\text{drive equilibrium: } RCHCHCH & \xrightarrow{\Delta, \text{H}_2\text{O}} \text{RCHCHCH}
\end{align*}
\]

Intramolecular aldol condensation

Unstrained rings preferred

Reactions of $\alpha,\beta$-unsaturated Aldehydes and Ketones

9. Hydrogenation (Section 18-8)

\[
\begin{align*}
\text{H}_2, \text{Pd, CH}_3\text{CH}_2\text{OH} & \xrightarrow{\text{H}^+, \text{H}_2\text{O}} \text{RCHCHCH}
\end{align*}
\]
10. Addition of Halogen (Section 18-8)

\[
\begin{align*}
\text{C} &= \text{C} \\
\text{X} &\xrightarrow{\text{X}_2, \text{CCl}_4} \text{C} \text{C} \text{C} \\
\text{X} &\text{X}
\end{align*}
\]

11. Condensations with Amine Derivatives (Section 18-8)

\[
\begin{align*}
\text{C} &= \text{C} \\
\text{Z} &\xrightarrow{\text{ZNH}_2} \text{C} \text{C} \text{C} \\
\end{align*}
\]

Conjugate Additions to \(\alpha,\beta\)-Unsaturated Aldehydes and Ketones

12. Hydrogen Cyanide Addition (Section 18-9)

\[
\begin{align*}
\text{C} &= \text{C} \\
\text{CN} &\xrightarrow{\text{KCN}, \text{H}^+} \text{C} \text{C} \text{C} \\
\text{CN} &\text{H}
\end{align*}
\]

13. Water, Alcohols, Amines (Section 18-9)

\[
\begin{align*}
\text{C} &= \text{C} \\
\text{OH} &\xrightarrow{\text{H}_2\text{O}} \text{C} \text{C} \text{C} \\
\text{OR} &\xrightarrow{\text{ROH}} \text{C} \text{C} \text{C} \\
\text{RNH} &\xrightarrow{\text{RNH}_2} \text{C} \text{C} \text{C}
\end{align*}
\]

14. Organometallic Reagents (Section 18-10)

\[
\begin{align*}
\text{C} &= \text{C} \\
\text{R} &\xrightarrow{1. \text{RLi}, (\text{CH}_3\text{CH}_2)_2\text{O}, 2. \text{H}^+, \text{H}_2\text{O}} \text{C} \text{C} \text{C} \\
\end{align*}
\]

Additions of RMgX may be 1,2 or 1,4, depending on reagent and substrate structure.
Cuprate additions followed by enolate alkylations

1. \( \text{R}_2\text{CuLi}, \text{THF} \)
2. \( \text{R}/\text{H} \rightarrow \text{X} \)

\( \begin{array}{c}
\text{C}=\text{C} \quad \text{1. R}_2\text{CuLi, THF} \\
\text{1. } \text{R}_2\text{CuLi, THF} \\
\text{2. R}/\text{H} \rightarrow \text{X} \\
\end{array} \)

15. Michael Addition (Section 18-11)

\( \begin{array}{c}
\text{O} \quad \text{C}=\text{C} \quad \text{O} \\
\text{O} \quad \text{C}=\text{C} \quad \text{R} \quad \text{RC} \quad \text{CR} \quad \text{H} \\
\text{R} \quad \text{R} \quad \text{R} \quad \text{R} \quad \text{R} \quad \text{R} \\
\end{array} \)

16. Robinson Annulation (Section 18-11)

Important Concepts

1. Hydrogens next to the carbonyl group (\( \alpha \)-hydrogens) are acidic because of the electron-withdrawing nature of the functional group and because the resulting enolate ion is resonance stabilized.

2. Electrophilic attack on enolates can occur at both the \( \alpha \)-carbon and the oxygen. Haloalkanes usually prefer the \( \alpha \)-carbon. Protonation of the oxygen leads to enols.

3. Enamines are neutral analogs of enolates. Resonance donation of the nitrogen lone pair imparts nucleophilic character on the remote double bond carbon, which can be alkylated to give iminium cations that hydrolyze to aldehydes and ketones on aqueous work-up.

4. Aldehydes and ketones are in equilibrium with their tautomeric enol forms; the enol–keto conversion is catalyzed by acid or base. This equilibrium allows for facile \( \alpha \)-deuteration and stereochemical equilibration.

5. \( \alpha \)-Halogenation of carbonyl compounds may be acid or base catalyzed. With acid, the enol is halogenated by attack at the double bond; subsequent renewed enolization is slowed down by the halogen substituent. With base, the enolate is attacked at carbon, and subsequent enolate formation is accelerated by the halogens introduced.

6. Enolates are nucleophilic and reversibly attack the carbonyl carbon of an aldehyde or a ketone in the aldol condensation. They also attack the \( \beta \)-carbon of an \( \alpha,\beta \)-unsaturated carbonyl compound in the Michael addition.

7. \( \alpha,\beta \)-Unsaturated aldehydes and ketones show the normal chemistry of each individual double bond, but the conjugated system may react as a whole, as revealed by the ability of these compounds to undergo acid- and base-mediated 1,4-additions. Cuprates add in 1,4-manner, whereas alkyllithiums normally attack the carbonyl function.

Problems

32. Underline the \( \alpha \)-carbons and circle the \( \alpha \)-hydrogens in each of the following structures.

(a) \( \text{CH}_3\text{CH}_2\text{CCH}_2\text{CH}_3 \)
(b) \( \text{CH}_3\text{CCH(CH}_3)_2 \)
(c) \( \text{H}_3\text{C} \quad \text{O} \quad \text{CH}_3 \)
(d) \( \text{H}_3\text{C} \quad \text{O} \quad \text{CH}_3 \)
(e) \( \text{CH}_3 \quad \text{O} \quad \text{CH}_3 \)
(f) \( \text{CHO} \)
33. Write the structures of every enol and enolate ion that can arise from each of the carbonyl compounds illustrated in Problem 32.

34. What product(s) would form if each carbonyl compound in Problem 32 were treated with (a) alkaline D₂O; (b) 1 equivalent of Br₂ in acetic acid; (c) excess Cl₂ in aqueous base?

35. Describe the experimental conditions that would be best suited for the efficient synthesis of each of the following compounds from the corresponding nonhalogenated ketone.

36. Propose a mechanism for the following reaction. (Hint: Take note of all of the products that are formed and base your answer on the mechanism for acid-catalyzed bromination of acetone shown in Section 18-3.)

37. Give the product(s) that would be expected on reaction of 3-pentanone with 1 equivalent of LDA, followed by addition of 1 equivalent of

(a) CH₃CH₂Br  (b) (CH₃)₂CHCl  (c) (CH₃)₂CHCH₂OSO₂Cl₂  (d) (CH₃)₃CCl

38. Give the product(s) of the following reaction sequences.

39. The problem of double compared with single alkylation of ketones by iodomethane and base is mentioned in Section 18-4. Write a detailed mechanism showing how some double alkylation occurs even when only one equivalent each of the iodide and base is used. Suggest a reason why the enamine alkylation procedure solves this problem.

40. Would the use of an enamine instead of an enolate improve the likelihood of successful alkylation of a ketone by a secondary haloalkane?

41. Formulate a mechanism for the acid-catalyzed hydrolysis of the pyrrolidine enamine of cyclohexanone (shown in the margin).

42. Write the structures of the aldol condensation products of (a) pentanal; (b) 3-methylbutanal; (c) cyclopentanone.

43. Write the structures of the expected major products of crossed aldol condensation at elevated temperature between excess benzaldehyde and (a) 1-phenylethanol (acetophenone—see Section 17-1 for structure); (b) acetone; (c) 2,2-dimethylcyclopentanone.

44. Formulate a detailed mechanism for the reaction that you wrote in (c) of Problem 43.
45. Give the likely products for each of the following aldol addition reactions.

(a) \[ \text{NaOH, H}_2\text{O} \]
\[
\begin{array}{c}
\text{H}_2\text{C} & \text{CHO} & \text{NaOH, H}_2\text{O} \\
\text{H}_2\text{C} & \text{CHO} & \text{NaOH, H}_2\text{O}
\end{array}
\]

(b) \[ \text{NaOH, H}_2\text{O} \]
\[
\begin{array}{c}
\text{H}_2\text{C} & \text{CHO} & \text{NaOH, H}_2\text{O} \\
\text{H}_2\text{C} & \text{CHO} & \text{NaOH, H}_2\text{O}
\end{array}
\]

(c) \[ \text{NaOH, H}_2\text{O} \]
\[
\begin{array}{c}
\text{H}_2\text{C} & \text{CHO} & \text{NaOH, H}_2\text{O} \\
\text{H}_2\text{C} & \text{CHO} & \text{NaOH, H}_2\text{O}
\end{array}
\]

46. Rotundone (margin) is the natural product responsible for the peppery aroma in peppers, many herbs, and red wines (p. 846). What cyclic diketone will give rotundone upon intramolecular aldol condensation?

47. Write all possible products of the base-catalyzed crossed aldol reactions between each pair of reaction partners given below. (Hint: Multiple products are possible in every case; be sure to include thermodynamically unfavorable as well as favorable ones.)

(a) Butanal and acetaldehyde
(b) 2,2-Dimethylpropanal and acetophenone
(c) Benzaldehyde and 2-butanone

48. For each of the three crossed aldol reactions described in Problem 47, indicate which, if any, of the multiple possible products should predominate in the reaction mixture and explain why.

49. Aldol condensations may be catalyzed by acids. Suggest a role for H\textsuperscript{+} in the acid-catalyzed version. (Hint: Consider what kind of nucleophile might exist in acidic solution, where enolate ions are unlikely to be present.)

50. Reaction review. Without consulting the Reaction Road Maps on pp. 818–819, suggest reagents to convert butanal into each of the following compounds.

(a) \[
\begin{array}{c}
\text{Cl} & \text{H} & \text{Cl} & \text{H}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{Br} & \text{H} & \text{Br} & \text{H}
\end{array}
\]

(c) \[
\begin{array}{c}
\text{H} & \text{H}
\end{array}
\]

(d) \[
\begin{array}{c}
\text{H} & \text{H}
\end{array}
\]

(e) \[
\begin{array}{c}
\text{H} & \text{H}
\end{array}
\]

(f) \[
\begin{array}{c}
\text{H} & \text{H}
\end{array}
\]

51. Reaction review II. Without consulting the Reaction Road Maps on pp. 818–819, suggest reagents to convert acetophenone into each of the following compounds.

(a) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{CCl}_3
\end{array}
\]

(c) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{OH}
\end{array}
\]

(d) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]

(e) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]

(f) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{CH}_2\text{Br}
\end{array}
\]

52. Reaction review III. Without consulting the Reaction Road Maps on pp. 818–819, suggest reagents to convert 3-buten-2-one into each of the following compounds.

(a) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]

(b) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]

(c) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]

(d) \[
\begin{array}{c}
\text{C}_6\text{H}_5 & \text{H}
\end{array}
\]
53. A number of highly conjugated organic compounds have found use as sunscreens. One of the more widely used is 4-methylbenzylidene camphor (4-MBC), whose structure is shown in the margin. This compound is effective in absorbing so-called UV-B radiation (with wavelengths between 280 and 320 nm, responsible for most sunburns). Suggest a simple synthesis of this compound using a crossed aldol condensation.

54. **Challenge** The distillate from sandalwood is one of the oldest and most highly valued fragrances in perfumery. The natural oil is in short supply and, until recently, synthetic substitutes have been difficult to prepare. Polysantol® (margin) is the most successful of these substitutes. Its synthesis in 1984 involved the aldol condensation shown below.

(a) This synthetic step, although usable, had a significant drawback that was responsible for its modest yield (60%). Identify this problem in detail.

(b) A solution that avoids conventional aldol condensation was published in 2004. A bromoketone is prepared and, upon reaction with Mg metal, gives a magnesium enolate. This enolate then reacts with the aldehyde selectively to give a hydroxyketone that may be dehydrated to the desired product. Discuss how this approach solves the problem outlined in part (a).

55. Write the expected major product of reaction of each of the carbonyl compounds (i)–(iii) with each of the reagents (a)–(h).

56. Give the expected product(s) of each of the following reactions.
Problems

57. Write the products of each of the following reactions after aqueous work-up.

(a) \( \text{C}_6\text{H}_5\text{CCH}_3 + \text{CH}_2=\text{CHC}_2\text{H}_5 \stackrel{\text{LDA, THF}}{\longrightarrow} \)

(b) \( \text{C}_6\text{H}_5\text{CCH}_3 + \text{CH}_2=\text{CHC}_2\text{H}_5 \stackrel{\text{NaOH, H}_2\text{O}}{\longrightarrow} \)

(c) \( \text{H}_3\text{C}\text{CH}_3 \stackrel{1. \text{(CH}_3\text{)}_2\text{CuLi, THF}}{\longrightarrow} \)

(d) \( \text{H}_3\text{C}\text{CH}_3 \stackrel{2. \text{CH}_2=\text{CHC}_2\text{H}_5}{\longrightarrow} \)

58. Write the final products of the following reaction sequences.

(a) \( \text{CH}_3\text{CCH}_3 + \text{CH}_2=\text{CHC}_2\text{H}_5 \stackrel{\text{NaOCH}_3, \text{CH}_3\text{OH, } \Delta}{\longrightarrow} \)

(b) \( \text{CH}_3\text{CCH}_3 + \text{CH}_2=\text{CHC}_2\text{H}_5 \stackrel{\text{KOH, CH}_3\text{OH, } \Delta}{\longrightarrow} \)

(c) \( \text{CH}_3\text{CCH}_3 \stackrel{1. \text{LDA, THF}}{\longrightarrow} \)

(d) Write a detailed mechanism for reaction sequence (c). (Hint: Treat the 3-butyn-2-one reagent as a Michael acceptor in the first step.)

59. Propose syntheses of the following compounds by using Michael additions followed by aldol condensations (i.e., Robinson annulation). Each of the compounds shown has been instrumental in one or more total syntheses of steroidal hormones.

(a) \( \text{H}_3\text{C}\text{CH}_3 + \text{CO}_2\text{CH}_2\text{CH}_3 \stackrel{\text{LDA, THF}}{\longrightarrow} \)

(b) \( \text{H}_3\text{C}\text{CH}_3 + \text{CO}_2\text{CH}_2\text{CH}_3 \stackrel{\text{KOH, CH}_3\text{OH, } \Delta}{\longrightarrow} \)

(c) \( \text{CH}_3\text{CCH}_3 \stackrel{1. \text{LDA, THF}}{\longrightarrow} \)

(d) \( \text{CH}_3\text{CCH}_3 \stackrel{2. \text{HC=CCCH}_3}{\longrightarrow} \)

60. Would you expect addition of HCl to the double bond of 3-buten-2-one (shown in the margin) to follow Markovnikov’s rule? Explain your answer by a mechanistic argument.
61. Using the following information, propose structures for each of these compounds. (a) $\text{C}_5\text{H}_{10}\text{O}$, NMR spectrum A, UV $\lambda_{\text{max}}(\epsilon) = 280(18)$ nm; (b) $\text{C}_6\text{H}_8\text{O}$, NMR spectrum B, UV $\lambda_{\text{max}}(\epsilon) = 220(13,200), 310(40)$ nm; (c) $\text{C}_6\text{H}_{12}$, NMR spectrum C, UV $\lambda_{\text{max}}(\epsilon) = 189(8,000)$ nm; (d) $\text{C}_6\text{H}_2\text{O}$, NMR spectrum D, UV $\lambda_{\text{max}}(\epsilon) = 282(25)$ nm. (See the next page for spectrum D.)

Next, for each of the following reactions, name an appropriate reagent for the indicated interconversion. (The letters refer to the compounds giving rise to NMR spectra A through D.) (e) A $\rightarrow$ C; (f) B $\rightarrow$ D; (g) B $\rightarrow$ A.
62. **CHALLENGE**  Treatment of cyclopentane-1,3-dione with iodomethane in the presence of base leads mainly to a mixture of three products.

\[
\begin{align*}
\text{NaOH, CH₃I, CH₃CH₂OH} & \rightarrow \text{A} + \text{B} + \text{C}
\end{align*}
\]

(a) Give a mechanistic description of how these three products are formed.
(b) Reaction of product C with a cuprate reagent results in loss of the methoxy group. For example,

\[
\begin{align*}
\text{C} & \xrightarrow{1. \text{(CH₃CH₂CH₂CH₂)₂CuLi, THF}} \xrightarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{D}
\end{align*}
\]

Suggest a mechanism for this reaction, which is another synthetic route to enones substituted at the β-carbon. **(Hint:** See Exercise 18-24.)

63. **CHALLENGE**  A somewhat unusual synthesis of cortisone-related steroids includes the following two reactions.
64. The following steroid synthesis contains modified versions of two key types of reactions presented in this chapter. Identify these reaction types and give detailed mechanisms for each of the transformations shown.

(a) Propose mechanisms for these two transformations. Be careful in choosing the initial site of deprotonation in the starting enone. The alkenyl hydrogen, in particular, is not acidic enough to be the one initially removed by base in this reaction.

(b) Propose a sequence of reactions that will connect the carbons marked by arrows in the third structure shown to form another six-membered ring.

65. Devise reasonable plans for carrying out the following syntheses. Ignore stereochemistry in your strategies.

(a) , starting from cyclohexanone

(b) , starting from 2-cyclohexenone (Hint: Prepare in your first step.)
66. Write reagents (a, b, c, d, e) where they have been omitted from the following synthetic sequence. Each letter may correspond to one or more reaction steps. This sequence is the beginning of a synthesis of germanicol, a naturally occurring triterpene. The diol used in the step between (a) and (b) provides selective protection of the more reactive carbonyl group. [Hint: See Problem 63 when formulating (b).]

![Chemical structures](image)

**Team Problem**

67. When 2-methylcyclopentanone is treated with the bulky base triphenylmethyl lithium under the two sets of conditions shown, the two possible enolates are generated in differing ratios. Why is this so?

![Chemical structures](image)

To tackle this problem, you have to invoke the principles of kinetic versus thermodynamic control (review Sections 11-6, 14-6, and 18-2); that is, which enolate is formed faster and which one is more stable? Divide your team so that one group considers conditions A and the other conditions B. Use curved arrows to show the flow of electrons leading to each enolate. Then assess whether your set of conditions is subject to enolate equilibration (thermodynamic control) or not (kinetic control). Reconvene to discuss these issues and draw a qualitative potential-energy diagram depicting the progress of deprotonation at the two α sites.

*An electron-transfer process (compare alkyne reduction, Section 13-6) that is the equivalent of adding hydride, H−, to the β-carbon. The product is the enolate of the saturated ketone.*
Preprofessional Problems

68. When 3-methyl-1,3-diphenyl-2-butanone is treated with excess D₂O in the presence of catalytic acid, some of its hydrogens are replaced by deuterium. How many? (a) One; (b) two; (c) three; (d) six; (e) eight.

69. How would you best classify the following reaction? (a) Wittig reaction; (b) cyanohydrin formation; (c) conjugate addition; (d) aldol addition.

\[
\begin{align*}
H_2C\equiv CHCH=NH_2 & \quad \xrightarrow{\text{HNC}^-} \quad \text{NCCH}_2\text{CH}≡\text{CHNH}_2 \\
\end{align*}
\]

70. The aqueous hydroxide-promoted reaction of the compound shown in the margin with (CH₃)₃CCHO yields exclusively one compound. Which one is it?

(a) \( \text{H}_3\text{CC-CH=CHC(CH}_3\text{)OH} \)  (b) \( \text{H}_3\text{CC-CH=CHOC(CH}_3\text{)OH} \)  
(c) \( \text{(CH}_3\text{)₃CCH=CHCH=CHCH}_3\text{)OH} \)  (d) \( \text{(CH}_3\text{)₃CCH=CH-C(CH}_3\text{)OH} \)

71. The \(^1\text{H NMR spectrum of 2,4-pentanedi} \)ne indicates the presence of an enol tautomer of the dione. What is its most likely structure?

(a) \( \text{OH} \quad \text{OH} \)  (b) \( \text{C=O} \quad \text{OH} \)  (c) \( \text{C=O} \quad \text{OH} \)  (d) \( \text{H}_3\text{C-C=C-OH} \)
What types of compounds are the end products of biological metabolism? We inhale oxygen and exhale carbon dioxide, one product of the oxidation of organic compounds (Chapter 3). **Carboxylic acids** also are major products of biochemistry occurring under oxidizing conditions and are thus widespread throughout living systems on Earth. You are probably familiar with the bottle of wine that has turned to vinegar, the result of enzymatic oxidation of ethanol to acetic acid. Carboxylic acids are characterized by the presence of the **carboxy group**, a functional group containing a hydroxy unit attached to a carbonyl carbon. This substituent is written COOH or CO₂H; both representations are used in this chapter.

Carboxylic acids not only are widely distributed in nature, they are also important industrial chemicals. For example, besides being the most important building block in the assembly of complex biological molecules, acetic acid is an industrial commodity that is produced in very large quantities.

Much of the functional behavior of carboxylic acids can be anticipated if we view them structurally as hydroxy carbonyl derivatives. Thus, the hydroxy hydrogen is acidic, the oxygens are basic and nucleophilic, and the carbonyl carbon is subject to nucleophilic attack.

In this chapter, we first introduce the system of naming carboxylic acids and then list some of their physical and spectroscopic characteristics. We then examine their acidity and basicity, two properties that are strongly influenced by the interaction between the electron-withdrawing carbonyl group and the hydroxy function. Methods for the preparation of the carboxy group are considered next, followed by a survey of its reactivity. Reactions of carboxylic acids will feature a new two-step substitution pathway, *addition–elimination*, for the replacement of the hydroxy group by other nucleophiles, such as halide, alkoxide, and amide. The chemistry of the carboxylic acid derivatives, which result from these transformations, is the subject of Chapter 20.

The carboxylic acid fexofenadine (Allegra) is a top-selling non-sedating antihistamine drug for the treatment of allergy symptoms. It contains a stereocenter, but both enantiomers are equally effective, hence it is sold as a racemate.
19-1 Naming the Carboxylic Acids

Like other organic compounds, many carboxylic acids have common names that are used frequently in the literature. These names often indicate the natural sources from which the acids were first isolated (Table 19-1). Chemical Abstracts retains the common names for the two simplest, formic and acetic acids. The carboxy function and the functional groups of its derivatives take precedence in naming over any other group discussed so far.

The overall “order of precedence” of the most common functional groups is given below. In any molecule containing more than one functional group, the group highest in precedence is entered as a suffix in the name, and all other substituents as prefixes. For example, consider HOCH₂CH₂COCH₂CHO, a molecule containing alcohol, ketone, and aldehyde functions. In its name, the first two groups appear as prefixes (hydroxy- and oxo-, respectively), while the aldehyde group, being of highest precedence, is signified by the suffix -al: This compound is 5-hydroxy-3-oxopentanal. Alkenes and alkynes are exceptions. They rank below the amines in order of precedence, but when a carbon–carbon double or triple bond is part of the parent chain or ring of a molecule, we insert -ene- or -yn- just before the suffix for the highest-ranking functional group. The following examples of names for carboxylic acids illustrate these principles.

### Table 19-1 Names and Natural Sources of Carboxylic Acids

\(^a\)Used by Chemical Abstracts.
The IUPAC system derives the names of the carboxylic acids by replacing the ending \(-e\) in the name of the alkane by \(-oic\) acid. The \textbf{alkanoic acid} stem is numbered by assigning the number 1 to the carboxy carbon and labeling any substituents along the longest chain incorporating the \(\text{CO}_2\text{H}\) group accordingly.

In multiply functionalized carboxylic acids, the main chain is chosen to include other functional groups as much as possible. Saturated cyclic acids are named as \textbf{cycloalkane-carboxylic acids}. Their aromatic counterparts are the \textbf{benzoic acids}. In these compounds, the carbon attached to the carboxy functional group is Cl.

2-Hydroxybenzoic (salicylic) acid has been known for over 2000 years as an analgesic (pain-killing) folk remedy present in willow bark (\textit{salix}, Latin, willow). The acetic acid ester of salicylic acid is better known as aspirin (Chemical Highlight 22-2).

Dicarboxylic acids are referred to as \textbf{dioic acids}.

Their common names again derive from their natural origins. For example, butanedioic (succinic) acid was discovered in the distillate from amber (\textit{succinum}, Latin, amber), and \textit{trans}-2-butenedioic (fumaric) acid is found in the plant \textit{Fumaria}, which was burned in ancient times to ward off evil spirits (\textit{fumus}, Latin, smoke).
Chapter 19
Carboxylic Acids

In Summary
The systematic naming of the carboxylic acids is based on the alkanoic acid stem. Cyclic derivatives are called cycloalkanecarboxylic acids, their aromatic counterparts are referred to as benzoic acids, and dicarboxylic systems are labeled alkanedioic acids.

19-2 Structural and Physical Properties of Carboxylic Acids

What is the structure of a typical carboxylic acid? What are the characteristic physical properties of carboxylic acids? This section answers these questions, beginning with the structure of formic acid. We shall see that carboxylic acids exist mainly as hydrogen-bonded dimers.

Formic acid is planar

The molecular structure of formic acid is shown in Figure 19-1. It is roughly planar, as expected for a hydroxy-substituted carbonyl compound, with an approximately trigonal carbonyl carbon. (Compare the structure of methanol, Figure 8-1, with that of acetaldehyde, Figure 17-2.) These structural characteristics are found in carboxylic acids in general.

The carboxy group is polar and forms hydrogen-bonded dimers

The carboxy function derives strong polarity from the carbonyl double bond and the hydroxy group, which forms hydrogen bonds to other polarized molecules, such as water, alcohols, and other carboxylic acids. Not surprisingly, therefore, the lower carboxylic acids (up to butanoic acid) are completely soluble in water. As neat liquids and even in fairly dilute solutions (in aprotic solvents), carboxylic acids exist to a large extent as hydrogen-bonded dimers, each \( O - H \cdot \cdot O \) interaction ranging in strength from about 6 to 8 kcal mol\(^{-1}\) (25 to 34 kJ mol\(^{-1}\)).

Table 19-2 shows that carboxylic acids have relatively high melting and boiling points, because they form hydrogen bonds in the solid as well as the liquid state.

Carboxylic Acids Form Dimers Readily

\[
2 \text{RCOOH} \rightarrow \text{R-C} \cdot \cdot \cdot \text{O-C-R}
\]

Two hydrogen bonds

Table 19-2 shows that carboxylic acids have relatively high melting and boiling points, because they form hydrogen bonds in the solid as well as the liquid state.

Carboxylic acids, especially those possessing relatively low molecular weights and correspondingly high volatility, exhibit characteristically strong odors. For example, the presence of butanoic acid contributes to the characteristic strong flavor of many cheeses, and \((E)-3\text{-methyl-2-hexenoic acid}\) is one of the principal compounds responsible for the smell of human sweat.

Exercise 19-1

Give systematic names or write the structure, as appropriate, of the following compounds.

(a) \( \text{Br-Cl-COOH} \)  
(b) \( \text{CH}_{2}=\text{O} \)  
(c) \( \text{CH}_{3}\text{O-NO}_{2} \)  
(d) \( 2,2\text{-Dibromohexanedioic acid} \)  
(e) \( 4\text{-Hydroxypentanoic acid} \)  
(f) \( 4\text{-}(1,1\text{-Dimethylethyl})\text{benzoic acid} \)
In Summary
The carboxy function is planar and contains a polarizable carbonyl group. Carboxylic acids exist as hydrogen-bonded dimers and exhibit unusually high melting and boiling points.

19-3 Spectroscopy and Mass Spectrometry of Carboxylic Acids
The polarizable double bond and the hydroxy group also shape the spectra of carboxylic acids. In this section, we show how both NMR and IR methods are used to characterize the carboxy group. We also illustrate how carboxylic acids fragment in the mass spectrometer.

The carboxy hydrogen and carbon are deshielded
As in aldehydes and ketones, the hydrogens positioned on the carbon next to the carbonyl group are slightly deshielded in $^1$H NMR spectra. The effect diminishes rapidly with increasing distance from the functional group. The hydroxy proton resonates at very low field ($\delta = 10-13$ ppm). As in the NMR spectra of alcohols, its chemical shift varies strongly with concentration, solvent, and temperature, because of the strong ability of the OH group to enter into hydrogen bonding. The $^1$H NMR spectrum of pentanoic acid is shown in Figure 19-2.

$^1$H NMR Chemical Shifts of Alkanoic Acids

<table>
<thead>
<tr>
<th>Derivative</th>
<th>$^1$H NMR Chemical Shifts</th>
</tr>
</thead>
<tbody>
<tr>
<td>CH$_3$COOH</td>
<td>$\delta = 2.08$ ppm</td>
</tr>
<tr>
<td>CH$_3$CH$_2$COOH</td>
<td>$\delta = 1.16$ ppm</td>

<tr>
<td>(CH$_3$)$_2$CHCOOH</td>
<td>$\delta = 1.21$ ppm</td>
</tr>
<tr>
<td>HCOOH</td>
<td>$\delta = 8.08$ ppm</td>
</tr>
</tbody>
</table>

The $^{13}$C NMR chemical shifts of carboxylic acids also are similar to those of the aldehydes and ketones, with moderately deshielded carbons next to the carbonyl group and the typically low-field carbonyl absorptions. However, the amount of deshielding is smaller because the positive polarization of the carboxy carbon is somewhat attenuated by the presence of the extra OH group.

</table>
This attenuation is best understood by writing resonance forms. Recall from Section 17-2 that aldehydes and ketones are described by two such representations. The dipolar Lewis structure indicates the polarization of the C=O bond. Even though it is a minor contributor (because of the lack of an octet on carbon), it explains the deshielding of the carbonyl carbon. In carboxylic acids, however, the corresponding dipolar form contributes less to the resonance hybrid: The hydroxy oxygen can donate an electron pair to give a third arrangement in which the carbon and both oxygen atoms have octets. The degree of positive charge on the carbonyl carbon and therefore its deshielding are greatly reduced. The changes in electron density distribution around the carbonyl function when going from acetone to acetic acid are shown in their respective electrostatic potential maps. The strongly positive polarization (blue) of the carbonyl carbon in the ketone is diminished in the acid (green).

**Resonance in Aldehydes and Ketones**

\[
\begin{array}{c}
\text{CH}_3\text{C} & \text{\equiv} & \text{O} \\
\text{H}_3\text{C} & \text{C} & \text{R} \leftrightarrow \text{H}_3\text{C} & \text{C} & \text{R}
\end{array}
\]

The contribution of the second resonance form, though minor, explains the strong deshielding of the carbonyl and adjacent carbons.

**Resonance in Carboxylic Acids**

\[
\begin{array}{c}
\text{CH}_3\text{COOH} & \text{\equiv} & \text{O} \\
\text{R} & \text{\equiv} & \text{OH}
\end{array}
\]

The third resonance form explains the attenuated deshielding of the carbonyl carbon relative to that of aldehydes and ketones.
The carboxy group shows two important IR bands

The carboxy group consists of a carbonyl group and an attached hydroxy substituent. Consequently, both characteristic stretching frequencies are seen in the infrared spectrum. The O–H bond gives rise to a very broad band at a lower wavenumber (2500–3300 cm$^{-1}$) than is observed for alcohols, largely because of strong hydrogen bonding. The IR spectrum of propanoic acid is shown in Figure 19-3.

Exercise 19-2

Working with the Concepts: Deducing the Structure of Carboxylic Acids from NMR Data

A foul-smelling carboxylic acid with b.p. 164°C gave the following NMR data: $^1$H NMR: $\delta = 1.00$ (t, $J = 7.4$ Hz, 3 H), 1.65 (sextet, $J = 7.5$ Hz, 2 H), 2.31 (t, $J = 7.4$ Hz, 2 H), and 11.68 (s, 1 H) ppm; $^{13}$C NMR: $\delta = 13.4, 18.5, 36.3,$ and 179.6 ppm. Assign a structure to it.

Strategy

A good place to start is the $^{13}$C NMR spectrum, because it gives you, in addition to confirming the presence of a carboxy carbon, the number of additional unique carbon atoms in the molecule. The $^1$H NMR spectrum will expand on that information through the number of signals (hence the number of different hydrogens), their chemical shift (hence possibly the presence of other functional groups), integration (hence the relative abundance of each type of hydrogen), and spin–spin splitting (hence the number of equivalent neighbors of the hydrogen giving rise to a particular signal).

Solution

• The $^{13}$C NMR spectrum shows a total of four signals, one of which, at $\delta = 179.6$ ppm, is due to the carboxy carbon. This leaves us with three additional peaks, all in the saturated carbon region (Section 10-9). One of them ($\delta = 36.3$ ppm) is slightly deshielded relative to the other two, likely a carbon atom next to the carboxy group.
• Turning to the $^1$H NMR spectrum, we can identify the carboxy hydrogen at $\delta = 11.68$ ppm, in addition to three additional signals. Again, all of the latter appear in the saturated region (Table 10-2), one of them ($\delta = 2.31$ ppm) slightly deshielded relative to the other two, likely attached to the carbon next to the carboxy group.
• Focusing next on the integrated values for the hydrogen signals, we note that their ratios relative to the single carboxy proton are 3 : 2 : 2. The highest-field absorption, at $\delta = 1.00$ ppm, integrates for 3 H and is likely due to the presence of a methyl group. The signal at $\delta = 2.31$ ppm, suspected to be relatively deshielded by the attached carboxy function, integrates for 2 H, pointing to the presence of a $–\text{CH}_2\text{COOH}$ substructure.
• An analysis of the splitting patterns suggests that the methyl group, a triplet, has two equivalent hydrogen neighbors, indicating the presence of $\text{CH}_3–\text{CH}_2–$. Moreover, the signal at $\delta = 2.31$ ppm is also a triplet, extending the suggested substructure above to $–\text{CH}_3\text{CH}_2\text{COOH}$.
• Putting all of this information together leads to the solution: $\text{CH}_3\text{CH}_2\text{CH}_2\text{COOH}$ (butanoic or “butyric” acid, with the smell of rancid butter). We can confirm this assignment by looking at the multiplicity of the $^1$H NMR signal for the $\text{CH}_2$ fragment flanked by $\text{CH}_3$ on one, and $\text{CH}_2$ on the other side, $\text{CH}_2\text{CH}_2\text{CH}_2\text{COOH}$. Assuming that the coupling constants in both directions will be very similar, the $(N + 1)$ rule predicts a sextet, as is indeed observed.

Exercise 19-3

Try It Yourself

Assign the structure of a carboxylic acid on the basis of the following NMR data: $^1$H NMR: $\delta = 1.20$ (d, $J = 7.5$ Hz, 6 H), 2.58 (septet, $J = 7.5$ Hz, 1 H), and 12.17 (s, 1 H) ppm; $^{13}$C NMR: $\delta = 18.7, 33.8,$ and 184.0 ppm. (Caution: The $^{13}$C NMR spectrum reveals only the number of unique carbon atoms in the molecule. Hint: The presence of a signal integrating for 6 H in the $^1$H NMR spectrum is significant. One carbon cannot be attached to six hydrogens.)
Figure 19-3 IR spectrum of propanoic acid: ν\textsubscript{O-H stretch} = 3000 cm\textsuperscript{-1}; ν\textsubscript{C=O stretch} = 1715 cm\textsuperscript{-1}. The peaks associated with these stretching vibrations are broad because of hydrogen bonding.

Mass spectra of carboxylic acids show three modes of fragmentation

The mass spectra of carboxylic acids typically show fairly weak molecular ions, because fragmentation occurs readily in several ways. In common with aldehydes and ketones, both α cleavage and McLafferty rearrangement are observed. In addition, cleavage at the C3–C4 bond occurs together with migration of an α-hydrogen to oxygen, because a resonance-stabilized carbocation results:

**Mass Spectral Fragmentation of Carboxylic Acids**

\[
\begin{align*}
\text{RCH}_2\text{CH}_2\text{CH}_2\text{C}=\text{O} & \rightarrow \text{RCH}_2\text{CH}_2\text{CH}_2\text{C}^+ = \text{m/z} = 45 \\
\text{Protonated CO}_2
\end{align*}
\]

\[
\begin{align*}
\text{RCH}_2\text{CH}=_\text{CH}_2\text{C}=\text{O} & \rightarrow \text{RCH}=_\text{CH}_2\text{C}^+ = \text{m/z} = 60 \\
\text{Acetic acid enol}
\end{align*}
\]

\[
\begin{align*}
\text{RCH}_2\text{CH}_2\text{CH}_2\text{C}^+=\text{H} & \rightarrow \text{RCH}_2\text{CH}_2\text{CH}(_\text{C}=\text{O}) = \text{m/z} = 73 \\
\text{Protonated propenoic acid}
\end{align*}
\]

Figure 19-4 shows the mass spectrum of butanoic acid.

**Exercise 19-4**

Figure 19-5 shows the mass spectrum of pentanoic acid. Identify the peaks resulting from the three cleavage modes illustrated on the following page.
In Summary  The NMR signals for carboxylic acids reveal highly deshielded acid protons and carbonyl carbons and moderately deshielded nuclei next to the functional group. The infrared spectrum shows characteristic bands at about 2500–3300 (O–H) and 1710 (C=O) cm$^{-1}$. The mass spectra of carboxylic acids reflect three characteristic modes of fragmentation.

19-4 Acidic and Basic Character of Carboxylic Acids

Like alcohols (Section 8-3), carboxylic acids exhibit both acidic and basic character: Deprotonation to carboxylate ions is relatively easy, protonation more difficult.

Carboxylic acids are relatively strong acids

Carboxylic acids have much lower pK$_a$ values than alcohols do, even though the relevant hydrogen in each case is that of a hydroxy group.
Why do carboxylic acids dissociate to a greater extent than do alcohols? The difference is that the hydroxy substituent of a carboxylic acid is attached to a carbonyl group, whose positively polarized and sp²-hybridized carbonyl carbon exerts a powerful electron-withdrawing inductive effect. In addition, the carboxylate ion is significantly stabilized by resonance, much as is the enolate ion formed by deprotonation of the α-carbon in aldehydes and ketones (Section 18-1).

Resonance in Carboxylate and Enolate Ions

\[
\begin{align*}
\text{Carboxylate ion} & : \\
B^- + RCOH & \rightleftharpoons BH + \left[ R\text{C} \biggm< \underset{\text{O}}{\text{O}} \right. \\
\text{Enolate ion} & : \\
B^- + R'CCH_2R & \rightleftharpoons BH + \left[ R'C \biggm< \underset{\text{O}}{\text{O}} \right.
\end{align*}
\]

In contrast with enolates, two of the three resonance forms in carboxylate ions are equivalent (Section 1-5). As a result, carboxylates are symmetric, with equal carbon–oxygen bond lengths (1.26 Å), in between the lengths typical of the carbon–oxygen double (1.20 Å) and single (1.34 Å) bonds in the corresponding acids (see Figure 19-1). The electrostatic potential map of acetate ion in the margin shows the equal distribution of negative charge (red) over the two oxygens.

Electron-withdrawing substituents increase the acidity of carboxylic acids

We saw previously (Section 8-3) that the inductive effect of electron-withdrawing groups close to the hydroxy function increases the acidity of alcohols. A similar phenomenon is observed in carboxylic acids. Table 19-3 shows the pKₐ values of selected acids. Note that two or three electron-withdrawing groups on the α-carbon can result in carboxylic acids whose strength approaches that of some inorganic (mineral) acids.

Exercise 19-5

In the following sets of acids, rank the compounds in order of decreasing acidity.

(a) CH₃CH₂COOH  CH₃CHCOOH  CH₃CBr₂COOH  
(b) CH₂CHCH₂COOH  CH₂CHCH₂COOH
(c) COOH  COOH  COOH  

Exercise 19-5
The dioic acids have two $pK_a$ values, one for each CO$_2$H group. In ethanedioic (oxalic) and propanedioic (malonic) acids, the first $pK_a$ is lowered by the electron-withdrawing inductive effect of the second carboxy group on the first. In the higher dioic acids, the two $pK_a$ values are close to those of monocarboxylic acids.

The relatively strong acidity of carboxylic acids means that their corresponding carboxylate salts are readily made by treatment of the acid with base, such as NaOH, Na$_2$CO$_3$, or NaHCO$_3$. These salts are named by specifying the metal and replacing the ending -ic acid in the acid name by -ate. Thus, HCOO$^-\text{Na}^+$ is called sodium formate; CH$_3$COO$^-\text{Li}^+$ is named lithium acetate; and so forth. Carboxylate salts are much more water soluble than the corresponding acids because the polar anionic group is readily solvated.

### Carboxylate Salt Formation

![Chemical reaction diagram]

**4,4-Dimethylpentanoic acid** (Slightly water soluble) $\xrightarrow{\text{NaOH, H}_2\text{O}}$ **Sodium 4,4-dimethylpentanoate** (Highly water-soluble salt)

**Carboxylic acids may be protonated on the carbonyl oxygen**

The lone electron pairs on both of the oxygen atoms in the carboxy group can, in principle, be protonated, just as alcohols are protonated by strong acids to give alkyl-oxonium ions (Sections 8-3 and 9-2). It has been found that it is the carbonyl oxygen that is more basic. Why? Protonation at the carbonyl oxygen gives a species whose positive charge is delocalized by resonance. The alternative possibility, resulting from protonation at the hydroxy group, does not benefit from such stabilization (see also Exercise 2-9).
Chapter 19

Protonation of a Carboxylic Acid

Resonance stabilization is not possible

Note that protonation is nevertheless very difficult, as is shown by the very high acidity ($pK_a = -6$) of the conjugate acid. We shall see, however, that such protonations are important in many reactions of the carboxylic acids and their derivatives.

**Exercise 19-6**

The $pK_a$ of protonated acetone is $-7.2$ and that of protonated acetic acid is $-6.1$. Explain.

**In Summary** Carboxylic acids are acidic because the polarized carbonyl carbon is strongly electron withdrawing and deprotonation gives resonance-stabilized anions. Electron-withdrawing groups increase acidity, although this effect wears off rapidly with increasing distance from the carboxy group. Protonation is difficult, but possible, and occurs on the carbonyl oxygen to give a resonance-stabilized cation.

**19-5 Carboxylic Acid Synthesis in Industry**

Carboxylic acids are useful reagents and synthetic precursors. The two simplest ones are manufactured on a large scale industrially. Formic acid is employed in the tanning process in the manufacture of leather and in the preparation of latex rubber. It is synthesized efficiently by the reaction of powdered sodium hydroxide with carbon monoxide under pressure. This transformation proceeds by nucleophilic addition followed by protonation.

**Formic Acid Synthesis**

$$\text{NaOH} + \text{CO} \xrightarrow{150^\circ C, 100 \text{ psi}} \text{HCOO}^- \text{Na}^+ + \text{H}_2\text{O} \rightarrow \text{HCOOH}$$

There are three important industrial preparations of acetic acid: ethene oxidation through acetaldehyde (Section 12-16); air oxidation of butane; and carbonylation of methanol. The mechanisms of these reactions are complex.

**Acetic Acid by Oxidation of Ethene**

$$\text{CH}_2=\text{CH}_2 \xrightarrow{\text{O}_2, \text{H}_2\text{O}, \text{catalytic PdCl}_2 \text{ and CuCl}_2, \text{Wacker process}} \text{CH}_3\text{CHO} \xrightarrow{\text{O}_2, \text{catalytic Co}^{3+}, \text{15–20 atm, 180}^\circ \text{C}} \text{CH}_3\text{COOH}$$

**Acetic Acid by Oxidation of Butane**

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \xrightarrow{\text{O}_2, \text{catalytic Co}^{3+}, \text{15–20 atm, 180}^\circ \text{C}} \text{CH}_3\text{COOH}$$

**Acetic Acid by Carbonylation of Methanol**

$$\text{CH}_4\text{OH} \xrightarrow{\text{CO}_2, \text{catalytic Rh}^{3+}, \text{I}_2, \text{30–40 atm, 180}^\circ \text{C}, \text{Monsanto process}} \text{CH}_3\text{COOH}$$
Global demand of acetic acid exceeds 6.5 million tons ($6.5 \times 10^9$ kg) annually. It is used to manufacture monomers for polymerization, such as methyl 2-methylpropenoate (methyl methacrylate; Table 12-3), as well as pharmaceuticals, dyes, and pesticides. Two dicarboxylic acids in large-scale chemical production are hexanedioic (adipic) acid, used in the manufacture of nylon (see Chemical Highlight 21-4), and 1,4-benzenedicarboxylic (terephthalic) acid, whose polymeric esters with diols are fashioned into plastic sheets, films, and bottles for soft drinks.

19-6 Methods for Introducing the Carboxy Functional Group

The oxidation of primary alcohols and aldehydes to carboxylic acids by aqueous Cr(VI) was described in Sections 8-6 and 17-4. This section presents two additional reagents suitable for this purpose. It is also possible to introduce the carboxy function by adding a carbon atom to a haloalkane. This transformation can be achieved in either of two ways: the carbonation of organometallic reagents or the preparation and hydrolysis of nitriles.

Oxidation of primary alcohols and of aldehydes furnishes carboxylic acids

Primary alcohols oxidize to aldehydes, which in turn may readily oxidize further to the corresponding carboxylic acids.

![Carboxylic Acids by Oxidation](image)

In addition to aqueous CrO$_3$, KMnO$_4$ and nitric acid (HNO$_3$) are frequently used in this process. Because it is one of the cheapest strong oxidants, nitric acid is often chosen for large-scale and industrial applications.

$$2\text{HNO}_3 + \text{ClCH}_2\text{CH}_2\text{CH}_2\text{Cl} \rightarrow \text{ClCH}_2\text{CH}_2\text{COH} + 2\text{NO}_2 + \text{H}_2\text{O}$$

**Exercise 19-7**

Give the products of nitric acid oxidation of (a) pentanal; (b) 1,6-hexanediol; (c) 4-(hydroxymethyl)cyclohexanecarbaldehyde.

Organometallic reagents react with carbon dioxide to give carboxylic acids

Organometallic reagents attack carbon dioxide (usually in the solid form known as “dry ice”) much as they would attack aldehydes or ketones. The product of this carbonation process is a carboxylate salt, which upon protonation by aqueous acid yields the carboxylic acid.
Recall that an organometallic reagent is usually made from the corresponding haloalkane: $RX + \text{Mg} \rightarrow \text{RMgX}$. Hence, carbonation of the organometallic reagent allows the two-step transformation of $RX$ into $RCOOH$, the carboxylic acid with one more carbon. For example,

$$\begin{align*}
\text{Cl} & \quad \text{MgCl} \\
\text{CH}_3\text{CH}_2\text{CHCH}_3 & \quad \text{THF} & \quad \text{CH}_3\text{CH}_2\text{CHCH}_3 \\
+ & \quad \rightarrow & \quad \rightarrow \\
\text{CO}_2 & \quad \text{H}_2\text{O} & \quad \text{COOH}
\end{align*}$$

2-Chlorobutane

2-Methylbutanoic acid

### Nitriles hydrolyze to carboxylic acids

Another method for converting a haloalkane into a carboxylic acid with an additional carbon atom is through the preparation and hydrolysis of a nitrile, $RC\equiv N$. Recall (Section 6-2) that cyanide ion, $\text{CN}^-$, is a good nucleophile and may be used to synthesize nitriles through $S_N2$ reactions. Hydrolysis of the nitrile in hot acid or base furnishes the corresponding carboxylic acid (and ammonia or ammonium ion).

### Carboxylic Acids from Haloalkanes Through Nitriles

$$\begin{align*}
\text{RX} & \quad \text{RC\equiv N} \\
-\text{CN} & \quad 1. \text{HO}^- \\
-\text{X} & \quad 2. \text{H}_2\text{O} \quad \text{NH}_3 \text{ or NH}_4^+
\end{align*}$$

The mechanism of this reaction will be described in detail in Section 20-8.

Carboxylic acid synthesis with the use of nitrile hydrolysis is preferable to Grignard carbonation when the substrate contains other groups that react with organometallic reagents, such as the hydroxy, carbonyl, and nitro functionalities.

### Exercise 19-8

#### Working with the Concepts: Carboxylic Acids from Haloalkanes

Suggest a method for accomplishing the conversion shown below. Several steps may be necessary.

**Strategy**

Before you start, inspect both structures carefully. Notice that the target molecule has an additional carbon atom that must be introduced. The last two methods in the section above provide possible options, but neither one can be applied directly to the starting material. The carbonyl function will interfere with any attempt to proceed using organometallic reagents and will also react with cyanide ion. Let us look at each of these options.

We know from Section 17-11 that cyanide addition is reversible and can be avoided under basic conditions. Can we therefore displace bromide by cyanide and follow with hydrolysis under basic conditions? Look more closely at the substrate—Br is attached to a tertiary carbon. The necessary $S_N2$ displacement will not occur; only elimination will take place (Section 7-8).

Fortunately, organometallic reagents can be prepared from almost any type of halogenated compound, including tertiary haloalkanes, provided that interference from other functional groups can be avoided. This realization gives us the framework for a solution.
Hydrolysis of the nitrile group in a cyanohydrin, prepared by addition of HCN to an aldehyde or a ketone (Section 17-11), is a general route to 2-hydroxycarboxylic acids, which possess antiseptic properties.

\[
\begin{align*}
\text{CHO} & \quad \text{NaCN, NaHSO}_3, \text{H}_2\text{O} & \quad \text{H} & \quad \text{H} \\
\text{Br} & \quad \text{O} & \quad \text{Br} & \quad \text{O} \\
\text{H} & \quad \text{C} & \quad \text{CN} & \quad \text{OH} \\
\text{Br} & \quad \text{OCH}_2\text{CH}_2\text{OH}, \text{H}^+ & \quad \text{Br} & \quad \text{O} \\
\text{H} & \quad \text{C} & \quad \text{COOH}
\end{align*}
\]

- Protect the aldehyde group in a way that will allow formation and use of a Grignard reagent: Form the cyclic acetal using 1,2-ethanediol and acid catalysis.
- Following the sequence in the section above, prepare the Grignard reagent and add it to CO₂.
- Protonate the resulting carboxylate under acidic, aqueous conditions. The acetal hydrolyzes as well, deprotecting the aldehyde function:

\[
\begin{align*}
\text{Br} & \quad \text{H} & \quad \text{O} & \quad \text{Br} & \quad \text{O} \\
\text{H} & \quad \text{C} & \quad \text{CN} & \quad \text{OH} \\
\text{Br} & \quad \text{OCH}_2\text{CH}_2\text{OH}, \text{H}^+ & \quad \text{Br} & \quad \text{O} \\
\text{H} & \quad \text{C} & \quad \text{COOH}
\end{align*}
\]

**Exercise 19-9**

**Try It Yourself**

Using chemical equations, show how you would convert each of the following halogenated compounds into a carboxylic acid with one additional carbon atom. If more than one method can be used successfully, show all. If not, give the reason behind your choice of approach.

(a) 1-Chloropentane;
(b) iodocyclopentane;
(c) 4-bromobutanoic acid (Hint: See Sections 8-7 and 8-9);
(d) chloroethene (Hint: See Section 13-9);
(e) bromocyclopropane (Hint: See Problem 60 of Chapter 6).

Hydrolysis of the nitrile group in a cyanohydrin, prepared by addition of HCN to an aldehyde or a ketone (Section 17-11), is a general route to 2-hydroxycarboxylic acids, which possess antiseptic properties.

\[
\begin{align*}
\text{CHO} & \quad \text{OH} & \quad \text{OH} \\
\text{Br} & \quad \text{O} & \quad \text{OCH}_3
\end{align*}
\]

**Exercise 19-10**

Suggest ways to effect the following conversions (more than one step will be required).

(a) \[\text{CHO} \rightarrow \text{HOCHCOOH}\]
(b) \[\text{H}_3\text{C} \quad \text{COOH}\]
(c) \[\text{Br} \quad \text{COOH} \rightarrow \text{H}_3\text{C} \quad \text{COOH}\]

(Caution: Pay attention to the stereochemistry!)

**In Summary** Several reagents oxidize primary alcohols and aldehydes to carboxylic acids. A haloalkane is transformed into the carboxylic acid containing one additional carbon atom either by conversion into an organometallic reagent and carbonation or by displacement of halide by cyanide followed by nitrile hydrolysis.
19-7 Substitution at the Carboxy Carbon: The Addition–Elimination Mechanism

The carbonyl group in carboxylic acids shows reactivity similar to that in aldehydes and ketones: It is subject to attack by nucleophiles at carbon and electrophiles at oxygen. However, the presence of the carboxy OH group in the structure adds another dimension to the chemical function of carboxylic acids: Just as in alcohols, this OH may be converted into a leaving group (Section 9-2). As a result, after nucleophilic addition to the carbonyl carbon takes place, the leaving group may depart, resulting in a net substitution process and a new carbonyl compound. This section introduces this process and the general mechanisms by which it takes place.

The carbonyl carbon is attacked by nucleophiles

As we have learned from our study of aldehydes and ketones, carbonyl carbons are electrophilic and can be attacked by nucleophiles. This type of reactivity is observed in the carboxylic acids and the carboxylic acid derivatives, substances with the general formula RCOL (L stands for leaving group).

In contrast to the addition products of aldehydes and ketones (Sections 17-5 through 17-7), the intermediate formed upon attack of a nucleophile on a carboxy carbon can decompose by eliminating a leaving group. The result is substitution of the nucleophile for the leaving group via a process called addition–elimination.

Substitution at the carboxy carbon occurs by addition–elimination

The carbonyl carbon is trigonal and sp²-hybridized. As we have seen in the reactions of alkenes and benzenes (Chapters 12 and 15), the substitution mechanisms associated with saturated, tetrahedral, sp³-hybridized carbon atoms do not typically occur in unsaturated, trigonal planar systems. Their planarity renders backside, S_N2-type displacement geometrically difficult, and sp²-hybridized carbon atoms form poor carbocations, disfavoring S_N1.

Substitution by the addition–elimination sequence combines two simple mechanistic processes. Addition of a nucleophile to the carbon of a carbonyl group is a reaction we know well. Elimination is just the mechanistic reverse of the addition process. Mechanism type 4(a) from Section 2-2 may be used to illustrate both, as follows.

Forward direction—addition: \( X^- + A = B \rightarrow X - A - B^- \)

Reverse direction—elimination: \( X^- + A - B^- \rightarrow X^- + A = B \)

When the site of attack (atom A) already contains a potential leaving group (Y), then the two steps above can occur one after the other to give net substitution of X for Y:

General Mechanistic Pattern for an Addition–Elimination Sequence

\[
\begin{align*}
X^- & \quad \rightarrow \quad Y \\
A = B & \quad \leftrightarrow \quad X - A - B^- \\
\text{Addition of } X & \quad \leftrightarrow \quad \text{Elimination of } Y \\
X & \quad \rightarrow \quad X = A + B + Y^-
\end{align*}
\]

As this general scheme shows, both steps in an addition–elimination sequence may be reversible. The scheme below shows addition–elimination as applied to a carboxylic acid derivative. The intermediate species formed after addition but before elimination (in contrast
to both starting material and product) contains a tetrahedral carbon center. It is therefore called a **tetrahedral intermediate**.

**Nucleophilic Substitution by Addition–Elimination**

Substitution by addition–elimination is the most important pathway for the formation of carboxylic acid derivatives as well as for their interconversion—that is, RCL → RCL’. The remainder of this section and those that follow will describe how such derivatives are prepared from carboxylic acids, and Chapter 20 will explore their properties and chemistry.

**Addition–elimination is catalyzed by both base and acid**

Addition–elimination reactions may be carried out under either basic or acidic conditions. We have seen how additions of nucleophiles to aldehydes and ketones (Sections 17-5 through 17-9; Table 17-4) may be catalyzed by either bases or acids. The same is true for additions of nucleophiles to carboxylic acid derivatives. Eliminations from the tetrahedral intermediate are similarly catalyzed: Recall that this process is mechanistically just the reverse of addition; therefore, the same catalytic effects are observed. Let us examine the roles of both base and acid in detail.

All nucleophiles are Lewis bases. However, a nucleophile with a removable proton (Nu–H) may be deprotonated by a strong base (denoted as `B`) to give the negatively charged and thus more strongly nucleophilic `Nu`, which is the attacking species (Step 1). Addition–elimination occurs (Step 2), and the base may be regenerated (Step 3), making it a catalyst for the overall process. Typical nucleophiles in sequences such as this include water and alcohols, which upon deprotonation give hydroxide and alkoxide ions, respectively.

**Mechanism of Base-Catalyzed Addition–Elimination**

**Step 1.** Deprotonation of NuH

\[ \text{NuH} + \text{B} \rightleftharpoons \text{Nu}^- + \text{BH} \]

**Step 2.** Addition–elimination

**Step 3.** Regeneration of catalyst

\[ \text{Nu}^- + \text{L} + \text{B} \rightleftharpoons \text{Nu} + \text{LH} + \text{B}^- \]

(Alternatively, `:`L may act as a base in step 1)
In cases where the nucleophile is already strong, base catalysis is unnecessary, and the entire mechanism may be described by Step 2, above.

Addition–elimination reactions may also benefit from acid catalysis. The acid functions in two ways: First, it protonates the carbonyl oxygen (Step 1), activating the carbonyl group toward nucleophilic attack (Section 17-5). Second, protonation of L (Step 2) makes it a better leaving group (recall Section 6-7 and 9-2).

Mechanism of Acid-Catalyzed Addition–Elimination

**Step 1. Protonation**

\[
\begin{align*}
\text{RCO}_2^- \quad + \quad H^+ & \quad \rightarrow \quad \text{RCO}_2H \\
\end{align*}
\]

**Step 2. Addition–elimination**

\[
\begin{align*}
\text{R}^- \quad \text{NuH} & \quad \rightarrow \quad \text{RCO}_2^+ \quad \text{Nu} \\
\text{RCO}_2^+ \quad \text{Nu} & \quad \rightarrow \quad \text{RCO}_2^- \quad + \quad \text{NuH} \\
\end{align*}
\]

**Step 3. Deprotonation; regeneration of catalytic proton**

\[
\begin{align*}
\text{RCO}_2^- \quad + \quad H^+ & \quad \rightarrow \quad \text{RCO}_2H \\
\end{align*}
\]

Substitution in carboxylic acids is inhibited by a poor leaving group and the acidic proton

We can apply the general addition–elimination process to the conversion of carboxylic acids into their derivatives. However, we must first overcome two problems. First, we know that the hydroxide ion is a poor leaving group (Section 6-7). Second, the carboxy proton is acidic, and most nucleophiles are bases (Section 6-8). Therefore, the desired nucleophilic attack (path \(a\) in the following equation) can encounter interference from an acid-base reaction (path \(b\)). Indeed, if a nucleophile is very basic, such as alkoxide, formation of the carboxylate ion will be essentially irreversible, and nucleophilic addition to the carbonyl carbon becomes very difficult.

Competing Reactions of a Carboxylic Acid with a Nucleophile

On the other hand, with less basic nucleophiles, especially under acidic conditions, the ready reversibility of carboxylate formation may permit nucleophilic addition to compete and ultimately lead to substitution through the addition–elimination mechanism. A typical example is the esterification of a carboxylic acid (Section 9-4), in which an alcohol and a carboxylic acid react to yield an ester and water. The nucleophile, an alcohol, is a weak base, and acid is present to protonate both the carbonyl oxygen, activating it toward nucleophilic addition, and the carboxy OH, converting it into a better leaving group, water.

**Esterification**

\[
\begin{align*}
\text{RCOOH} \quad + \quad \text{R’OH} & \quad \rightarrow \quad \text{RCOOR’} \quad + \quad \text{H}_2\text{O} \\
\end{align*}
\]
Acid Catalysis in Esterification

Step 1. Protonation of the carboxy group activates it toward addition of an alcohol (R’OH).

\[
\begin{align*}
\text{Starting} & \quad \text{Protonated} \\
\text{carboxylic acid} & \quad \text{carboxylic acid} \\
\end{align*}
\]

Step 2. Tetrahedral intermediate forms by addition of R’OH and loss of H⁺.

Step 3. Protonation of an OH oxygen makes it a better leaving group, allowing its departure.

The sections that follow will examine this and other carboxy substitutions in detail.

Exercise 19-11

Write out Step 2 of the above sequence in full.

In Summary  Nucleophilic attack on the carbonyl group of carboxylic acid derivatives is a key step in substitution by addition–elimination. Either acid or base catalysis may be observed. For carboxylic acids, the process is complicated by the poor leaving group (hydroxide) and competitive deprotonation of the acid by the nucleophile, acting as a base. With less basic nucleophiles, addition can occur.

19-8 Carboxylic Acid Derivatives: Acyl Halides and Anhydrides

With this section, we begin a survey of the preparation of carboxylic acid derivatives. Replacement of the hydroxy group in RCOOH by halide gives rise to acyl halides; substitution by alkanoate (RCOO⁻) furnishes carboxylic anhydrides. Both processes first require transformation of the hydroxy functionality into a better leaving group.

Acyl halides are formed by using inorganic derivatives of carboxylic acids

The conversion of carboxylic acids into acyl halides employs the same reagents used in the synthesis of haloalkanes from alcohols (Section 9-4): SOCl₂ and PBr₃. The problem to be solved in both cases is identical—changing a poor leaving group (OH) into a good one.
Chapter 19

Carboxylic Acids

(These reactions fail with formic acid, HCOOH, because fornyl chloride, HCOCl, and fornyl bromide, HCOBr, are unstable. See Exercise 15-33.)

These transformations begin with the conversion of the carboxylic acid into an inorganic derivative in which the substituent on the carbonyl carbon is a good leaving group:

\[
\begin{align*}
\text{RCHO} & \quad + \quad \text{Cl}_2\text{SO} \quad \rightarrow \quad \text{RCSOCl} \quad + \quad \text{HCl} \\
-\ddot{\text{O}}\dddot{\text{H}} & \quad \text{is a poor leaving group} \\
\end{align*}
\]

\[
\begin{align*}
\text{RCHO} & \quad + \quad \text{BrP} \quad \rightarrow \quad \text{RPOBr} \quad + \quad \text{HBr} \\
-\ddot{\text{O}}\dddot{\text{H}} & \quad \text{is a poor leaving group} \\
\end{align*}
\]

\[
\begin{align*}
\text{RCHO} & \quad + \quad \text{ClP} \quad \rightarrow \quad \text{RPOCl} \quad + \quad \text{HCl} \\
-\ddot{\text{O}}\dddot{\text{H}} & \quad \text{is a poor leaving group} \\
\end{align*}
\]

Exercise 19-12

Working with the Concepts: Acyl Chlorosulfite Formation

Propose a mechanism for the reaction of SOCl₂ with a carboxylic acid to give the inorganic derivative (an acyl chlorosulfite) shown above.

**Strategy**

It is tempting to employ the same steps for this problem as we used in the conversion of an alcohol into the corresponding alkyl chlorosulfite, ROSOCl, upon reaction with SOCl₂ (Section 9-4), namely, displacement of chloride from sulfur by the hydroxy group of the alcohol:

\[
\begin{align*}
\text{RCH}_2\text{OH} & \quad + \quad \text{Cl}_2\text{SO} \quad \rightarrow \quad \text{RCH}_2\text{OSOCl} \quad + \quad \text{H}^+ \quad + \quad \text{Cl}^- \\
\end{align*}
\]

However, direct application of this mechanism to a carboxylic acid is not likely to be correct. We saw in Section 19-5 that protonation of a carboxylic acid occurs at the carbonyl oxygen atom, not on the oxygen of the hydroxy group. The reason is straightforward: Protonation of the carbonyl oxygen gives a resonance-stabilized intermediate, whereas reaction at OH does not. The same can be said of reaction of a carboxylic acid with any electrophile, such as the sulfur in SOCl₂ or the phosphorus in PBr₃.

**Solution**

- It is more likely that the transformation in question proceeds as follows:

\[
\begin{align*}
\text{RCHO} & \quad + \quad \text{Cl}_2\text{SO} \quad \rightarrow \quad \text{RCSOCl} \quad + \quad \text{H}^+ \quad + \quad \text{Cl}^- \\
\end{align*}
\]

- This reaction pathway converts the carbonyl oxygen, rather than the hydroxy, into the leaving group.
- To our knowledge, this specific mechanism has not been tested experimentally. We present it as an example of a mechanistic hypothesis that is proposed for a set of reacting species, based on experimental observations of other similar species.
Acid-catalyzed addition–elimination follows.

**Mechanism of Acyl Chloride Formation with Thionyl Chloride**

**Step 1. Addition**

$$\text{R} - \text{C} = \text{O} \cdot \text{Cl} + \text{H}^+ \rightarrow \text{R} - \text{C} = \text{O} + \text{Cl}^-$$

**Step 2. Elimination**

$$\text{R} - \text{C} = \text{O} \cdot \text{S} \cdot \text{Cl} \rightarrow \text{R} - \text{C} + \text{S} = \text{O} + \text{H}^+ + \text{Cl}^-$$

The mechanism of acyl bromide formation using phosphorus tribromide (PBr₃) is similar (see Section 9-4).

**Acids combine with acyl halides to produce anhydrides**

The electronegative power of the halogens in acyl halides activates the carbonyl function to attack by other, even weak, nucleophiles (Chapter 20). For example, treatment of acyl halides with carboxylic acids results in **carboxylic anhydrides**.

$$\text{RCOCR}$$

Carboxylic anhydride

$$\text{CH₃CH₂CH₂COH} + \text{ClCCH₂CH₂CH₃} \xrightarrow{\Delta, 8 \text{ h} - \text{HCl}} \text{CH₃CH₂CH₂COCCCH₂CH₂CH₃}$$

Butanoic acid  Butanoyl chloride  85%  Butanoic anhydride

As the name indicates, carboxylic anhydrides are formally derived from the corresponding acids by loss of water. Although carboxylic acid dehydration is not a general method for anhydride synthesis, cyclic examples may be prepared by heating dicarboxylic acids. A condition for the success of this transformation is that the ring closure lead to a five- or six-membered ring product.
Cyclic Anhydride Formation

Because the halogen in the acyl halide and the RCO₂ substituent in the anhydride are good leaving groups and because they activate the adjacent carbonyl function, these carboxylic acid derivatives are useful synthetic intermediates for the preparation of other compounds, a topic to be discussed in Sections 20-2 and 20-3.

Exercise 19-14

Suggest two preparations, starting from carboxylic acids or their derivatives, for each of the following compounds.

(a) \( \text{CH}_3\text{COCCH}_2\text{CH}_3 \)
(b) \( \text{CH}_3\text{CHCCl} \)

Exercise 19-15

Propose a mechanism for the thermal formation of butanedioic anhydride from the dioic acid.

In Summary

The hydroxy group in COOH can be replaced by halogen by using the same reagents used to convert alcohols into haloalkanes—SOCl₂ and PBr₃. The resulting acyl halides are sufficiently reactive to be attacked by carboxylic acids to generate carboxylic anhydrides. Cyclic anhydrides may be made from dicarboxylic acids by thermal dehydration.

19-9 Carboxylic Acid Derivatives: Esters

Esters have the general formula RCO₂R’. Their widespread occurrence in nature and many practical uses make them perhaps the most important of the carboxylic acid derivatives. This section describes the mineral acid–catalyzed reaction of carboxylic acids with alcohols that forms esters.

Carboxylic acids react with alcohols to form esters

When a carboxylic acid and an alcohol are mixed together, no reaction takes place. However, upon addition of catalytic amounts of a mineral acid, such as sulfuric acid or HCl, the two components combine in an equilibrium process to give an ester and water (Section 9-4). This method of ester formation was first described by the legendary German chemist Emil Fischer and his coworker Arthur Speier in 1895. It is therefore called Fischer-Speier or (more commonly) Fischer esterification.

Acid-Catalyzed (Fischer) Esterification

\[
\text{RCOH} + \text{R’OH} \overset{\text{H}^+}{\longrightarrow} \text{RCOR’} + \text{H}_2\text{O}
\]

Carboxylic acid \( \longrightarrow \) Alcohol \( \rightarrow \) Ester \( \rightarrow \) Water
Esterification is not very exothermic: $\Delta H^\circ$ is usually close to 0. The associated entropy change is also small; therefore $\Delta G^\circ \approx 0$ and $K \approx 1$. How can the equilibrium be shifted toward the ester product? One way is to use an excess of either of the two starting materials; another is to remove the ester or the water product from the reaction mixture. In practice, esterifications are most often achieved by using the alcohol as a solvent.

\[
\text{Acetic acid} + \text{Solvent} \xrightarrow{\text{H}_2\text{SO}_4, \Delta} \text{Methyl acetate}
\]

Exercise 19-16

Show the products of the acid-catalyzed reaction of each of the following pairs of compounds.
(a) Methanol + pentanoic acid; (b) formic acid + 1-pentanol; (c) cyclohexanol + benzoic acid; (d) 2-bromoacetic acid + 3-methyl-2-butanol.

The opposite of esterification is ester hydrolysis. This reaction is carried out under the same conditions as esterification, but, to shift the equilibrium, an excess of water is used in a water-miscible solvent.

\[
\text{Ethyl 2,2-dimethylhexanoate} \xrightarrow{\text{H}_2\text{SO}_4, \text{HOH}, \text{acetone}, \Delta} \text{2,2-Dimethylhexanoic acid}
\]

Exercise 19-17

Give the products of acid-catalyzed hydrolysis of each of the following esters.
(a) \(\text{CH}_3(\text{CH}_2)_3\text{C}=\text{CCH}_2\text{CH}_2\text{COC(CH}_3)_2\)
(b) \(\text{O} \quad \text{O} \quad \text{O} \quad \text{O}
\]
(c) \(\text{CH}_3\text{CH}_2\text{CHCH}_2\text{OCOCC(CH}_3)_3\)

Esterification proceeds through acid-catalyzed addition–elimination

The presence of the acid catalyst features prominently in the mechanism of ester formation: It causes the carbonyl function to undergo nucleophilic attack by the alcohol (methanol in this example, step 2) and the hydroxy group to leave as water (step 3). We previewed this mechanism earlier (Section 19-7). Here we present it with full details.

**Mechanism of Acid-Catalyzed Esterification**

**Step 1.** Protonation of the carboxy group

\[
\begin{align*}
\text{R}^+\text{CO}_2\text{H} & \quad \xrightarrow{+\text{H}^+} \quad \text{R}^+\text{CO}_2\text{H}^+ \\
\text{R}^+\text{CO}_2\text{H}^+ & \quad \xrightarrow{-\text{H}^-} \quad \text{R}^+\text{CO}_2\text{H} \\
\text{R}^+\text{CO}_2\text{H} & \quad \xrightarrow{+\text{H}^+} \quad \text{R}^+\text{CO}_2\text{H}^+ \\
\text{R}^+\text{CO}_2\text{H}^+ & \quad \xrightarrow{-\text{H}^-} \quad \text{R}^+\text{CO}_2\text{H} \\
\text{R}^+\text{CO}_2\text{H} & \quad \xrightarrow{+\text{H}^+} \quad \text{R}^+\text{CO}_2\text{H}^+ \\
\text{R}^+\text{CO}_2\text{H}^+ & \quad \xrightarrow{-\text{H}^-} \quad \text{R}^+\text{CO}_2\text{H} \\
\end{align*}
\]

Step 2. Attack by methanol

Initially, protonation of the carbonyl oxygen gives a delocalized carbocation (step 1). Now the carbonyl carbon is susceptible to nucleophilic attack by methanol. Proton loss from the initial adduct furnishes the tetrahedral intermediate (step 2). This species is a crucial relay point, because it can react in either of two ways in the presence of the mineral acid catalyst. First, it can lose methanol by the reverse of steps 1 and 2. This process, beginning with protonation of the methoxy oxygen, leads back to the carboxylic acid. The second possibility, however, is protonation at either hydroxy oxygen, leading to elimination of water and to the ester (step 3). All the steps are reversible; therefore, either addition of excess alcohol or removal of water favors esterification by shifting the equilibria in steps 2 and 3, respectively. Ester hydrolysis proceeds by the reverse of the sequence and is favored by aqueous conditions.

Exercise 19-18

Give the mechanism of esterification of a general carboxylic acid RCOOH with methanol in which the alcohol oxygen is labeled with the $^{18}$O isotope (CH$_3^{18}$OH). Does the labeled oxygen appear in the ester or in the water product?

Hydroxy acids may undergo intramolecular esterification to lactones

When hydroxy carboxylic acids are treated with catalytic amounts of mineral acid, cyclic esters—or lactones—may form. This process is called intramolecular esterification and is favorable for formation of five- and six-membered rings. Unlike the intermolecular esterification, the equilibrium is now favored by entropy and therefore particularly facile: Water is expelled from the starting material.
Exercise 19-19

Working with the Concepts: A Multistep Mechanism

Explain the following result mechanistically.

\[
\text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{COOH} \xrightarrow{\text{H}_2\text{SO}_4, \text{H}_2\text{O}} \text{A lactone}
\]

Strategy
The starting compound possesses a five-membered ring hemiacetal group, which, as we saw in Section 17-7, can be a reasonably stable structure. Hemiacetals equilibrate with their open-chain hydroxycarbonyl isomers in the presence of aqueous acid or base:

\[
\text{HOCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{COOH} \rightleftharpoons \text{CH}_2\text{COOH} + \text{CH}_2\text{COOH}
\]

The structure that results contains three functional groups: an aldehyde carbonyl, an alcohol hydroxy, and a carboxylic acid carboxy.

Solution
• Intramolecular reaction of the hydroxy group with the carboxylic acid function gives the cyclic ester (lactone) product shown above.
• We complete the solution to the exercise by writing out the mechanism, step by step.

Exercise 19-20

Try It Yourself

If the starting compound in Exercise 19-19 were labeled with the $^{18}$O isotope at its ring oxygen atom, where would the $^{18}$O label end up in the product?

In Summary Carboxylic acids react with alcohols to form esters, as long as a mineral acid catalyst is present. This reaction is only slightly exothermic, and its equilibrium may be shifted in either direction by the choice of reaction conditions. The reverse of ester formation is ester hydrolysis. The mechanism of esterification is acid-catalyzed addition of alcohol to the carbonyl group followed by acid-catalyzed dehydration. Intramolecular ester formation results in lactones, favored only when five- or six-membered rings are produced.
19-10 Carboxylic Acid Derivatives: Amides

As we saw earlier (Section 17-9), amines also are capable of attacking the carbonyl function. When the carbonyl is that of a carboxylic acid, the product is a carboxylic amide,* the last major class of carboxylic acid derivatives. The mechanism is again addition–elimination but is complicated by acid-base chemistry.

**Amines react with carboxylic acids as bases and as nucleophiles**

Nitrogen lies to the left of oxygen in the periodic table. Therefore, amines (Chapter 21) are better bases as well as better nucleophiles than alcohols (Section 6-8). To synthesize carboxylic amides, therefore, we must address the problem discussed in Section 19-7: interference from competing acid-base reaction. Indeed, exposure of a carboxylic acid to an amine initially forms an ammonium carboxylate salt, in which the negatively charged carboxylate is very resistant to nucleophilic attack.

![Ammonium Salts from Carboxylic Acids]

Notice that salt formation, though very favorable, is nonetheless reversible. Upon heating, a slower but thermodynamically favored reaction between the acid and the amine can take place. The acid and the amine are removed from the equilibrium, and eventually salt formation is completely reversed. In this second mode of reaction, the nitrogen acts as a nucleophile and attacks the carbonyl carbon. Completion of an addition–elimination sequence leads to the amide. Although it is convenient, this method suffers from the high temperatures required to reverse ammonium carboxylate formation. Therefore, better procedures rely on the use of activated carboxylic acid derivatives, such as acyl chlorides (Chapter 20).

![Formation of an Amide from an Amine and a Carboxylic Acid]

In the mechanism shown above, the elimination step is shown to proceed from a zwitterionic tetrahedral intermediate. However, the prevalence of such a species is likely to be highly pH dependent. Thus, an alternative possibility is to eliminate water from a neutral species,

*Do not confuse the names of carboxylic amides with those of the alkali salts of amines, also called amides (e.g., lithium amide, LiNH₂).
as shown in the margin. Amide formation is reversible. Thus, treatment of amides with hot aqueous acid or base regenerates the component carboxylic acids and amines.

**Dicarboxylic acids react with amines to give imides**

Dicarboxylic acids may react twice with the amine nitrogen of ammonia or of a primary amine. This sequence gives rise to **imides**, the nitrogen analogs of cyclic anhydrides (cf. p. 892).

\[
\begin{align*}
\text{Butanedioic acid} & \rightarrow \text{CH}_2\text{COOH} \quad \text{NH}_3 \quad \text{CH}_2\text{COOH} \\
& \rightarrow \text{CH}_2\text{COO}^-\text{NH}_4^+ \quad \text{290^\circ C} \\
& \rightarrow \text{H}_2\text{C} \quad \text{C} \quad \text{NH} \quad \text{H}_2\text{C} \quad \text{N} \\
& \rightarrow \text{83\% Butanimide (Succinimide)}
\end{align*}
\]

Recall the use of \(N\)-halobutanimides in halogenations (Section 14-2).

**Amino acids cyclize to lactams**

In analogy to hydroxycarboxylic acids, some amino acids undergo cyclization to the corresponding cyclic amides, called **lactams** (Section 20-6).

\[
\begin{align*}
\text{H}_2\text{NCH}_2\text{CH}_2\text{CH}_2\text{CO}^+ & \leftrightarrow \text{HINCH}_2\text{CH}_2\text{CH}_2\text{COH} \\
\rightarrow \text{O} & \rightarrow \text{O} \\
\Delta & \rightarrow \text{H}_2\text{O} \\
& \rightarrow \text{86\% A lactam}
\end{align*}
\]

The penicillin class of antibiotics derives its biological activity from the presence of a lactam function (see Chemical Highlight 20-2). Lactams are the nitrogen analogs of lactones (Section 19-9).

**Exercise 19-21**

Formulate a detailed mechanism for the formation of butanimide from butanedioic acid and ammonia.

**In Summary**

Amines react with carboxylic acids to form amides by an addition–elimination process that begins with nucleophilic attack by the amine on the carboxy carbon. Amide formation is complicated by reversible deprotonation of the carboxylic acid by the basic amine to give an ammonium salt.

**19-11 Reduction of Carboxylic Acids by Lithium Aluminum Hydride**

Lithium aluminum hydride is capable of reducing carboxylic acids all the way to the corresponding primary alcohols, which are obtained upon aqueous acidic work-up.

**Reduction of a Carboxylic Acid**

\[
\text{RCOOH} \quad \xrightarrow{\text{1. LiAlH}_4, \text{THF}} \quad \text{RCH}_2\text{OH} \quad \xrightarrow{\text{2. } \text{H}^+, \text{H}_2\text{O}}
\]
Example:

$$\text{COOH} \xrightarrow{1. \text{LiAlH}_4, \text{THF}} \text{CH}_2\text{OH}$$

Although the exact mechanism of this transformation is not completely understood, it is clear that the hydride reagent first acts as a base, forming the lithium salt of the acid and hydrogen gas. Carboxylate salts are generally resistant to attack by nucleophiles. Yet, despite the negative charge, lithium aluminum hydride is so reactive that it is capable of donating two hydrides to the carbonyl function of the carboxylate, possibly assisted by aluminum (margin; see also Section 8-6). The product of this sequence, a simple alkoxide, gives the alcohol after protonation.

**Double Hydride Additions to Carboxylate Ion**

$$\text{R} \xrightarrow{\text{H}_3\text{AlH}_3} \text{CH}_2\text{OH}$$

**Exercise 19-22**

Propose synthetic schemes that produce compound B from compound A.

(a) CH$_3$CH$_2$CH$_2$CN  \(\rightarrow\) CH$_3$CH$_2$CH$_2$CH$_2$OH  \(\rightarrow\) CH$_2$COOH

(b) CH$_3$CH$_2$COOH  \(\rightarrow\) CH$_2$CD$_2$OH

**In Summary** The nucleophilic reactivity of lithium aluminum hydride is sufficiently great to effect the reduction of carboxylates to primary alcohols.

**19-12 Bromination Next to the Carboxy Group: The Hell-Volhard-Zelinsky Reaction**

Like aldehydes and ketones, alkanolic acids can be monobrominated at the alpha-carbon by exposure to Br$_2$. The addition of a trace amount of PBr$_3$ is necessary to get the reaction started. Because the highly corrosive PBr$_3$ is difficult to handle, it is often generated in the reaction flask (in situ). This is achieved by the addition of a little elemental (red) phosphorus to the mixture of starting materials; it is converted into PBr$_3$ instantaneously by the bromine present.

**A Hell-Volhard-Zelinsky* Reaction**

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{COOH} \xrightarrow{\text{Br}_2, \text{trace P}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CHCH}_2\text{COOH} + \text{HBr}$$

\(80\%\)

2-Bromopentanoic acid

The acyl bromide, formed by the reaction of PBr$_3$ with the carboxylic acid (Section 19-8), is subject to rapid acid-catalyzed enolization. The enol is brominated to give the 2-bromoacyl bromide. This derivative then undergoes an exchange reaction with unreacted acid to furnish the product bromoacid and another molecule of acyl bromide, which reenters the reaction cycle.

**Mechanism of the Hell-Volhard-Zelinsky Reaction**

**Step 1.** Acyl bromide formation (see Exercise 19-12 and Section 19-8)

$$3 \text{RCH}_2\text{COH} \xrightarrow{\text{PBr}_3} 3 \text{RCH}_2\text{CBr} + \text{H}_3\text{PO}_3$$

*Professor Carl M. Hell (1849–1926), University of Stuttgart, Germany; Professor Jacob Volhard (1834–1910), University of Halle, Germany; Professor Nicolai D. Zelinsky (1861–1953), University of Moscow.
Step 2. Enolization

\[
RCH_2CBr + H^+ \rightarrow RCH=C\overset{\text{Enol}}{Br} \overset{\text{OH}}{\rightarrow}
\]

Step 3. Bromination

\[
RCH=C\overset{\text{OH}}{Br} + Br-Br \rightarrow RCHCBr + HBr
\]

Step 4. Exchange

\[
RCHCBr + RCH_2COH \rightarrow RCHCOH + RCH_2CBr \overset{\text{Reenters}}{\text{Reenters step 2}}
\]

Exercise 19-23

Formulate detailed mechanisms for steps 2 and 3 of the Hell-Volhard-Zelinsky reaction. (Hints: Review Sections 18-2 for step 2 and 18-3 for step 3.)

The bromocarboxylic acids formed in the Hell-Volhard-Zelinsky reaction can be converted into other 2-substituted derivatives. For example, treatment with aqueous base gives 2-hydroxy acids, whereas amines yield \(\alpha\)-amino acids (Chapter 26). An example of amino acid synthesis is the preparation of racemic 2-aminohexanoic acid (norleucine, a naturally occurring but rare amino acid) shown here.

\[
\begin{align*}
\text{Hexanoic acid} & \rightarrow \text{2-Bromohexanoic acid} \\
& \rightarrow \text{2-Aminohexanoic acid (Norleucine)}
\end{align*}
\]

In Summary With trace amounts of phosphorus (or phosphorus tribromide), carboxylic acids are brominated at C2 (the Hell-Volhard-Zelinsky reaction). The transformation proceeds through 2-bromoacyl bromide intermediates.

19-13 Biological Activity of Carboxylic Acids

Considering the variety of reactions that carboxylic acids can undergo, it is no wonder that they are very important, not only as synthetic intermediates in the laboratory, but also in biological systems. This section will provide a glimpse of the enormous structural and functional diversity of natural carboxylic acids. A discussion of amino acids will be deferred to Chapter 26.

As Table 19-1 indicates, even the simplest carboxylic acids are abundant in nature. Formic acid is present not only in ants, where it functions as an alarm pheromone, but also in plants. For example, one reason why human skin hurts after it touches the stinging nettle is that formic acid is deposited in the wounds.

Acetic acid is formed through the enzymatic oxidation of ethanol produced by fermentation. Vinegar is the term given to the dilute (ca. 4–12%) aqueous solution thus generated in ciders, wines, and malt extracts. Louis Pasteur in 1864 established the involvement of bacteria in the oxidation stage of this ancient process.
**CHEMICAL HIGHLIGHT 19-1**

**Soaps from Long-Chain Carboxylates**

The sodium and potassium salts of long-chain carboxylic acids have the property of aggregating as spherical clusters called *micelles* in aqueous solution. In such aggregates, the hydrophobic alkyl chains (Section 8-2) of the acids come together in space because of their attraction to one another by London forces (Section 2-6) and their tendency to avoid exposure to polar water. As shown above, the polar, water-solvated carboxylate “head groups” form a spherical shell around the hydrocarbonlike center.

---

**Fatty acids are derived from coupling of acetic acid**

Acetic acid exhibits diverse biological activities, ranging from a defense pheromone in some ants and scorpions to the primary building block for the biosynthesis of more naturally occurring organic compounds than any other single precursor substance. For example, 3-methyl-3-butenyl pyrophosphate, the crucial precursor in the buildup of the terpenes (Section 14-10), is made by the enzymatic conversion of three molecules of \( \text{CH}_3\text{COOH} \) into an intermediate called *mevalonic acid*. Further reactions degrade the system to the five-carbon (isoprene) unit of the product.

\[
3 \text{CH}_3\text{COOH} \xrightarrow{\text{Enzymes}} \text{CH}_3\text{CH}==\text{CHCH}_2\text{OH}
\]

\[
\xrightarrow{\text{Enzymes}} \text{CH}_3==\text{COOH}
\]

**Mevalonic acid**

\[
\xrightarrow{\text{Enzymes}} \text{CH}_2==\text{CH}_2\text{O}\text{P-O-P-O}\text{OH}
\]

**3-Methyl-3-butenyl pyrophosphate**
Chapter 19

A conceptually more straightforward mode of multiple coupling is found in the biosynthesis of fatty acids. This class of compounds derives its name from its source, the natural fats, which are esters of long-chain carboxylic acids (see Section 20-4). Hydrolysis or saponification (so called because the corresponding salts form soaps; sapo, Latin, soap—see Chemical Highlight 19-1) yields the corresponding fatty acids. The most important of them are between 12 and 22 carbons long and may contain cis carbon–carbon double bonds.

\[
\begin{align*}
\text{Hexadecanoic acid} & : \quad \text{(Palmitic acid)} \\
\text{cis-9-Octadecenoic acid} & : \quad \text{(Oleic acid)}
\end{align*}
\]

In accord with their biosynthetic origin, fatty acids consist mostly of even-numbered carbon chains. A very elegant experiment demonstrated that linear coupling occurred in a highly
In a regular fashion. In it, singly labeled radioactive \(^{(14}C\) acetic acid was fed to several organisms. The resulting fatty acids were labeled only at every other carbon atom.

\[
\text{Organism} \quad \text{CH}_3^{14}\text{COOH} \quad \text{Organism} \quad \text{CH}_3^{14}\text{CH}_2\text{CH}_2^{14}\text{CH}_2\text{CH}_2^{14}\text{CH}_2\text{CH}_2^{14}\text{CH}_2\text{CH}_2^{14}\text{CH}_2\text{CH}_2^{14}\text{CH}_2\text{CH}_2^{14}\text{COOH}
\]

Labeled hexadecanoic (palmitic) acid

The mechanism of chain formation is very complex, but the following scheme provides a general idea of the process. A key player is the mercapto group of an important biological relay compound called coenzyme A (abbreviated HSCoA; Figure 19-6). This function binds acetic acid in the form of a \textit{thiol ester} called acetyl CoA. Carboxylation transforms some of this thiol ester into malonyl CoA. The two acyl groups are then transferred to two molecules of \textit{acyl carrier protein}. Coupling occurs with loss of CO\(_2\) to furnish a 3-oxobutanoic thiol ester.

**Coupling of Acetic Acid Units**

\textbf{Step 1.} Thiol ester formation

\[
\text{Acetic acid} \quad \text{CH}_3\text{COOH} \quad + \quad \text{HSCoA} \quad \text{Coenzyme A} \quad \longrightarrow \quad \text{Acetyl coenzyme A} \quad \text{CH}_3\text{CSCoA} \quad + \quad \text{HOH}
\]

\textbf{Step 2.} Carboxylation

\[
\text{Malonyl CoA} \quad \text{HOCCH}_2\text{CSCoA} \quad + \quad \text{CO}_2 \quad \text{Acetyl CoA carboxylase} \quad \longrightarrow \quad \text{Malonyl CoA} \quad \text{HOCCH}_2\text{CSCoA}
\]

\textbf{Step 3.} Acetyl and malonyl group transfers

\[
\text{Acyl carrier protein} \quad \text{HOCCH}_2\text{CSCoA} \quad + \quad \text{HSCoA} \quad \longrightarrow \quad \text{Acyl carrier protein} \quad \text{HOCCH}_2\text{CSCoA}
\]
Step 4. Coupling

\[
\text{O} \quad \text{O} \quad \text{protein} \quad \xrightarrow{\text{CH}_3\text{CS} - \text{protein}} \quad \text{O} \quad \text{O} \quad \text{protein} \\
\text{HOCC}(\text{CH}_2\text{CS} \quad \text{protein}) \quad \xrightarrow{-\text{CO}_2} \quad \text{CH}_3\text{C}(\text{CH}_2\text{CS} \quad \text{protein})
\]

A 3-oxobutanoic thiol ester

Reduction of the ketone function to a methylene group follows. The resulting butanoic thiol ester repeatedly undergoes a similar sequence of reactions elongating the chain, always by two carbons. The eventual product is a long-chain acyl group, which is removed from the protein by hydrolysis.

\[
\text{CH}_3\text{CH}_2\quad(\text{CH}_2\text{CH}_2)_n\text{CH}_2\text{C} - \text{Sprotein} \quad \xrightarrow{\text{H}_2\text{O}} \quad \text{CH}_3\text{CH}_2\quad(\text{CH}_2\text{CH}_2)_n\text{CH}_2\text{C} - \text{OH} + \text{HSprotein}
\]

Fatty acid
Arachidonic acid is a biologically important unsaturated fatty acid

Naturally occurring unsaturated fatty acids are capable of undergoing further transformations leading to a variety of unusual structures. An example is arachidonic acid, which is the biological precursor to a multitude of important chemicals in the human body, such as prostaglandins (Chemical Highlight 11-1), thromboxanes, prostacyclins, and leukotrienes.

Each of these compounds possesses powerful biological properties. For example, some of the prostaglandins are responsible for the tissue inflammation associated with rheumatoid arthritis. The salicylate derivative aspirin (Chemical Highlight 22-2) is capable of combating such symptoms by inhibiting the conversion of arachidonic acid into prostaglandins. In the early 1990s, asthma, a condition that afflicts some 15 million Americans, was recognized to be a chronic inflammatory disease. Recent research has shown that the leukotrienes mediate airway inflammation, and the thromboxanes contribute to
Chapter 19

Exercise 19-24

Identify the arachidonic acid backbone in each of its four derivatives just shown.
Nature also produces complex polycyclic carboxylic acids

Many biologically active natural products that have carboxy groups as substituents of complex polycyclic frames have physiological potential that derives from other sites in the molecule. In these compounds the function of the carboxy group may be to impart water solubility, to allow for salt formation or ion transport, and to enable micellar-type aggregation. Two examples are gibberellic acid, one of a group of plant growth-promoting substances manufactured by fermentation, and lysergic acid, a major product of hydrolyzed extracts of ergot, a fungal parasite that lives on grasses, including rye. Many lysergic acid derivatives possess powerful psychotomimetic activity. In the Middle Ages, thousands who ate rye bread contaminated by ergot experienced the poisonous effects characteristic of these compounds: hallucinations, convulsions, delirium, epilepsy, and death. The synthetic lysergic acid diethylamide (LSD) is one of the most powerful hallucinogens known. The effective oral dose for humans is only about 0.05 mg.

In Summary The numerous naturally occurring carboxylic acids are structurally and functionally diverse. The condensation of multiple acetyl units gives rise to the straight-chain fatty acids. The fatty acids in turn are converted into a wide array of substances exhibiting varied biological and, often, useful medicinal properties.

THE BIG PICTURE

The carboxylic acid functional group combines the carbonyl group of the aldehydes and ketones with the hydroxy group of the alcohols. The carbonyl group enhances the acidity of the hydroxy hydrogen, and the hydroxy group gives rise to the addition–elimination pathway for substitution about the carbonyl carbon. Such substitution reactions result in the formation of the carboxylic acid derivatives known as halides, anhydrides, esters, and amides. These derivatives are important starting points for the synthesis of a variety of other classes of compounds. The next chapter will reveal the remarkable chemical versatility that has made these derivatives mainstays of laboratory chemistry as well as countless naturally occurring biological processes.

After we have completed our presentation of carbonyl chemistry, the only simple compound class left to be discussed will be the amines (Chapter 21). The final five chapters of the text will deal with compounds combining multiple functional groups, with an emphasis on those of synthetic and biochemical importance.
CHAPTER INTEGRATION PROBLEMS

19-25. Propose a mechanism for the exchange between an acyl bromide and a carboxylic acid, as it occurs in step 4 of the Hell-Volhard-Zelinsky reaction.

\[
\begin{align*}
\text{RCHCBr} + \text{RCH}_2\text{COH} & \quad \xrightarrow{\text{Br}} \quad \text{RCHCOH} + \text{RCH}_2\text{CBr} \\
\end{align*}
\]

SOLUTION

First we must consider exactly what changes have occurred and then by which pathways these changes could have taken place. The two starting compounds have exchanged Br and OH substituents on their carbonyl carbons. Given the main chapter theme, addition–elimination pathways for carbonyl substitution reactions, let us look for a logical way to enable that process.

The \(\alpha\)-bromoacyl bromide has a strongly electrophilic \((\delta^+\) carbonyl carbon, because of the electron-withdrawing effects of the two bromines. This acyl bromide is therefore a good candidate to be attacked by the most nucleophilic atom in the two compounds, the carbonyl oxygen of the carboxylic acid: Recall that the carbonyl oxygen is the most favorable site for attachment of electrophiles, because the species that results is resonance stabilized:

\[
\begin{align*}
\text{RCH}_2\text{O} & \quad \xrightarrow{\text{Br}} \quad \text{RCH}_2\text{O} \\
\end{align*}
\]

Elimination of bromide ion from this tetrahedral intermediate gives a protonated anhydride. Readition of bromide to the activated carbonyl group in the anhydride gives a new tetrahedral intermediate. At this stage the exchange sequence can be completed by elimination of the carboxylic acid. This process may be viewed as involving the shift of a proton from one oxygen to another using a six-membered-ring transition state, similar to those we have seen on several previous occasions. This step results directly in the formation of the exchanged product molecules, an \(\alpha\)-bromocarboxylic acid and an acyl bromide unsubstituted at the \(\alpha\)-carbon:

\[
\begin{align*}
\text{RCH}_2\text{O} & \quad \xrightarrow{\text{Br}} \quad \text{RCH}_2\text{O} \\
\end{align*}
\]

19-26. Lactones with rings of more than six members may be synthesized if ring strain and transannular interactions are minimized (see Sections 4-2 through 4-5 and 9-6). One of the most important commercial musk fragrances is a dilactone, ethylene brassylate. Its synthesis, illustrated here, begins with acid-catalyzed reaction of tridecanedioic acid with 1,2-ethanediol, which yields a substance A with the molecular formula \(\text{C}_{15}\text{H}_{28}\text{O}_{5}\). Under the conditions in which it forms, substance A converts into a polymer (lower left structure). Strong heating reverses polymer formation, regenerating substance A. In a slower process, it transforms into the final macrocyclic product.
Commercial Synthesis of a Macrocyclic Musk

\[
\begin{align*}
\text{Tridecanedioic acid} & \quad \text{(Brassylic acid)} \\
\text{1,2-Ethandiol} & \quad \text{(Ethylene glycol)}
\end{align*}
\]

\[
\text{HO} \quad \text{(lower right structure), which is distilled from the reaction mixture, thereby shifting the equilibria in its favor.}
\]

\[
O \quad \text{O} \quad \text{O} \\
\text{O} \quad \text{C} - (\text{CH}_2)_{11} - \text{C} \quad \text{O} \quad \text{OH} \\
\text{HO} \quad \text{OH} \\
\text{HOCH}_2\text{CH}_2\text{OH} \\
\text{HOCH}_2\text{CH}_2\text{OH}
\]

\[
\begin{align*}
\text{HO} & \quad \text{(lower right structure), which is distilled from the reaction mixture, thereby shifting the equilibria in its favor.}
\end{align*}
\]

a. Suggest a structure for compound A.

SOLUTION

What information do we possess regarding this compound? We have its molecular formula and the structures both of its immediate precursors and of two of its products. It is possible to arrive at the solution by using any of these clues. For example, the polymeric product is constructed of repeating monomer units, each of which contains an ethylene glycol ester of brassylic acid, just missing the OH from the carboxy group at the left and the H from the hydroxy group at the right. Indeed, the formula of this unit is C\(_{15}\)H\(_{26}\)O\(_4\), or structure A less one molecule of water. If we simply write its structure and then add the missing elements of a molecule of water, we get A, the monoester shown.

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{O} & \quad \text{B} \quad \text{O} \\
\text{O} & \quad \text{B} \quad \text{O} \\
\text{B} & \quad \text{O} \\
\text{N} & \quad \text{OO} \\
\text{C} & \quad \text{H}_{28} \text{O}_5
\end{align*}
\]

To use another approach, the molecular formulas of the two starting materials add up to C\(_{15}\)H\(_{30}\)O\(_6\), or A + H\(_2\)O. Therefore, A is the product of a reaction that combines brassycic acid and ethylene glycol, and releases a molecule of water in the process, exactly what is observed in esterification.

b. Propose mechanisms for the reactions that interconvert structure A with both the polymer and the macrocycle.

SOLUTION

Both reactions are examples of esterifications. Polymer formation begins with ester formation between the hydroxy group of one molecule of structure A and the carboxy group of another. We follow the pattern of addition–elimination (Section 19-9), making use of acid catalysis as specified in the original equation. Remember: The answers to mechanism problems should make use of only those chemical species actually specified in the reaction. The mechanistic sequence of steps is adapted directly from the text examples: (1) protonation of the carbonyl carbon to be attacked, (2) nucleophilic addition of a hydroxy oxygen to form the tetrahedral intermediate, (3) protonation of one hydroxy group of the intermediate to form a good leaving group, (4) departure of water, and (5) proton loss from oxygen to yield the final product.
The product of this process is a dimer; repetition of such ester formation many times at both ends of this molecule eventually gives rise to the polyester observed in the reaction. The same steps take place in reverse to convert the polymer back into monoester A upon heating.

What about the mechanism for macrocyclic lactone formation? We realize that the process must be intramolecular to form a ring (compare Sections 9-6 and 17-7). We can write exactly the same sequence of steps as we did for esterification, but we use the free hydroxy group at one end of molecule A to attack the carboxy carbon at the other end.
Macrocyclic lactone synthesis is a topic of considerable interest to the pharmaceutical industry because this function constitutes the basic framework of many medicinally valuable compounds. Examples include erythromycin A, a widely used macrolide antibiotic (Chemical Highlight 20-2), and tacrolimus (FK-506), a powerful immunosuppressant that shows great promise in controlling the rejection of transplanted organs in human patients.

New Reactions

\text{RCOOH} & \rightarrow \text{RCH}_2\text{OH} \\
1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O} & \\
2. \text{H}^+, \text{H}_2\text{O}
\end{align*}
\]

12. Bromination: Hell-Volhard-Zelinsky Reaction (Section 19-12)

\[
\begin{align*}
\text{RCH}_2\text{COOH} & \xrightarrow{\text{Br}_2, \text{trace P}} \text{RCHCOOH}
\end{align*}
\]
Important Concepts

1. **Carboxylic acids** are named as alkanoic acids. The carbonyl carbon is numbered 1 in the longest chain incorporating the carboxy group. Dicarboxylic acids are called alkanedioic acids. Cyclic and aromatic systems are called cycloalkanecarboxylic and benzoic acids, respectively. In these systems the ring carbon bearing the carboxy group is assigned the number 1.

2. The carboxy group is approximately trigonal planar. Except in very dilute solution, carboxylic acids form dimers by hydrogen bonding.

3. The carboxylic acid proton chemical shift is variable but relatively high ($\delta = 10–13$), because of hydrogen bonding. The carbonyl carbon is also relatively deshielded but not as much as in aldehydes and ketones, because of the resonance contribution of the hydroxy group. The carboxy function shows two important infrared bands, one at about 1710 cm$^{-1}$ for the C=O bond and a very broad band between 2500 and 3300 cm$^{-1}$ for the O–H group. The mass spectrum of carboxylic acids shows facile fragmentation in three ways.

4. The carbonyl group in carboxylic acids undergoes nucleophilic displacement via the addition–elimination pathway. Addition of a nucleophile gives an unstable tetrahedral intermediate that decomposes by elimination of the hydroxy group to give a carboxylic acid derivative.

5. Lithium aluminum hydride is a strong enough nucleophile to add to the carbonyl group of carboxylate ions. This process allows the reduction of carboxylic acids to primary alcohols.

Problems

27. Name (IUPAC or Chemical Abstracts system) or draw the structure of each of the following compounds.

(a) $\text{CH}_2\text{Cl}_2\text{CO}_2\text{H}$  
(b) $\text{O}\text{H}\text{C}\text{OH}$  
(c) $\text{BrC}\text{C}\text{H}\text{C}\text{H}_3\text{CO}_2\text{H}$  
(d) $\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$  
(e) $\text{HO}_2\text{C}\text{O}_2\text{H}$  
(f) $\text{O}\text{H}\text{C}\text{C}\text{H}$  
(g) $\text{CO}_2\text{H}$  
(h) Phtholic acid  
(i) 4-Aminobutanoic acid (also known as GABA, a critical participant in brain biochemistry);  
(j) meso-2,3-dimethylbutanedioic acid;  
(k) 2-oxopropanoic acid (pyruvic acid);  
(l) trans-2-formyl-cyclohexanecarboxylic acid;  
(m) (Z)-3-phenyl-2-butenoic acid;  
(n) 1,8-naphthalenedicarboxylic acid.

28. Name each of the following compounds according to IUPAC or Chemical Abstracts. Pay attention to the order of precedence of the functional groups.

(a) $\text{HO}\text{C}\text{H}$  
(b) $\text{C}\text{O}_2\text{H}$  
(c) $\text{CO}_2\text{H}$  
(d) $\text{CH}_2\text{NO}_2\text{R}$

29. Rank the group of molecules shown here in decreasing order of boiling point and solubility in water. Explain your answers.

30. Rank each of the following groups of organic compounds in order of decreasing acidity.

(a) $\text{CH}_3\text{CH}_2\text{CO}_2\text{H}, \text{CH}_3\text{CCH}_2\text{OH}, \text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$  
(b) $\text{BrCH}_2\text{CO}_2\text{H}, \text{ClCH}_2\text{CO}_2\text{H}, \text{FCH}_2\text{CO}_2\text{H}$
31. Propose a structure for a compound that displays the spectroscopic data that follow. The molecular ion in the mass spectrum appears at \( m/z = 116 \). IR \( \tilde{\nu} = 1710 \) (s) and 3000 (s, broad) cm\(^{-1}\). \(^1\)H NMR: \( \delta = 0.94 \) (t, \( J = 7.0 \) Hz, 6 H), 1.59 (m, 4 H), 2.36 (quin, \( J = 7.0 \) Hz, 1 H), and 12.04 (broad s, 1 H) ppm; \(^{13}\)C NMR: 11.7, 24.7, 48.7, and 183.0 ppm.
Reactions of Carboxylic Acids

1. $\text{RCOR'}$ → $\text{RCO}^+$
   - 9-4, 19-9
2. $\text{ROH}$ → $\text{RC}^+$
   - 19-4
3. $\text{R'OH, H}^+$ → $\text{OH}$
4. $\text{RCX}$ (X = Cl, Br) → $\text{RCO}^+$
   - 19-8
5. $\text{ROCCl}$ → $\text{R'}$
   - 19-8
6. $\text{R'Cl}$ → $\text{R'}$
   - 19-10, 26-4, 26-6, 26-7
7. $\text{RCH}_2\text{OH}$ → $\text{RCH}_2\text{COH}$
   - 23-2
8. $\text{RCH}_2\text{COH}$ → $\text{RCH}_2\text{COOH}$
   - 23-2
9. $\text{RCH}_2\text{COOH}$ → $\text{RCH}$
   - 24-9
10. $\text{Br}_2, \text{P}$ → $\text{Br}^-$

Substrate:
- $\text{RCH}_2\text{COH}$
- $\text{HOOCCHCOOH}$
- $\text{RCH}_2\text{COOH}$
- $\text{RCH}$

Reagents:
- $\text{SOCl}_2$
- $\text{PBr}_3$
- $\text{LiAlH}_4$
- $\text{Fe}^{3+}, \text{H}_2\text{O}_2$

Additional reactions:
- $\text{RCCH}_2\text{R}$ → $\text{RCCH}_{2}\text{R'}$
- $\text{RCCHOH}$ → $\text{RCCOOH}$
- $\text{RCH}_2\text{OH}$ → $\text{RCH}_2\text{COH}$
- $\text{RCH}_2\text{COH}$ → $\text{RCH}_2\text{COOH}$
- $\text{RCH}_2\text{COOH}$ → $\text{RCH}$

Equations:
- $\text{RCOR'} + \text{H}_2\text{O} \rightarrow \text{RCOOH} + \text{R'}\text{OH}$
- $\text{RCO}^+ + \text{Cl}^- \rightarrow \text{RCOCI}$
- $\text{RCOCI} + \text{H}_2\text{O} \rightarrow \text{RCO}^+ + \text{H}_2\text{O}_2$
- $\text{RCOR} + \text{Br}_2 \rightarrow \text{RCCl} + \text{HBr}$
- $\text{RCH}_2\text{OH} + \text{LiAlH}_4 \rightarrow \text{RCH}_2\text{COH}$
- $\text{RCH}_2\text{COH} + \text{Fe}^{3+}, \text{H}_2\text{O}_2 \rightarrow \text{RCH}_2\text{COOH}$
32. (a) An unknown compound A has the formula C\textsubscript{7}H\textsubscript{12}O\textsubscript{2} and infrared spectrum A (p. 917). To which class does this compound belong? (b) Use the other spectra (NMR-B, p. 917, and F, p. 919; IR-D, E, and F, pp. 918–919) and spectroscopic and chemical information in the reaction sequence to determine the structures of compound A and the other unknown substances B through F. References are made to relevant sections of earlier chapters, but do not look them up before you have tried to solve the problem without the extra help. (c) Another unknown compound, G, has the formula C\textsubscript{8}H\textsubscript{14}O\textsubscript{4} and the NMR and IR spectra labeled G (p. 920). Propose a structure for this molecule. (d) Compound G may be readily synthesized from B. Propose a sequence that accomplishes this efficiently. (e) Propose a completely different sequence from that shown in (b) for the conversion of C into A. (f) Finally, construct a synthetic scheme that is the reverse of that shown in (b); namely, the conversion of A into B.

\[ \text{C}_6\text{H}_{10} \xrightarrow{1. \text{Hg(OCCH}_3)_2, \text{H}_2\text{O}} \text{C}_6\text{H}_{12}\text{O} \xrightarrow{2. \text{NaBH}_4} \text{C}_6\text{H}_{12}\text{O} \]

\( ^{13}\text{C} \text{ NMR}: \delta = 22.1 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 24.4 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 25.9 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 35.5 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 69.5 \) ppm

\( ^{1}\text{H} \text{ NMR-B} \)

\[ \text{C}_6\text{H}_{10} \xrightarrow{\text{P}} \text{C}_6\text{H}_{12} \xrightarrow{\text{P}} \text{C}_6\text{H}_{12} \text{O} \xrightarrow{1. \text{BH}_3, \text{THF}} \text{C}_6\text{H}_{14}\text{O} \xrightarrow{2. \text{Ho}^+, \text{H}_2\text{O}_2} \text{A} \]

\( ^{13}\text{C} \text{ NMR}: \delta = 23.8 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 26.5 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 40.4 \)
\( ^{13}\text{C} \text{ NMR}: \delta = 208.5 \) ppm

\( ^{1}\text{H} \text{ NMR-F} \)

33. Give the products of each of the following reactions.

(a) \((\text{CH}_3)_2\text{CHCH}_2\text{CO}_2\text{H} + \text{SOCl}_2 \rightarrow \)

(b) \((\text{CH}_3)_2\text{CHCH}_2\text{CO}_2\text{H} + \text{CH}_3\text{COBr} \rightarrow \)

(c) \(\text{COOH} + \text{CH}_3\text{CH}_2\text{OH} \rightarrow \text{H}^+ \rightarrow \)

(d) \(\text{CH}_3\text{O} \xrightarrow{\text{COOH} + \text{NH}_3} \)

(e) Product of (d), heated strongly

(f) Phthalic acid [Problem 27(h)], heated strongly

34. When 1,4- and 1,5-dicarboxylic acids, such as butanedioic (succinic) acid (Section 19-8), are treated with \text{SOCl}_2 or \text{PBr}_3 in attempted preparations of the diacyl halides, the corresponding cyclic anhydrides are obtained. Explain mechanistically.

35. Reaction review. Without consulting the Reaction Road Map on p. 914, suggest reagents to convert each of the following starting materials into hexanoic acid: (a) hexanal; (b) methyl hexanoate; (c) 1-bromopentane; (d) 1-hexanol; (e) hexanenitrile.

36. Reaction review II. Without consulting the Reaction Road Map on p. 915, suggest reagents to convert hexanoic acid into each of the following compounds: (a) 1-hexanol; (b) hexanoic anhydride; (c) hexanoyl chloride; (d) 2-bromohexanoic acid; (e) ethyl hexanoate; (f) hexanamide.

37. Fill in suitable reagents to carry out the following transformations.

(a) \((\text{CH}_3)_2\text{CHCH}_2\text{CHO} \rightarrow (\text{CH}_3)_2\text{CHCH}_2\text{CO}_2\text{H} \)

(b) \((\text{CH}_3)_2\text{CHO} \rightarrow \)

(c) \(\text{Br} \rightarrow \text{CO}_2\text{H} \)

(d) \((\text{CH}_3)_2\text{CHCl} \rightarrow \text{OH} \rightarrow \)

(e) \((\text{CH}_3)_2\text{CO}_2\text{H} \rightarrow \)

(f) \((\text{CH}_3)_2\text{CO}_2\text{H} \rightarrow (\text{CH}_3)_2\text{CO}_2\text{CH}(\text{CH}_3)_2 \)

Propose syntheses of each of the following carboxylic acids that employ at least one reaction that forms a carbon–carbon bond.

(a) $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$

(b) $\text{CH}_3\text{CHCH}_2\text{CO}_2\text{H}$

(c) $\text{H}_3\text{C}\begin{array}{c} \text{C} \\ \text{CH}_3 \end{array}\text{CO}_2\text{H}$
39. (a) Write a mechanism for the esterification of propanoic acid with $^{18}$O-labeled ethanol. Show clearly the fate of the $^{18}$O label. (b) Acid-catalyzed hydrolysis of an unlabeled ester with $^{18}$O-labeled water ($\text{H}_2^{18}\text{O}$) leads to incorporation of some $^{18}$O into both oxygens of the carboxylic acid product. Explain by a mechanism. (Hint: You must use the fact that all steps in the mechanism are reversible.)
40. Give the products of reaction of propanoic acid with each of the following reagents.

(a) SOCl₂  
(b) PBr₃  
(c) CH₃CH₂COBr + pyridine  
(d) (CH₃)₂CHOH + HCl

(e) CH₂NH₂  
(f) Product of (e), heated strongly  
(g) LiAlH₄, then H⁺, H₂O  
(h) Br₂, P

41. Give the product of reaction of cyclopentanecarboxylic acid with each of the reagents in Problem 40.
42. **CHALLENGE** When methyl ketones are treated with a halogen in the presence of base, the three hydrogen atoms on the methyl carbon are replaced to give a CX₃-substituted ketone. This product is not stable under the basic conditions and proceeds to react with hydroxide, ultimately furnishing the carboxylic acid (as its conjugate base) and a molecule of HCX₃, which has the common name *haloform* (i.e., chloroform, bromoform, and iodoform, for X = Cl, Br, and I, respectively). For example:

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{RCCBr}_3 & + \quad \text{OH} \quad \longrightarrow \quad \text{RCO}_2^- & + \quad \text{HBr}_3
\end{align*}
\]

Propose a series of mechanistic steps to convert the tribromoketone into the carboxylate. What is the leaving group? Why do you think this species is capable of acting as a leaving group in this process?

43. Interpret the labeled peaks in the mass spectrum of 2-methylhexanoic acid (MS-H).

![Mass Spectrum](image)

**MS-H**

44. Suggest a preparation of hexanoic acid from pentanoic acid.

45. Give reagents and reaction conditions that would allow efficient conversion of 2-methylbutanoic acid into (a) the corresponding acyl chloride; (b) the corresponding methyl ester; (c) the corresponding ester with 2-butanol; (d) the anhydride; (e) the N-methylamide;

\[
\begin{align*}
\text{(f) CH}_3\text{CH}_2\text{CHCH}_2\text{OH} & \quad \text{(g) CH}_3\text{CH}_2\text{CCO}_2\text{H} \\
\text{Br} & \quad \text{CH}_3
\end{align*}
\]

46. Treatment of 4-pentenoic acid (margin) with Br₂ in the presence of dilute aqueous base yields a nonacidic compound with the formula C₅H₇BrO₂. (a) Suggest a structure for this compound and a mechanism for its formation. (b) Can you find a second, isomeric product whose formation is also mechanistically reasonable? (c) Discuss the issues that contribute to determining which of the two is the major product in this reaction. (Hint: Review Section 12-6.)

47. Show how the Hell-Volhard-Zelinsky reaction might be used in the synthesis of each of the following compounds, beginning in each case with a simple monocarboxylic acid. Write detailed mechanisms for all the reactions in one of your syntheses.
48. The Hell-Volhard-Zelinsky reaction produces only bromocarboxylic acids. However, modified procedures have been developed to convert acyl chlorides into α-chloro- and α-bromoacyl chlorides by reaction with N-chloro- and N-bromobutanimide (N-chloro- and N-bromosuccinimide, NCS and NBS: Section 14-2), respectively. Reaction with I₂ gives α-iodoacyl chlorides. (SOCl₂ is used as the solvent to maintain the acyl chloride functional group.) Suggest a mechanism for any one of these processes.

\[
\begin{align*}
\text{(a)} & \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{COCl} \\
\text{(b)} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{COCl} \\
\text{(c)} & \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{COCl} \\
\text{(d)} & \quad \text{HO}_2\text{CCH}_3\text{SSCH}_2\text{CO}_2\text{H} \\
\text{(e)} & \quad \text{(CH}_3\text{CH}_2\text{)}_2\text{NCH}_2\text{CO}_2\text{H} \\
\text{(f)} & \quad \text{(C}_6\text{H}_5\text{)}_3\text{PCH}_2\text{CO}_2\text{H Br}^{-} \\
\end{align*}
\]

49. How would you expect the acidity of acetamide to compare with that of acetic acid? With that of acetone? Which protons in acetamide are the most acidic? Where would you expect acetamide to be protonated by very strong acid?

50. Attempted CrO₃ oxidation of 1,4-butanediol to butanedioic acid results in significant yields of “γ-butyrolactone.” Explain mechanistically.

51. Following the general mechanistic scheme given in Section 19-7, write detailed mechanisms for each of the following substitution reactions. (Note: These transformations are part of Chapter 20, but try to solve the problem without looking ahead.)

\[
\begin{align*}
\text{(a)} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CHClCOCl} \quad \text{NCS, HCl, SOCl}_2, 70^\circ\text{C} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CHClCOCl} \quad \text{84\%} \\
\text{b} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CHBrCOCl} \quad \text{NBS, HBr, SOCl}_2, 70^\circ\text{C} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CHBrCOCl} \quad \text{71\%} \\
\text{c} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CHICOCl} \quad \text{I}_2, HI, SOCl}_2, 85^\circ\text{C} & \quad \text{C}_6\text{H}_5\text{CH}_2\text{CHICOCl} \quad \text{75\%} \\
\end{align*}
\]

52. Suggest structures for the products of each reaction in the following synthetic sequence.
53. $S_{N}2$ reactions of simple carboxylate ions with haloalkanes (Section 8-5) in aqueous solution generally do not give good yields of esters. (a) Explain why this is so. (b) Reaction of 1-iodobutane with sodium acetate gives an excellent yield of ester if carried out in acetic acid (as shown here). Why is acetic acid a better solvent for this process than water?

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{I} + \text{CH}_3\text{CO}^-\text{Na}^+ \xrightarrow{\text{CH}_3\text{CO}_2\text{H}, 100^\circ\text{C}} \text{CH}_3\text{CH}_2\text{CH}_2\text{OCCH}_3 + \text{Na}^+\text{I}^-
\]

54. The iridoids are a class of monoterpenes with powerful and varied biological activities. They include insecticides, agents of defense against predatory insects, and animal attractants. The following reaction sequence is a synthesis of neonepetalactone, one of the nepetalactones, which are primary constituents of catnip. Use the information given to deduce the structures that have been left out, including that of neonepetalactone itself.

55. **Challenge** Propose two possible mechanisms for the following reaction. (Hint: Consider the possible sites of protonation in the molecule and the mechanistic consequences of each.) Devise an isotope-labeling experiment that might distinguish your two mechanisms.

56. Propose a short synthesis of 2-butynoic acid, $\text{CH}_3\text{C}≡\text{CCO}_2\text{H}$, starting from propyne. (Hint: Review Sections 13-2 and 13-5.)

57. The benzene rings of many compounds in nature are prepared by a biosynthetic pathway similar to that operating in fatty acid synthesis. Acetyl units are coupled, but the ketone functions are not reduced. The result is a polyketide thiolester, which forms rings by intramolecular aldol condensation.
**Carboxylic Acids**

\[
\text{CH}_3\text{C}\text{H}_2\text{C}\text{H}_2\text{C}\text{H}_2\text{C}-\text{S}\text{protein} \\
\text{Polyketide thiolester}
\]

\(\text{o-Orsellinic acid [for structure, see Problem 27(g)] is a derivative of salicylic acid and is prepared biosynthetically from the polyketide thiolester shown. Explain how this transformation might take place. Hydrolysis of the thiolester to give the free carboxylic acid is the last step.}

**Team Problem**

58. Section 19-9 showed you that 4- and 5-hydroxy acids can undergo acid-catalyzed intramolecular esterification to produce the corresponding lactone in good yield. Consider the following two examples of lactonization. Divide the analysis of the reaction sequences among your group. Propose reasonable mechanisms to explain the respective product formation.

Reconvene to present your mechanisms to each other.

**Preprofessional Problems**

59. What is the IUPAC name of the compound shown?

(a) \((E)-3\)-Methyl-2-hexenoic acid  
(b) \((Z)-3\)-Methyl-2-hexenoic acid  
(c) \((E)-3\)-Methyl-3-hexenoic acid  
(d) \((Z)-3\)-Methyl-3-hexenoic acid

60. Select the acid with the highest \(K_a\) (i.e., lowest \(pK_a\)).

(a) \(\text{H}_3\text{C}\text{CO}_2\text{H}\)  
(b)  
(c)  
(d) \(\text{Cl}_2\text{CH}\text{CO}_2\text{H}\)

61. The acid whose structure is shown in the margin can best be prepared via one of these sequences. Which one?

(a) \(\text{H}_3\text{C}\text{Br} + \text{Br}_3\text{C}\text{CO}_2\text{H} \xrightarrow{\text{K}} \text{Benzene}\)

(b) \((\text{CH}_3)_3\text{C}\text{I} \xrightarrow{\text{Mg, ether}} \text{CO}_2\xrightarrow{\text{H}^+, \text{H}_2\text{O (work-up)}}\)

(c) \( \text{C(CH}_3)_3 \xrightarrow{\text{K}\text{MnO}_4} \)

(d) \( \text{H}_3\text{C} \xrightarrow{\text{K}\text{MnO}_4} \text{C(CH}_3)_3 \)
When complex organic systems have evolved in nature, they are frequently made by the combination of carboxyl carbonyl groups and the heteroatoms of alcohols, amines, or thiols. Why? The addition–elimination processes introduced in Chapter 19 provide mechanistic pathways of relatively low activation energy for the interconversion of variously substituted carboxylic acid derivatives, many of which play central roles in biology (Chapter 26). Chemists find these compounds similarly useful, as we shall see in this chapter, which deals with the chemistry of four major carboxylic acid derivatives: halides, anhydrides, esters, and amides. Each has a substituent, $L$, that can function as a leaving group in substitution reactions. We already know, for instance, that displacement of the halide in $RCX$ by a carboxy group leads to anhydrides.

$\text{Carboxylic acid derivatives}$

We begin with a comparison of the structures, properties, and relative reactivities of carboxylic acid derivatives. We then explore the chemistry of each type of compound. Halides and anhydrides are valuable reagents in the synthesis of other carbonyl compounds. Esters and amides are enormously important in nature; for example, the esters include common flavoring agents, waxes, fats, and oils; among the amides we find urea and penicillin. The alkanenitriles, $RC\equiv N$, are also treated here because they have similar reactivity.

The sturdiness of the amide linkage is amply demonstrated by the properties of poly($p$-phenylene terephthalamide), which is used in bulletproof vests and body armor under the commercial name of Kevlar. Developed by DuPont chemist Stephanie Kwolek, Kevlar is 16 times as stiff as nylon, the polymer formerly used in such applications. Kevlar's properties derive from the planarity of its benzene rings combined with restricted rotation about the amide linkages (Section 20-6). Thousands of law enforcement officers owe their lives to this remarkable material, which can stop the bullet from a 9-mm handgun traveling at 1200 feet per second.
20-1 Relative Reactivities, Structures, and Spectra of Carboxylic Acid Derivatives

Carboxylic acid derivatives undergo substitution reactions with nucleophiles, such as water, organometallic compounds, and hydride reducing agents. These transformations proceed through the familiar (often acid- or base-catalyzed) addition–elimination sequence (Section 19-7).

Addition–Elimination in Carboxylic Acid Derivatives

The relative reactivities of the substrates follow a consistent order: Acyl halides are most reactive, followed by anhydrides, then esters, and finally the amides, which are least reactive.

Relative Reactivities of Carboxylic Acid Derivatives
in Nucleophilic Addition–Elimination with Water

The order of reactivity depends directly on the structure of L: how good a leaving group it is and what effect it has on the adjacent carbonyl function. This effect can be understood by looking at the degree to which the various resonance forms A–C contribute to the structure of the carboxylic acid derivative. In this picture, B is a very minor contributor, because it is an electron sextet structure. We have used such forms only to emphasize the polarity of the carbonyl function. This leaves us with A and the dipolar alternative C. A will always be major, because it has no charge separation (Section 1-5). The question is to what extent C helps to stabilize the functional group by delocalization of the lone pairs on the substituent L onto the carbonyl oxygen.

Resonance in Carboxylic Acid Derivatives

Nonoctet, minor
The answer to this question lies in the electronegativity of L: Decreasing electronegativity goes with increasing contribution of C. As we saw in Section 6-7, decreasing electronegativity also goes hand in hand with decreasing leaving-group ability, and in turn with decreasing acidity of the conjugate acid.

Thus, dipolar resonance form C is most important when L is NR₂, because nitrogen is the least electronegative atom in the series. Consequently, amides are the least reactive carboxylic acid derivatives. In esters, the contribution of C is somewhat diminished, because oxygen is more electronegative than nitrogen. Nonetheless, resonance remains strong (see also Section 16-1) and, while esters are more reactive than amides, they are still rather resistant to nucleophilic attack. On the other hand, in anhydrides, the lone pairs on the central oxygen are shared by two carbonyl groups, making them less available for resonance as in C. For that reason, they are more reactive than esters. Finally, acyl halides are the most reactive for two reasons: relative electronegativity (F, Cl; Table 1-2) and poor overlap of the large halogen π orbitals (Cl, Br, I; Section 1-6) with the relatively small 2π lobes of the carbonyl carbon. The electrostatic potential maps in the margin depict examples of the two extremes: acetyl chloride and acetamide. In the chloride, the carbonyl carbon is much more positively charged (blue) than in the amide (green). Simultaneously, the extent of electron donation by the L group (Cl versus NH₂) is greater in the amide, as indicated by the greater negative charge on the carbonyl oxygen (red).

**Exercise 20-1**

**Working with the Concepts: Relative Reactivity of Carboxylic Acid Derivatives**

Phosgene, phenylmethyl chloroformate, bis(1,1-dimethylethyl) dicarbonate, dimethyl carbonate, and urea are derivatives of carbonic acid H₂CO₃ (made by dissolving CO₂ in water). Rank them in order of decreasing reactivity in nucleophilic addition–eliminations.

- Phosgene
- Phenylmethyl chloroformate
- Bis(1,1-dimethylethyl) dicarbonate
- Dimethyl carbonate
- Urea

**Strategy**

All of these compounds possess heteroatom (O, N, or halogen)-containing substituents on both sides of the carbonyl carbon, as does carboxylic acid, HOOCOH. The arguments about relative reactivity of carboxylic acid derivatives made in this section apply here in the same way.

**Solution**

• To a first approximation, the effects of the substituents on either side of the carbonyl carbon may be considered to be additive. The only difference is that the effect of the second substituent on the carbonyl is somewhat reduced, because the two groups have to compete with each other for resonance with the C=O π bond.
• Thus phosgene, with halogens on both sides, may be considered as a “double acyl halide” and is the most reactive.
• Reactivity decreases in the order in which the compounds are illustrated: The chloroformate is “half halide/half ester”; both carbonyls in the dicarbonate are “half anhydride/half ester”; the carbonate is a “double ester”; and urea is a “double amide” and the least reactive.
The greater the resonance, the shorter the C–L bond

The extent of resonance can be observed directly in the structures of carboxylic acid derivatives. In the progression from acyl halides to esters and amides, the C–L bond becomes progressively shorter, owing to increased double-bond character (Table 20-1). The NMR spectra of amides reveal that rotation about this bond has become restricted. For example, N,N-dimethylformamide at room temperature exhibits two singlets for the two methyl groups, because rotation about the C–N bond is very slow on the NMR time scale. The evidence points to considerable π overlap between the lone pair on nitrogen and the carbonyl carbon, as a result of the increased importance of the dipolar resonance form in amides. The measured barrier to this rotation is about 21 kcal mol⁻¹ (88 kJ mol⁻¹).

**Exercise 20-3**

The methyl group in the ¹H NMR spectrum of 1-acetyl 2-phenylhydrazide, shown in the margin, exhibits two singlets at δ = 2.02 and 2.10 ppm at room temperature. Upon heating to 100°C in the NMR probe, the same compound gives rise to only one signal in that region. Explain.

**Table 20-1**

Exercise 20-4

The mass spectrum of methyl pentanoate (molecular weight = 116) shows fragmentation peaks at m/z = 85, 74, and 57. Assign these peaks.

**Carboxylic acid derivatives are basic and acidic**

The extent of resonance in carboxylic acid derivatives is also seen in their basicity (protonation at the carbonyl oxygen) and acidity (enolate formation). In all cases, protonation requires strong acid, but it gets easier as the electron-donating ability of the L group increases. Protonation is important in acid-catalyzed nucleophilic addition–elimination reactions.
Protonation of a Carboxylic Acid Derivative

\[ \text{RCO}^+ \xrightarrow{H^+} \text{RC}^+ \xrightarrow{H^+} \text{R}^+ \text{C}^+ \xrightarrow{H^+} \text{R}^+ \text{C}^+ \]

A relatively strong contribution of this resonance form stabilizes the protonated species.

Exercise 20-5

The oxygen in acetyl chloride is much less basic than the one in acetamide. Explain, using resonance structures.

For related reasons, the acidity of the hydrogens next to the carbonyl group increases along the series. The acidity of a ketone lies between those of an acyl chloride and an ester.

Acidity of α-Hydrogens in Carboxylic Acid Derivatives in Comparison with Acetone

\[
pK_a \quad \begin{array}{cccc}
\text{CH}_3\text{CN(CH}_3)_2 & < & \text{CH}_3\text{COCH}_3 & < & \text{CH}_3\text{CCH}_3 & < & \text{CH}_3\text{CCl} \\
\approx 30 & ~ & ~ & ~ & ~ & ~ & ~
\end{array}
\]

Exercise 20-6

Give an example of a reaction from Chapter 19 that takes advantage of the relatively high acidity of the α-hydrogens in acyl halides.

In Summary

The relative electronegativity and the size of L in RCL controls the extent of resonance of the lone electron pair(s) and the relative reactivity of a carboxylic acid derivative in nucleophilic addition–elimination reactions. This effect manifests itself structurally and spectroscopically, as well as in the relative acidity and basicity of the α-hydrogen and the carbonyl oxygen, respectively.

20-2 Chemistry of Acyl Halides

The acyl halides, RCX, are named after the alkanoic acid from which they are derived. The halides of cycloalkanecarboxylic acids are called cycloalkane carboxyl halides.

Acyl halides undergo addition–elimination reactions in which nucleophiles displace the halide leaving group. These compounds are so reactive that catalysts are usually not necessary for their conversion.
Figure 20-1 shows a variety of nucleophilic reagents and the corresponding products. It is because of this wide range of reactivity that acyl halides are useful synthetic intermediates. Let us consider these transformations one by one (except for anhydride formation, which was covered in Section 19-8). Examples will be restricted to acyl chlorides, which are the most readily accessible, but their transformations can be generalized to a considerable extent to the other acyl halides.

**Water hydrolyzes acyl chlorides to carboxylic acids**

Acyl chlorides react with water, often violently, to give the corresponding carboxylic acids and hydrogen chloride. This transformation is a simple example of addition–elimination and is representative of most of the reactions of this class of compounds.

**Acyl Chloride Hydrolysis**

\[
\text{CH}_3\text{CH}_2\text{CCl} + \text{HOH} \longrightarrow \text{CH}_3\text{CH}_2\text{COH} + \text{HCl} \\
100\% \\
\text{Propanoyl chloride} \\
\text{Propanoic acid}
\]

**Mechanism of Acyl Chloride Hydrolysis**

Acyl chlorides react with water, often violently, to give the corresponding carboxylic acids and hydrogen chloride. This transformation is a simple example of addition–elimination and is representative of most of the reactions of this class of compounds.

**Alcohols convert acyl chlorides into esters**

The analogous reaction of acyl chlorides with alcohols is a highly effective way of producing esters. A base such as an alkali metal hydroxide, pyridine, or a tertiary amine is usually added to neutralize the HCl by-product. Because acyl chlorides are readily made from the corresponding carboxylic acids (Section 19-8), the sequence RCOOH $\xrightarrow{}$ RCOCl $\xrightarrow{}$ RCOOR$'$ is a good method for esterification. By maintaining neutral or basic conditions, this preparation avoids the equilibrium problem of acid-catalyzed ester formation (Fischer esterification, Section 19-9).

Exercise 20-7

You have learned that 2-methyl-2-propanol (tert-butyl alcohol) dehydrates in the presence of acid (Section 9-2). Suggest a synthesis of 1,1-dimethylethyl acetate (tert-butyl acetate, shown in the margin) from acetic acid. Avoid conditions that might dehydrate the alcohol.

Amines convert acyl chlorides into amides

Secondary and primary amines, as well as ammonia, convert acyl chlorides into amides. As shown in the first example below, aqueous ammonia works quite well for the synthesis of simple amides: \( \text{NH}_3 \), being a much stronger nucleophile than water, reacts preferentially with the carbonyl derivative. As in ester formation, the \( \text{HCl} \) formed is neutralized by added base (which can be excess amine).

**Amides from Acyl Halides**

\[
\text{PhCCl} + \text{NH}_3 \xrightarrow{\text{H}_2\text{O}} \text{PhCONH}_2 + \text{NH}_4\text{Cl} \quad 86\%

\]

Propenoyl chloride  \( N \)-Methylpropenamide

The mechanism of this transformation is, again, addition–elimination, beginning with attack of the nucleophilic amine nitrogen at the carbonyl carbon.

**Mechanism of Amide Formation from Acyl Chlorides**

Note that in the last step, a proton must be lost from nitrogen to give the amide. Consequently, tertiary amines (which have no hydrogens on nitrogen) cannot form amides. Instead, they...
convert acyl halides to acyl ammonium salts. In these species, the nitrogen has no lone electron pair to stabilize the carbonyl function by resonance. On the contrary, the positive charge activates the carbonyl carbon to nucleophilic attack. Consequently, acyl ammonium salts show reactivity that is similar to those of acyl halides. A useful consequence of this behavior is that acylations of other functions can be carried out in the presence of tertiary amino substituents.

**Acetylation of a tert-Amino Alcohol**

![Acetylation reaction diagram]

**Exercise 20-8**

Some amide preparations from acyl halides require a primary or secondary amine that is too expensive to use also as the base to neutralize the hydrogen halide. Suggest a solution to this problem.

**Organometallic reagents convert acyl chlorides into ketones**

Organometallic reagents (RLi and RMgX) attack the carbonyl group of acyl chlorides to give the corresponding ketones. However, these ketone products are themselves prone to further attack by the relatively unselective organolithium (RLi) and Grignard (RMgX) reagents to give alcohols (see Section 8-8). Ketone formation is best achieved by using diorganocuprates (Section 18-10), which are more selective than RLi or RMgX and do not add to the product ketone.

**Formation of a Ketone from an Acyl Halide**

![Formation of a ketone from an acyl halide reaction diagram]

**Reduction of acyl chlorides results in aldehydes**

We can convert an acyl chloride into an aldehyde by hydride reduction. In this transformation, we again face a selectivity problem: Sodium borohydride and lithium aluminum hydride convert aldehydes into alcohols. To prevent such overreduction, we must modify LiAlH₄ by letting it react first with three molecules of 2-methyl-2-propanol (tert-butyl alcohol; see Section 8-6). This treatment neutralizes three of the reactive hydride atoms, leaving one behind that is nucleophilic enough to attack an acyl chloride but not the resulting aldehyde.

**Reductions by Modified Lithium Aluminum Hydride**

(a) \[\text{CH}_3\text{CH}₂\text{CH}_2\text{OH}\]

(b) \[\text{CH}_3\text{CH}₂\text{CH}_2\text{O}⁻\]

(c) \[\text{CH}_3\text{CH}₂\text{CH}_2\text{N(CH}_3\text{)}₂\]

(d) \[\text{CH}_3\text{CH}₂\text{CH}_2\text{CO}⁻\]

(e) \[\text{CH}_3\text{CH}₂\text{CH}_2\text{CH}₂\text{OH}\]

**In Summary** Acyl chlorides are attacked by a variety of nucleophiles, the reactions leading to new carboxylic acid derivatives, ketones, and aldehydes by addition–elimination mechanisms. The reactivity of acyl halides makes them useful synthetic relay points on the way to other carbonyl derivatives.

**20-3 Chemistry of Carboxylic Anhydrides**

Carboxylic anhydrides, \(\text{RCOCR}\), are named by simply adding the term *anhydride* to the acid name (or names, with regard to mixed anhydrides). This method also applies to cyclic derivatives.

1,2-Benzenedicarboxylic anhydride (Phthalic anhydride)

\[\text{CH}_3\text{COCCH}_3\]

Acetic propanoic anhydride (A mixed anhydride)

Acetic anhydride

2-Butenedioic anhydride (Maleic anhydride)

Pentanedioic anhydride (Glutaric anhydride)

The reactions of carboxylic anhydrides with nucleophiles, although less vigorous, are completely analogous to those of the acyl halides. The leaving group is a carboxylate instead of a halide ion.

Exercise 20-10

Treatment of butanedioic (succinic) anhydride with ammonia at elevated temperatures leads to a compound C\(_5\)H\(_5\)NO\(_2\). What is its structure? (Hint: Consult Section 19-10.)

Exercise 20-11

Formulate the mechanism for the reaction of acetic anhydride with methanol in the presence of sulfuric acid.

Although the chemistry of carboxylic anhydrides is very similar to that of acyl halides, anhydrides have some practical advantages. Acyl halides are so reactive that they are difficult to store for extended periods without some hydrolysis occurring due to exposure to atmospheric moisture. As a result, chemists usually prepare acyl halides immediately before they are to be used. Anhydrides, being slightly less reactive toward nucleophiles, are more stable, and several (including all the examples illustrated in this section) are commercially available. Consequently, carboxylic anhydrides are often the preferred reagents for the preparation of many carboxylic acid derivatives.
In Summary  Anhydrides react with nucleophiles in the same way as acyl halides do, except that the leaving group is a carboxylate ion. Cyclic anhydrides furnish dicarboxylic acid derivatives.

20-4 Chemistry of Esters

As mentioned in Section 19-9, esters, RCOR’, constitute perhaps the most important class of carboxylic derivatives. They are particularly widespread in nature, contributing especially to the pleasant flavors and aromas of many flowers and fruits. Esters undergo typical carbonyl chemistry but with reduced reactivity relative to that of either acyl halides or carboxylic anhydrides. This section begins with a discussion of ester nomenclature. Descriptions follow of the transformations that esters undergo with a variety of nucleophilic reagents.

Esters are alkyl alkanoates

Esters are named as alkyl alkanoates. The ester grouping, –COR, as a substituent is called alkoxy carbonyl. A cyclic ester is called a lactone (the common name, Section 19-9); the systematic name is oxacycloalkanone (Section 25-1). Its common name is preceded by α-, β-, γ-, δ-, and so forth, depending on ring size.

In addition to their prevalence in plants, esters play biological roles in the animal kingdom. Section 12-17 included several examples of esters that function as insect pheromones. Perhaps the most bizarre of these esters is \((Z)-7\text{-dodecenyl acetate}\), a component of the pheromone mixture in several species of moths. This same compound was recently found to also be the mating pheromone of the elephant (who said nature has no sense of humor?). Section 20-5 will describe a number of more conventional biological functions of esters.
Lactones (cyclic esters) are also widely distributed in nature. The ready availability of γ-valerolactone from renewable plant-derived sources has led to its serious consideration as a potential “green” biofuel. Problem 46(d) describes this development in more detail.

**Exercise 20-12**

Name the following esters.

(a) \[ \text{ester} \]

(b) \[ CH_3OCCH_2CH_2COCH_3 \]

(c) \[ CH_2=CHCO_2CH_3 \]

In industry, lower esters, such as ethyl acetate (b.p. 77°C) and butyl acetate (b.p. 127°C), are used as solvents. For example, butyl butanoate has replaced the ozone-depleting trichloroethane as a cleaning solvent in the manufacture of electronic components such as computer chips. Higher nonvolatile esters are used as softeners (called plasticizers; see Section 12-15) for brittle polymers—in flexible tubing (e.g., Tygon tubing), rubber pipes, and upholstery.

**Esters hydrolyze to carboxylic acids; the leaving-group problem**

Esters undergo nucleophilic substitution reactions by means of addition–elimination pathways, albeit with reduced reactivity relative to halides and anhydrides. Thus, catalysis by acid or base becomes a frequent necessity. For example, esters are cleaved to carboxylic acids and alcohols in the presence of excess water and strong acid, and the reaction requires heating to proceed at a reasonable rate. The mechanism of this transformation is the reverse of acid-catalyzed esterification (Section 19-9). As in esterification, the acid serves two purposes: It protonates the carbonyl oxygen to make the ester more reactive toward nucleophilic attack, and it protonates the alkoxy oxygen in the tetrahedral intermediate to make it a better leaving group.

**Exercise 20-13**

**Working with the Concepts: Ester Hydrolysis in Acid**

Formulate a mechanism for the acid-catalyzed hydrolysis of γ-butyrolactone.

**Strategy**
Find the structure of γ-butyrolactone (on the previous page). It is a cyclic ester. Find the general mechanism for addition–elimination under acidic conditions (Section 19-7). Substitute γ-butyrolactone for the general starting material in that mechanism, and proceed.

**Solution**

• Step by step: Begin with protonation of the carbonyl oxygen,

\[ \text{ester} \rightarrow \text{ester}^+ \]

• Continue with addition–elimination. Water is the nucleophile. Use protonation to turn the ring oxygen into a good leaving group. In the tetrahedral intermediate, cleave the bond between the (former) carbonyl carbon and the ring oxygen.

\[ \text{ester} \rightarrow \text{ester}^+ \rightarrow \text{ester}^+ \]

• Deprotonate the carbonyl oxygen. The mechanism is completed. You have your product.

\[ \text{ester} \rightarrow \text{ester}^+ \rightarrow \text{ester}^+ \]
Strong bases also promote ester hydrolysis through an addition–elimination mechanism (Sections 19-7 and 20-1). The base (B) converts the poor nucleophile water into the negatively charged and more highly nucleophilic hydroxide ion.

\[
\text{B}^- + \text{H}_2\text{O} \rightarrow \text{OH}^- + \text{B}^- \text{H}
\]

Ester hydrolysis is frequently achieved by using hydroxide itself, in at least stoichiometric amounts, as the base.

**Example of Ester Hydrolysis Using Aqueous Base**

\[
\begin{align*}
\text{OCH}_3 & \\
\text{1. KOH, H}_2\text{O, CH}_3\text{OH, } \Delta & \\
\text{2. H}^+ \text{, H}_2\text{O} & \\
\text{Methyl 3-methylbutanoate} & \rightarrow \text{3-Methylbutanoic acid} \\
\end{align*}
\]

**Mechanism of Base-Mediated Ester Hydrolysis**

**Step 1.** Addition–elimination

\[
\begin{align*}
\text{RCOCH}_3 + \text{OH}^- & \rightarrow \text{RCO}^- + \text{CH}_3\text{OH} \\
\text{Tetrahedral intermediate} & \\
\end{align*}
\]

**Step 2.** Deprotonation

\[
\begin{align*}
\text{RCO}^- + \text{CH}_3\text{OH}^- & \rightarrow \text{RCO}^- + \text{HOCH}_3 \\
\text{Favorable acid-base reaction of step 2 drives equilibrium of step 1} & \\
\end{align*}
\]

Ester hydrolysis in base (saponification, see Section 19-13) differs from the acid-catalyzed version in several ways. Consider the addition–elimination (step 1) first: The tetrahedral intermediate can revert to starting material by release of a hydroxide ion, or it can go forward toward product through expulsion of methoxide. Either way, the process requires loss of a poor leaving group. Both hydroxide and methoxide are strong bases, and strong bases are poor leaving groups (Section 6-7). How can these transformations take place at all?

The answer lies in part in the strength of the C=O bond and the associated stability of carbonyl compounds. The tetrahedral intermediate is so much higher in energy that its conversion to a carbonyl compound is typically exothermic even when a poor leaving group is expelled. In addition, the base-mediated process benefits from a very favorable acid-base reaction in step 2: The strong base methoxide, having been released at the addition–elimination stage, rapidly deprotonates the acid to give carboxylate ion. This step is very favorable and drives the entire hydrolysis sequence essentially to completion. Subsequent acidic aqueous work-up gives the carboxylic acid product.

**Exercise 20-14**

**Try It Yourself**

Formulate a mechanism for the base-mediated hydrolysis of γ-butyrolactone.
Transesterification takes place with alcohols

Esters react with alcohols in an acid- or base-catalyzed transformation called **transesterification**. This allows for the direct conversion of one ester into another without proceeding through the free acid. Like esterification, transesterification is a reversible reaction. To shift the equilibrium, a large excess of the alcohol is usually employed, sometimes in the form of solvent.

**Conversion of an Ethyl Ester into a Methyl Ester**

\[
\text{C}_{17}\text{H}_{35}\text{COCH}_{2}\text{CH}_{3} + \text{CH}_{3}\text{OH} \rightarrow \text{C}_{17}\text{H}_{35}\text{COCH}_{3} + \text{CH}_{3}\text{CH}_{2}\text{OH}
\]

**Conversion of a Lactone into an Open-Chain Ester**

Lactones are opened to hydroxy esters by transesterification.

The mechanisms of transesterification by acid and base are analogous to the mechanisms of the corresponding hydrolyses to the carboxylic acids. Thus, acid-catalyzed transesterification begins with protonation of the carbonyl oxygen, followed by nucleophilic attack of the alcohol on the carbonyl carbon. In contrast, under basic conditions the alcohol is first deprotonated, and the resulting alkoxide ion then adds to the ester carbonyl group.

**Exercise 20-15**

Formulate mechanisms for the acid- and base-catalyzed transesterifications of \(\gamma\)-butyrolactone by 3-bromo-1-propanol.

**Amines convert esters into amides**

Amines, which are more nucleophilic than alcohols, readily transform esters into amides. No catalyst is needed, but heating is required.

**Amide Formation from Methyl Esters**

**Uncatalyzed Conversion of an Ester into an Amide**

\[
\text{CH}_3\text{(CH}_2)_7\text{CH}==\text{CH(CH}_2)_2\text{COCH}_3 + \text{CH}_3\text{(CH}_2)_11\text{NH} \rightarrow \text{CH}_3\text{(CH}_2)_7\text{CH}==\text{CH(CH}_2)_2\text{C}N\text{H(CH}_2)_11\text{CH}_3 + \text{CH}_3\text{OH}
\]
Grignard reagents transform esters into alcohols

Esters can be converted into alcohols by using two equivalents of a Grignard reagent. In this way, ordinary esters are transformed into tertiary alcohols, whereas formate esters furnish secondary alcohols.

### Alcohols from Esters and Grignard Reagents

<table>
<thead>
<tr>
<th>Reaction</th>
<th>Product</th>

</tr>
</tbody>
</table>

The reaction begins with addition of the organometallic to the carbonyl function in the usual manner to give the magnesium salt of a hemiacetal (Section 17-7). At room temperature, rapid elimination results in the formation of an intermediate ketone (or aldehyde, from formates). The resulting carbonyl group then immediately adds a second equivalent of Grignard reagent (recall Section 8-8). Subsequent acidic aqueous work-up leads to the observed alcohol.

### Exercise 20-16

Propose a synthesis of triphenylmethanol, \((\text{C}_6\text{H}_5)_3\text{COH}\), beginning with methyl benzoate (shown in the margin) and bromobenzene.
Esters are reduced by hydride reagents to give alcohols or aldehydes

The reduction of esters to alcohols by LiAlH₄ requires 0.5 equivalent of the hydride, because only two hydrogens are needed per ester function.

**Reduction of an Ester to an Alcohol**

\[
\text{NCHCOCH₂CH₃} \rightarrow 1. \text{LiAlH}_4 (0.5 \text{ equivalent}), (\text{CH}_3\text{CH}_2)_2\text{O} \\
2. \text{H}^+, \text{H}_2\text{O} \rightarrow \text{NCHCH₂OH} \quad 90\%
\]

A milder reducing agent allows the reaction to be stopped at the aldehyde oxidation stage. Such a reagent is bis(2-methylpropyl)aluminum hydride (diisobutylaluminum hydride) when used at low temperatures in toluene.

**Reduction of an Ester to an Aldehyde**

\[
\text{H}_3\text{C} \quad \text{O} \\
\text{CH}_3\text{CHCOCH₂CH₃} \quad \text{CH}_3 \quad (\text{CH}_3\text{CHCH₂})_2\text{AlH} \\
\text{Ethyl 2-methylpropanoate} \quad \text{Bis(2-methylpropyl)aluminum hydride} (\text{Diisobutylaluminum hydride, DIBAL}) \rightarrow \text{CH₃CHCHO} \\
\text{2-Methylpropanal}
\]

**Esters form enolates that can be alkylated**

The acidity of the α-hydrogens in esters is sufficiently high that ester enolates are formed by treatment of esters with strong base at low temperatures. Ester enolates react like ketone enolates, undergoing alkylations.

**Alkylation of an Ester Enolate**

\[
\text{CH}_3\text{COCH₂CH₃} \quad \text{LDA, THF, –78°C} \rightarrow \text{CH}_2=\text{C} \quad \text{Br} \rightarrow \text{CH}_2=\text{CHCH}_2\text{CH}_2\text{COCH₂CH₃} \\
\text{Nucleophilic} \quad \text{Enolate ion} \quad \text{97%} \quad \text{Ethyl 4-pentenoate}
\]

The pKₐ of esters is about 25. Consequently, ester enolates exhibit the typical side reactions of strong bases: E2 processes (especially with secondary, tertiary, and β-branched halides) and deprotonations. The most characteristic reaction of ester enolates is the Claisen condensation, in which the enolate attacks the carbonyl carbon of another ester. This process will be considered in Chapter 23.

**Exercise 20-17**

Give the products of the reaction of ethyl cyclohexanecarboxylate with the following compounds or under the following conditions (and followed by acidic aqueous work-up, if necessary). (a) H⁺, H₂O; (b) HO⁻, H₂O; (c) CH₃O⁻, CH₃OH; (d) NH₃, Δ; (e) 2 CH₃MgBr; (f) LiAlH₄; (g) 1. LDA, 2. CH₃I.

**In Summary** Ester are named as alkyl alkanoates. Many of them have pleasant odors and are present in nature. They are less reactive than acyl halides or carboxylic anhydrides and therefore often require the presence of acid or base to transform. With water, esters hydrolyze to the corresponding carboxylic acids or carboxylates; with alcohols, they undergo transesterification and, with amines at elevated temperatures, furnish amides.
Grignard reagents add twice to give tertiary alcohols (or secondary alcohols, from formates). Lithium aluminum hydride reduces esters all the way to alcohols, whereas bis(2-methylpropyl)aluminum (disobutylaluminum) hydride allows the process to be stopped at the aldehyde stage. With LDA, it is possible to form ester enolates, which can be alkylated by electrophiles.

20-5 Esters in Nature: Waxes, Fats, Oils, and Lipids

Esters are essential components in the cells of all living organisms. This section introduces several of the most common types of natural esters with brief descriptions of their biological functions.

Esters are simple esters, whereas fats and oils are more complex

Esters made up of long-chain carboxylic acids and long-chain alcohols constitute waxes, which form hydrophobic (Section 8-2) and insulating coatings on the skin and fur of animals, the feathers of birds, and the fruits and leaves of many plants. Spermaceti and beeswax are liquids or very soft solids at room temperature and are used as lubricants. Sheep’s wool provides wool wax, which when purified yields lanolin, a widely used cosmetic base. The leaves of a Brazilian palm are the source of carnauba wax, a tough and water-resistant mixture of several solid esters. Carnauba wax is highly valued for its ability to take and maintain a high gloss and is used as a floor and automobile wax.

Triesters of 1,2,3-propanetriol (glycerol) with long-chain carboxylic acids constitute fats and oils (Sections 11-3 and 19-13). They are also called triglycerides. The acids in fats and oils (fatty acids) are typically unbranched and contain an even number of carbon atoms; if the fats are unsaturated, the double bonds are usually cis. Fats are biological energy reserves, which are stored in the body’s tissues until their metabolism leads ultimately to CO₂ and water. Oils have a similar function in plant seeds. As food components, fats and oils serve as solvents for food flavors and colors and contribute to a sense of “fullness” after eating, because they leave the stomach relatively slowly. Saturated fats containing hexadecanoic (palmitic), tetradecanoic (myristic), and dodecanoic (lauric) acids have been implicated as dietary factors in atherosclerosis (hardening of the arteries; Chemical Highlight 4-2). Fortunately for lovers of chocolate, cocoa butter is mainly a low-melting triglyceride that contains two molecules of octadecanoic (stearic) acid—which, despite being saturated, does not contribute to elevated low-density lipoprotein (LDL) levels or atherosclerosis—and one molecule of (Z)-9-octadecenoic (oleic) acid. The latter is also the chief fatty acid component of olive oil, the major source of dietary fat among the Greeks, who have very low rates of heart disease.

Lipids are biomolecules soluble in nonpolar solvents

Extraction of biological material with nonpolar solvents gives a wide assortment of compounds that includes terpenes and steroids (Section 4-7), fats and oils, and a variety of other low-polarity substances collectively called lipids (lipos, Greek, fat). Lipid fractions include phospholipids, important components of cell membranes, which are derived from carboxylic acids and phosphoric acid. In the phosphoglycerides, glycerol is esterified with two adjacent fatty acids and a phosphate unit that bears another substituent derived from a
low-molecular-weight alcohol such as choline, $[\text{HOCH}_2\text{CH}_2\text{N(CH}_3)_3\text{]}^+$ $-$ OH. The substance shown here is an example of a lecithin, a lipid found in the brain and nervous system.

Compounds such as these play roles in the transmission of nerve impulses and exhibit other biological effects. For example, a lipid containing the amide analog of oleic acid [(Z)-9-octadecenamide] was recently identified as an essential sleep-inducing agent in the brain; indeed, persons with lipid-restricted diets have difficulty experiencing deep sleep.

Because these molecules carry two long hydrophobic fatty acid chains and a polar head group (the phosphate and choline substituent), they are capable of forming micelles in aqueous solution (see Chemical Highlight 19-1). In the micelles, the phosphate unit is solubilized by water, and the ester chains are clustered inside the hydrophobic micellar sphere (Figure 20-2A).

Phosphoglycerides can also aggregate in a different way: They may form sheets called a lipid bilayer (Figure 20-2B). This capability is significant because, whereas micelles are usually limited in size (<200 Å in diameter), bilayers may be as much as 1 mm ($10^7$ Å) in length. This property makes them ideal constituents of cell membranes, which act as permeability barriers regulating molecular transport into and out of the cell. Lipid bilayers are relatively stable molecular assemblies. The forces that drive their formation are similar to those at work in micelles: London interactions (Section 2-6) between the hydrophobic alkane chains, and coulombic and solvation forces between the polar head groups and between these polar groups and water.

In Summary Waxes, fats, and oils are naturally occurring, biologically active esters. Lipids are a broad class of biological molecules soluble in nonpolar solvents. They include glycerol-derived triesters, which are components of cell membranes.
Chapter 20  Carboxylic Acid Derivatives

20-6 Amides: The Least Reactive Carboxylic Acid Derivatives

Among all carboxylic acid derivatives, the amides, RCNR₂, are the least susceptible to nucleophilic attack. After a brief introduction to amide naming, this section describes their reactions.

**Amides are named alkanamides, cyclic amides are lactams**

Amides are called **alkanamides**, the ending -e of the alkane stem having been replaced by -amide. In common names, the ending -ic of the acid name is replaced by the -amide suffix. In cyclic systems, the ending -carboxylic acid is replaced by -carboxamide. Substituents on the nitrogen are indicated by the prefix N- or N,N-, depending on the number of groups. Accordingly, there are primary, secondary, and tertiary amides.

**CHEMICAL HIGHLIGHT 20-1**

**Greener Alternatives to Petroleum: Fuels from Vegetable Oil**

The fuel of choice for Rudolph Diesel’s internal combustion engine, introduced to the world at the Paris Exposition in 1900, was peanut oil. Coming full circle after over a century, so-called biodiesel fuels have become popular alternatives to the petroleum-derived hydrocarbon mixtures widely used in diesel engines. Rudolph Diesel eventually found that pure vegetable oil was too viscous to be practical because it caused engine fouling in a relatively short time. However, a simple transesterification to generate a mixture of lower-molecular-weight methyl esters of long-chain fatty acids.

Typical vegetable oil

Formamide  
(A primary amide: two hydrogens bound to nitrogen)

N-Methylacetamide  
(A secondary amide: one hydrogen bound to nitrogen)

4-Bromo-N-ethyl-N-methylpentanamide  
(A tertiary amide)

Cyclohexanecarboxamide  
(Another primary amide)
There are several amide derivatives of carbonic acid, $\text{H}_2\text{CO}_3$: ureas, carbamic acids, and carbamic esters (urethanes).

Cyclic amides are called lactams (Section 19-10)—the systematic name is aza-2-cycloalkanones (Section 25-1)—and the rules for naming them follow those used for lactones. The penicillins are annulated $\beta$-lactams.
CHEMICAL HIGHLIGHT 20-2

Battling the Bugs: Antibiotic Wars

In late summer 1928, the Scottish bacteriologist Sir Alexander Fleming went on vacation. When he returned, the course of human history changed. Fleming had left a culture dish containing the bacterium *Staphylococcus aureus* on a laboratory bench. While he was gone, a cold spell stopped the growth of the bacterium. At the same time, mold spores of *Penicillium notatum* happened to drift up from the floor below, settling into his culture dish. By the time Fleming returned, the weather had warmed, and both microorganisms resumed growing. Intending to clean and sterilize the dish, he fortunately first noticed that *Penicillium* was destroying the bacteria colonies. The substance responsible for this antibiotic effect was isolated in 1939 and named penicillin (see structure, p. 945).

Fleming’s original mold produced benzylpenicillin, or penicillin G ($R = C_6H_5CH_2$). Many analogs have been subsequently synthesized, comprising a large class of so-called $\beta$-lactam antibiotics, after the strained four-membered lactam ring that characterizes them structurally as well as functionally (see also Chapter 7 Opening). Because ring strain is relieved upon ring opening, $\beta$-lactams are unusually reactive compared with ordinary amides. The enzyme *transpeptidase* catalyzes a crucial reaction in the biosynthesis of a polymer that maintains the structure of bacterial cell walls. A nucleophilic oxygen of the enzyme links with the carboxylic acid function of one amino acid, catalyzing its amide formation with the amine group of another amino acid molecule. Repetition of this process generates the polymer. Penicillin’s $\beta$-lactam carbonyl group reacts with the crucial enzyme oxygen readily and irreversibly, inactivating the enzyme, stopping cell-wall synthesis, and killing the bacterium.

Some bacteria are resistant to penicillin, because they produce an enzyme, *penicillinase*, that destroys the $\beta$-lactam ring in the antibiotic. Synthesis of analogs afforded a partial solution to this problem. Ultimately, however, it became necessary to turn to antibiotics with completely different modes of action. Erythromycin, produced by a strain of *Streptomyces* bacteria first found in soil samples in the Philippines in 1952, functions in a distinct manner. It is a large ring lactone that interferes with the bacterial ribosome, its cell-wall protein synthesis factory. Although erythromycin is unaffected by penicillinase, bacteria resistant to it have developed over the decades since its introduction into the antibiotic arsenal.

An even more complex antibiotic, vancomycin, was discovered in 1956, from fermentation of a bacterium originally found in the soils of the jungles of Borneo. When dangerous strains of *Staphylococcus aureus* possessing resistance to virtually every known antibiotic became serious threats to public health, “Vanco” (for “vanquish”) quickly became the “antibiotic of last resort.” Its effectiveness arises from an entirely novel chemical interaction: Its shape and structure allow it to form a tight network of hydrogen bonds with the amino acids at the end of the growing cell-wall polymer, preventing them from linking with additional amino acid units. Within a decade vancomycin-resistant strains of *S. aureus* appeared, in which a small structural change at the end of the polymer disrupts the ability of the antibiotic to bind. However, knowledge of the precise nature of this modification allowed the development in 2006 of a new vancomycin derivative in which the amide carbonyl group shown in red was replaced by a methylene (CH$_2$). This derivative, while much less active against the normal bacterium, is lethal to the vancomycin-resistant strain.

Amides are essential to biochemistry; amide groups link the amino acid subunits that make up the biopolymers called proteins (Chapter 26). Many simpler amides possess varied forms of biological activity. For example, anandamide (after the Sanskrit word *ananda*, bliss), the amide of arachidonic acid (Section 19-13) with 2-aminoethanol, has been found to bind to the same receptor in the brain as does tetrahydrocannabinol (Section 9-11), the active ingredient in marijuana. The release and binding of anandamide is the mechanism by which the body suppresses the perception of pain (Chapter 16, Problem 47). Anandamide has been isolated from chocolate, suggesting
The battle between scientists and the bacterial world continues: New antibacterials are continually being prepared and tested for potency. Tigecycline, introduced in 2006, is the first of a new class of antibiotics related to the tetracyclines and designed to overcome some of the bugs’ resistance strategies. Tigecycline works against some particularly nasty drug-defiant infections of the skin and internal organs, as well as penicillin-resistant *Streptococcus pneumoniae*.

Another tactic to foil the survival efforts of evolving pathogens was unveiled in 2007. A synthetic polyamide was built that causes the immune system to prepare antibodies against resistant strains of *Staphylococcus aureus*, responsible for nearly 100,000 infections and 20,000 deaths each year. Such substances have the potential to give rise to entirely novel vaccination strategies that could save thousands of lives.

Meanwhile, microbes continue to adapt and develop modifications to their biochemical machinery to foil antibiotic attack. Whether the “era of antibiotics” that began in the middle of the twentieth century will continue very far into the twenty-first is very much an open question.

that people who claim to be “addicted to chocolate” may really know what they are talking about.
Amide hydrolysis requires strong heating in concentrated acid or base

The amides are the least reactive of the carboxylic acid derivatives, in part because they are strongly stabilized by delocalization of the nitrogen lone pair (Section 20-1). As a consequence, their nucleophilic addition–eliminations require relatively harsh conditions. For example, hydrolysis to the corresponding carboxylic acid occurs only upon prolonged heating in strong aqueous acid or base by addition–elimination mechanisms. Acid hydrolysis liberates the amine in the form of an ammonium salt.

**Acid Hydrolysis of an Amide**

\[
\text{H}_2\text{SO}_4, \text{H}_2\text{O}, \Delta, 3 \text{ h} \quad \xrightarrow{} \quad \text{3-Methylpentanamide} \quad \xrightarrow{\text{HSO}_4^-} \quad \text{3-Methylpentanoic acid} + (\text{NH}_4)_2\text{SO}_4
\]

(See Problem 51)

Base hydrolysis requires loss of a very poor leaving group, in this case the inorganic amide ion, \(\text{\text{H}_2\text{NH}}\). The reaction proceeds because (as in ester hydrolysis) the tetrahedral intermediate is high in energy compared to the resonance-stabilized substrate and product molecules. In addition, the equilibrium is driven forward through very rapid protonation of the strongly basic leaving group by the carboxylic acid that is liberated in the elimination step. The overall process therefore furnishes the carboxylate salt, which is protonated during subsequent aqueous work-up to produce the acid.

**Base Hydrolysis of an Amide**

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CNHCH}_3 \quad \xrightarrow{\text{H}_2\text{O}, \Delta} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CO}^- + \text{CH}_3\text{NH}_2 \quad \xrightarrow{\text{H}_2\text{O}, \Delta} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{COH} + \text{CH}_3\text{NH}_3
\]

87% Butanoic acid

**Mechanism of Hydrolysis of Amides by Aqueous Base**

Inorganic amide ion: strong base

Tetrahedral intermediate

Amides can be reduced to amines or aldehydes

In contrast to carboxylic acids and esters, the reaction of amides with lithium aluminum hydride produces amines instead of alcohols.

**Reduction of an Amide to an Amine**

\[
N,N\text{-Diethyl-4-methylpentanamide} \quad \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O} \quad 2. \text{H}_2\text{O}} \quad \text{N,N\text{-Diethyl-4-methylpentanamine}}
\]

85%

The mechanism of reduction begins with hydride addition, which gives a tetrahedral intermediate. Elimination of an aluminum alkoxide leads to an iminium ion. Addition of a second hydride gives the final amine product.
Exercise 20-18

What product would you expect from LiAlH₄ reduction of the compound depicted in the margin?

Reduction of amides by bis(2-methylpropyl)aluminum hydride (diisobutylaluminum hydride) furnishes aldehydes. Recall that esters also are converted into aldehydes by this reagent (Section 20-4).

Reduction of an Amide to an Aldehyde

\[
\begin{align*}
\text{N,N-Dimethylpentanamide} & \quad \text{O} \\
& \quad \text{CH} \quad \text{N(CH₃)₂} \\
& \quad 1. \text{(CH₃CH₂)₂AlH}, (\text{CH₃CH₂})₂\text{O} \\
& \quad 2. \text{H⁺}, \text{H₂O} \\
\text{Pentanal} & \quad 92\%
\end{align*}
\]

Exercise 20-19

Working with the Concepts: Reduction of Amides

Treatment of amide A with LiAlH₄, followed by acidic aqueous work-up, gave compound B. Explain.

Strategy
Consider each step of the sequence individually. Identify the product of the first reaction and consider how it may be able to transform into the final product.

Solution
• What is the result of LiAlH₄ treatment of amide A? As shown in this section, the carboxamide function is reduced to that of a primary amine.
• The acetal group, being immune to strong bases and reducing agents, remains unchanged (Section 17-7). However, it hydrolyzes to give a ketone function upon the aqueous acidic work-up that follows the LiAlH₄ reduction. At this point we have the following aminoketone:

\[
\begin{align*}
\text{CH₃} & \quad \text{O} \\
\text{NH}_2 & \quad \text{NH}_2
\end{align*}
\]

• Comparison of this structure with that of the final product B shows that the amino nitrogen has become bonded to the carbonyl carbon to give a cyclic imine. Acid-catalyzed condensation of the amino with the carbonyl group (Section 17-9) provides a reasonable explanation for this transformation.
In Summary Carboxylic amides are named as alkanamides or as lactams if they are cyclic. They can be hydrolyzed to carboxylic acids by acid or base and reduced to amines by lithium aluminum hydride. Reduction by bis(2-methylpropyl)aluminum hydride (diisobutyl-aluminum hydride) stops at the aldehyde stage.

20-7 Amidates and Their Halogenation: The Hofmann Rearrangement

In amides, hydrogens on both the carbon and the nitrogen atoms next to the carbonyl group are acidic. Removal of the NH hydrogen, which has a pK$_a$ of about 22, with base leads to an amidate ion. The CH proton is less acidic, with a pK$_a$ of about 30 (Section 20-1); therefore, deprotonation of the $\alpha$-carbon, leading to an amide enolate, is more difficult.

Practically speaking, therefore, a proton may be removed from the $\alpha$-carbon only with tertiary amides, in which the nitrogen lacks attached hydrogen atoms.

The amidate ion formed by deprotonation of a primary amide is a synthetically useful nucleophile. This section focuses on one of its reactions, the Hofmann rearrangement.

Exercise 20-21

The pK$_a$ of 1,2-benzenedicarboximide (phthalimide, A) is 8.3, considerably lower than the pK$_a$ of benzamide (B). Why?

In the presence of base, primary amides undergo a special halogenation reaction, the Hofmann* rearrangement. In it, the carbonyl group is expelled from the molecule to give a primary amine with one carbon fewer in the chain.

*This is the Hofmann of the Hofmann rule of E2 reactions (Section 11-6).
The Hofmann rearrangement begins with deprotonation of nitrogen to form an amidate ion (step 1). Halogenation of the nitrogen follows, much like the α-halogenation of aldehyde and ketone enolates (step 2; see Section 18-3). Subsequently, the second proton on the nitrogen is abstracted by additional base to give an N-haloamide (step 3). This species, containing a weak nitrogen–halogen bond and a good potential leaving group, undergoes loss of halide ion accompanied by migration of the R group from the carbonyl carbon to nitrogen (step 4). The product of this rearrangement is an isocyanate, R—N=C=O, a nitrogen analog of carbon dioxide, O=C=O. The sp-hybridized carbonyl carbon in the isocyanate is highly electrophilic and is attacked by water to produce an unstable carbamic acid. Finally, the carbamic acid decomposes to carbon dioxide and the amine (step 5).

Mechanism of the Hofmann Rearrangement

**Step 1.** Amidate formation

**Step 2.** Halogenation

**Step 3.** N-Haloamide formation

**Step 4.** Rearrangement with halide elimination
Step 5. Hydration to the carboxylic acid and decomposition

\[ \text{R} = \text{N} = \text{C} = \text{O} \overset{\text{H}_2\text{O}}{\longrightarrow} \text{R} = \text{N} - \text{C} - \text{O}_{\cdot \cdot} \longrightarrow \text{RNH}_2 + \text{CO}_2 \]

A carboxylic acid

In the rearrangement, as the halide ion leaves, the alkyl group literally “slides” over from the carbonyl carbon to the nitrogen, keeping the same “face” toward the nitrogen that was previously bonded to carbon. Therefore, when this alkyl group is chiral, its original stereochemistry is retained during the course of the rearrangement. This kind of electronic “push–pull” process, in which a leaving group (pull) causes a neighboring (alkyl) group to migrate (push), has analogies in the acid-catalyzed rearrangement of 2,2-dimethyl-1-propanol (neopentyl alcohol; Section 9-3), the mechanism of alkylborane oxidation (Section 12-8), and the mechanism of the Baeyer-Villiger oxidation (Section 17-13).

“Push–Pull” Transition States

Exercise 20-22

Give the product of the following Hofmann rearrangement process.

\[ \text{CH}_3\text{C} = \text{CH}_2 \overset{\text{Cl}_2, \text{NaOH}, \text{H}_2\text{O}}{\longrightarrow} \text{RNH}_2 \]

Exercise 20-23

Write a detailed mechanism for the addition of water to an isocyanate under basic conditions and for the decarboxylation of the resulting carbamic acid.

Exercise 20-24

Suggest a sequence by which you could convert ester A into amine B.

In Summary  Treatment of primary and secondary amides with base leads to deprotonation at nitrogen, giving amidate ions. Bases abstract protons from the \( \alpha \)-carbon of tertiary amides. In the Hofmann rearrangement, primary amides react with halogens in base to furnish amines with one fewer carbon. In the course of this process an alkyl shift takes place, which converts an acyl nitrile into an isocyanate.
Methyl Isocyanate, Carbamate-Based Insecticides, and Safety in the Chemical Industry

The elimination of DDT (Chemical Highlight 3-2) and other chlorinated organic compounds from the pesticide arsenal necessitated changes in the approaches taken to control insect damage to food crops. Strategies based on yearly alternating application of insecticides with different modes of action have been developed to manage infestations while minimizing the development of insect strains that are pesticide resistant. The pyrethrins, derived from the natural insecticide chrysanthemic acid (Section 4-7), are one group in common use. Juvenile hormone analogs offer an alternative (Chemical Highlight 12-1). However, the need for insecticides capable of controlling a number of very stubborn species led to the development of several classes of substances that target insects’ nervous systems. Organic derivatives of phosphoric acid (organophosphates) are compounds in this category—you may be familiar with the names diazinon and malathion, both of which are organophosphates. Carbamates constitute another group of insect neurotoxins. Two examples are carbofuran (Furadan) and carbaryl (Sevin), both prepared by addition of phenols to methyl isocyanate:

\[ \text{Methyl isocyanate} \rightarrow \text{Carbofuran (Furadan)} \]
\[ \text{Methyl isocyanate} \rightarrow \text{Carbaryl (Sevin)} \]

Carbamate insecticides inhibit cholinesterase, an enzyme that is essential to the proper transmission of nerve impulses. Both carbofuran and carbaryl have become increasingly important in the control of specific pests such as the soybean aphid in the United States. Great care is essential when these substances are employed, because their neurotoxicity is not restricted to insects but extends to animals and humans as well. Their safe use is based partly on an understanding of the relationship between dosage and biological response: The exposure needed to elicit an effect is roughly proportional to the body weight of the target species. Thus the quantities of these toxins needed to kill insects are very small. The detailed protocols that have been developed for their safe use are designed to limit human exposure to amounts too small to give rise to any ill effects.

Nonetheless, the hazards of dealing with such substances were realized in a catastrophic manner in the early morning hours of December 3, 1984, in Bhopal, India. Safety protocols may have been compromised at a Union Carbide India Ltd. plant at which Sevin had been manufactured and which was in the process of being removed from service. An uncontrolled release of 40 metric tons of methyl isocyanate into the atmosphere took place, with horrific consequences: Hundreds of thousands were exposed, over 3000 died within hours, and tens of thousands more sustained debilitating injuries. The groundwater in the area remains contaminated, and disputes still rage over who will cover the costs of site remediation. This disaster, the worst chemical industrial accident in history, led to a complete reappraisal and redesign of the safety measures associated with the handling of toxic substances on a large scale. In 1988 the American Chemistry Council introduced the Responsible Care initiative, a program that mandates that all its member companies in the chemical industry voluntarily meet stricter standards of environmental, health, and safety performance than those required by the U.S. government. The Responsible Care program employs independent third-party certification to ensure that required targets are met. Over the lifetime of this program so far, member companies report 80% reduced emissions of environmental pollutants based on the standards of the U.S. Environmental Protection Agency and an overall worker safety record five times better than that of the U.S. manufacturing sector as a whole.

20-8 Alkanenitriles: A Special Class of Carboxylic Acid Derivatives

Nitriles, \( \text{RC} \equiv \text{N} \), are considered derivatives of carboxylic acids because the nitrile carbon is in the same oxidation state as the carboxy carbon and because nitriles are readily converted into other carboxylic acid derivatives. This section describes the rules for naming nitriles, the structure and bonding in the nitrile group, and some of its spectral characteristics. Then it compares the chemistry of the nitrile group with that of other carboxylic acid derivatives.
In IUPAC nomenclature, nitriles are named from alkanes. A systematic way of naming this class of compounds is as alkaniminitriles. In common names, the ending -ic acid of the carboxylic acid is usually replaced with -nitrile. The chain is numbered like those of carboxylic acids. Similar rules apply to dinitriles derived from dicarboxylic acids. The substituent CN is called cyano. Cyanocycloalkanes are called cycloalkancarbonitriles. We will retain the common name benzonitrile (from benzoic acid), rather than use the systematic benzenecarbonitrile.

![Image of nitrile structures]

**The C=N bond in nitriles resembles the C≡C bond in alkynes**

In the nitriles, both atoms in the functional group are sp hybridized and a lone electron pair on nitrogen occupies an sp hybrid orbital pointing away from the molecule along the C–N axis. The hybridization and structure of the nitrile functional group very much resemble those of the alkynes (Figure 20-3; see also Figures 13-1 and 13-2).

**Figure 20-3** (A) Orbital picture of the nitrile group, showing the sp hybridization of both atoms in the C≡N function. (B) Molecular structure of ethanenitrile (acetonitrile), which is similar to that of the corresponding alkyne. (C) Electrostatic potential map of ethanenitrile, depicting the positively polarized cyano carbon (blue) and the relatively negatively polarized nitrogen (green) with its lone electron pair (red).

In the infrared spectrum, the C≡N stretching vibration appears at about 2250 cm⁻¹, in the same range as the C≡C absorption, but much more intense. The ¹H NMR spectra of nitriles indicate that protons near the nitrile group are deshielded about as much as those in other carboxylic acid and alkyne derivatives (Table 20-3).

The ¹³C NMR absorption for the nitrile carbon appears at lower field (δ = 112–126 ppm) than that of the alkynes (δ ≈ 65–85 ppm), because nitrogen is more electronegative than carbon. Thus, nitriles are polarized, as shown in the electrostatic potential map in Figure 20-3C.

**Exercise 20-25**

1,3-Dibromopropane was treated with sodium cyanide in dimethyl sulfoxide-d₆ and the mixture monitored by ¹³C NMR. After a few minutes, four new intermediate peaks appeared, one of which was located well downfield from the others at δ = 117.6 ppm. Subsequently, another three peaks began growing at δ = 119.1, 22.6, and 17.6 ppm, at the expense of the signals of starting material and the intermediate. Explain.
Nitriles undergo hydrolysis to carboxylic acids

As mentioned in Section 19-6, nitriles can be hydrolyzed to give the corresponding carboxylic acids. The conditions are usually stringent, requiring concentrated acid or base at high temperatures.

\[
\text{N}≡\text{C(\text{CH}_2)_4\text{C}≡\text{N}} \xrightarrow{\text{H}^+, \text{H}_2\text{O}, \Delta} \text{HOOC(\text{CH}_2)_4\text{COOH}}
\]

Hexanedinitrile (Adiponitrile)  Hexanedioic acid (Adipic acid)

The mechanisms of these reactions proceed through the intermediate amide and include addition–elimination steps.

In the acid-catalyzed process, initial protonation on nitrogen facilitates nucleophilic attack by water. Loss of a proton from oxygen furnishes a neutral intermediate, which is a tautomer of an amide. A second protonation on the nitrogen occurs, followed again by deprotonation of oxygen and formation of the amide. Hydrolysis of the amide proceeds by the usual addition–elimination pathway.

In base-catalyzed nitrile hydrolysis, direct attack of hydroxide gives the anion of the amide tautomer, which protonates on nitrogen. The remaining proton on the oxygen is then removed by base and a second \( \text{N} \)-protonation gives the amide. Hydrolysis is completed as described in Section 20-6.

Organometallic reagents attack nitriles to give ketones

Strong nucleophiles, such as organometallic reagents, add to nitriles to give anionic imine salts. Work-up with aqueous acid gives the neutral imine, which is rapidly hydrolyzed to the ketone (Section 17-9).
Reduction of nitriles by hydride reagents leads to aldehydes and amines

As in its reactions with esters and amides, bis(2-methylpropyl)aluminum (diisobutylaluminum) hydride (DIBAL) adds to a nitrile only once to give an imine derivative. Aqueous hydrolysis then produces an aldehyde.

Treatment of nitriles with strong hydride reducing agents results in double hydride addition, giving the amine on aqueous work-up. The best reagent for this purpose is lithium aluminum hydride.

Exercise 20-26

The reduction of a nitrile by LiAlH₄ to give an amine adds four hydrogen atoms to the C≡N triple bond: two from the reducing agent and two from the water in the aqueous work-up. Formulate a mechanism for this transformation.

Like the triple bond of alkynes (Section 13-6), the nitrile group is hydrogenated by catalytically activated hydrogen. The result is the same as that of reduction by lithium aluminum hydride—amine formation. All four hydrogens are from the hydrogen gas.
In Summary  Nitriles are named as alkanenitriles. Both atoms making up the C–N unit are \( sp \) hybridized, the nitrogen bearing a lone pair in an \( sp \)-hybrid orbital. The nitrile stretching vibration appears at 2250 cm\(^{-1}\), the \(^{13}\)C NMR absorption at about 120 ppm. Acid- or base-catalyzed hydrolysis of nitriles gives carboxylic acids, and organometallic reagents (\( \text{RLi, RMgBr} \)) add to give ketones after hydrolysis. With bis(2-methylpropyl)aluminum hydride (diisobutylaluminum hydride, DIBAL), addition and hydrolysis furnishes aldehydes, whereas Li\( \text{AlH}_4 \) or catalytically activated hydrogen converts the nitrile function into the amine.

THE BIG PICTURE

In the past four chapters we have introduced all of the major compound classes based on the carbonyl functional group. Their similarities and differences are direct reflections of the fact that structure defines function in organic chemistry. The fundamental principles that govern carbonyl chemistry derive from concepts first introduced in Chapters 1 and 2:

- The strength and reactivity of polar bonds (Sections 1-3 and 2-3);
- The effects of resonance delocalization on structure and stability (Section 1-5);
- Direct and indirect applications of acid-base chemistry (Section 2-2).

Carbonyl chemistry illustrates so many basic features of organic chemistry that a careful study of it can serve as an excellent point of departure for developing a more comprehensive grasp of the properties of all of the other compound classes. If at any time in the future you find yourself needing to review your course in organic chemistry for any purpose, carbonyl chemistry will be a good place to start, because it will help you develop the insight to understand much of the rest of the subject matter with considerably more thoroughness.

In Chapter 21, we turn to the last simple compound class that will be covered in this course, the amines. Again, polar bonds and acid-base chemistry will play important roles.

CHAPTER INTEGRATION PROBLEMS

20-28. A useful synthesis of certain types of diols includes the reaction of a “bisGrignard” reagent with a lactone:

(a) Formulate a mechanism for this transformation.

SOLUTION

We begin by noticing that a lactone is merely a cyclic ester and therefore we may refer to the reaction of esters with Grignard reagents described in Section 20-4 as a guide for approaching this question.

Esters react sequentially with two equivalents of Grignard reagent: The first gives rise to an addition–elimination sequence that forms a new carbon–carbon bond, expels an alkoxide leaving group, and
produces a ketone. The second Grignard equivalent adds to the carbonyl carbon of this ketone, giving the final product, a tertiary alcohol. This problem modifies the pattern in two ways: The ester is cyclic; therefore, the first Grignard addition–elimination process opens the ring, and the alkoxide leaving group remains attached by a carbon chain in the intermediate ketone. Instead of two separate molecules of Grignard reagent, we have here a single molecule containing two Grignard functionalities. Therefore, when the second Grignard function adds to the same carbonyl carbon as did the first, it forms a new ring:

(b) Show how you would apply this general method to the synthesis of diols A and B.

SOLUTION
Referring to the mechanism in (a), we can generalize the pattern followed by this transformation as shown below.

The answers are

20-29. Clovene is a sesquiterpene that arises from acid-catalyzed rearrangement of caryophyllene (Problem 74 of Chapter 12—odor of cloves). The following sequence of transformations constitutes a part of a total synthesis of clovene, but the reagents have been omitted. Supply reasonable reagents
and reaction conditions for each transformation, some of which require more than one step. In some cases, you may need to refer to earlier chapters, especially Chapters 17 through 19, for information.

(a) A molecule containing methoxycarbonyl and hydroxy groups converts into a cyclic ester—a lactone. A change from one ester into another would be transesterification (Section 20-4), a reversible process catalyzed equally well by acid or base. How do we shift the equilibrium in the desired direction? Note that methanol is the by-product of the process; it has a low boiling point (65°C, Table 8-1) and may be driven off by heating the reaction mixture. Therefore, (a) is catalytic H⁺.

(b) The lactone converts into a diol. One could effect this change in two steps: Hydrolysis would cleave the lactone into a hydroxyacrylic acid (Section 20-4); subsequent reduction by LiAlH₄ would furnish the diol (Section 19-11). Much easier is LiAlH₄ reduction of the lactone, which would lead to the diol directly. Notice (Section 20-4) that, in the course of these reduction processes alkoxides are the initial products, requiring acidic work-up. Therefore, (b) is 1. LiAlH₄, ether (a typical solvent for such reductions) and 2. H⁺, H₂O.

c. This step requires some thought. There are two hydroxy groups to start with, and we want to oxidize only one. The usual methods based on, for example, Cr(VI) will not distinguish between them and cannot be used. However, one of the two –OH groups (the one on the ring) is allylic, and (Section 17-4) can be oxidized selectively to an α,β-unsaturated ketone by MnO₂, leaving the other unchanged. So, (c) is MnO₂, acetone.

d. Now we are back to more straightforward chemistry—oxidation of a primary alcohol to a carboxylic acid. Any Cr(VI) reagent in water will do, such as K₂Cr₂O₇ in aqueous acid (Sections 8-6 and 19-6). Thus (d) is K₂Cr₂O₇, H₂SO₄, H₂O.

e. Two functional group changes are evident: The enone C–C double bond has been reduced and the carboxy group esterified. We have seen reductions of enones to saturated ketones (Section 18-8); catalytic hydrogenation is the simplest applicable method (a metal–NH₃ reduction is unnecessary, because selectivity is not relevant). Methyl ester formation may be achieved in either of two ways (Sections 19-8, 19-9, and 20-2): via the acyl halide (made with SOCl₂) and CH₃OH or by direct acid-catalyzed reaction with CH₃OH. Does the order of steps matter? Neither acids nor esters are affected by catalytic hydrogenation conditions, and esterifications may be carried out in the presence of either enones or ordinary ketones, so the answer is no. For (e), then, 1. H₂, Pd–C, CH₃CH₂OH and 2. CH₃OH, H⁺.

f. Here is a curious pair of changes: The carbonyl moiety is protected as a cyclic acetal, and the ester function is hydrolyzed back to the –COOH group, which raises the question of why the latter was esterified in the first place. Most likely, the chemists working on this project tried to form the cyclic acetal on the molecule containing the free carboxy substituent and ran into difficulty. Protection of the carbonyl requires acid catalysis and 1,2-ethanediol (ethylene glycol, Section 17-8). Perhaps complications due to the formation of esters with the –COOH group were observed. In any event, esterification of the latter before acetalization apparently solved the problem. Thus, for (f), 1. HOCH₂CH₂OH, H⁺ and 2. –OH, H₂O (ester hydrolysis with base, Section 20-4, to prevent hydrolysis of the acetal unit).
g. The ring carbonyl group has been deprotected, and the carboxy group transformed into a ketone. For the first time in the synthesis, a new carbon–carbon bond has been introduced, between the carboxy carbon and an ethyl group. This process will most likely require the use of an organometallic reagent, from which the ring carbonyl has been protected in sequence (f). From which carboxylic acid derivatives can ketones be prepared? Acyl halides (Section 20-2) and nitriles (Section 20-8). Since you don’t know how to convert a carboxylic acid into its nitrile, we choose the following sequence for (g): 1. SOCl₂ (gives halide), 2. (CH₃CH₂)₂CuLi, ether (converts halo- into ethylcarbonyl), and 3. H⁺, H₂O (deprotects ring carbonyl, Section 17-8).

h. Another carbon–carbon bond is made, forming a ring. We trace the pattern of carbon atoms before and after this step to identify which ones were connected (see margin). They are the ring carbonyl carbon and the CH₂ of the ethyl group, α to the side-chain carbonyl. We have here an intramolecular aldol condensation (Section 18-7), readily achieved by aqueous base. So (h), the final step, is −OH, H₂O.

New Reactions

1. Order of Reactivity of Carboxylic Acid Derivatives (Section 20-1)

\[
\begin{array}{cccc}
\text{Amide} & \text{Ester} & \text{Anhydride} & \text{Acyl halide} \\
\text{RCNH}_2 & \text{RCOR} & \text{RCOCR} & \text{RCX}
\end{array}
\]

Esters and amides require acid or base catalysts to react with weak nucleophiles.

2. Basicity of the Carbonyl Oxygen (Section 20-1)

\[
\begin{array}{ccc}
\text{H⁺} & \text{L}^- & \text{L}^+ \\
\text{R} & \text{C} & \text{L} \\
\end{array}
\]

\[
\begin{array}{cccc}
\text{A} & \text{B} & \text{C} & \text{L} \\
\end{array}
\]

L⁻ - leaving group
Basicity increases with increasing contribution of resonance structure C.

3. Enolate Formation (Section 20-1)

\[
\begin{array}{ccc}
\text{H⁺} & \text{L}^- & \text{L}^+ \\
\text{RCH} & \text{C} & \text{L} \\
\end{array}
\]

\[
\begin{array}{cccc}
\text{A} & \text{B} & \text{C} & \text{L} \\
\end{array}
\]

Acidity of the neutral derivative generally increases with decreasing contribution of resonance structure C in the anion.

Reactions of Acyl Halides

4. Water (Section 20-2)

\[
\begin{array}{c}
\text{RCX} + \text{H}_2\text{O} \rightarrow \text{RCOH} + \text{HX} \\
\end{array}
\]

Carboxylic acid

5. Carboxylic Acids (Sections 19-8 and 20-2)

\[
\begin{array}{c}
\text{RCX} + \text{R'CO}_2\text{H} \rightarrow \text{RCOCR'} + \text{HX} \\
\end{array}
\]

Carboxylic anhydride

6. Alcohols (Section 20-2)

\[
\begin{array}{c}
\text{RCX} + \text{R'O}_2\text{H} \rightarrow \text{RCOR} + \text{HX} \\
\text{(Removed with pyridine, triethylamine, or other base)} \\
\end{array}
\]

Ester
7. Amines (Section 20-2)

\[
\text{RCX} + \text{R}’\text{NH}_2 \rightarrow \text{RCNHR’} + \text{HX}
\]

(Removed with pyridine, triethylamine, excess R’NH₂, or other base)

8. Cuprate Reagents (Section 20-2)

\[
\text{RCX} \xrightarrow{1. \text{R}’\text{CuLi, THF}} \text{RCR’} + \text{R’Cu} + \text{LiX}
\]

Ketone

9. Hydrides (Section 20-2)

\[
\text{RCX} \xrightarrow{1. \text{LiAl[OC(CH₃)₃]₃, H, (CH₃CH₂)O}} \text{RCH} + \text{LiX} + \text{Al[OC(CH₃)₃]₃}
\]

Aldehyde

Reactions of Carboxylic Acid Anhydrides

10. Water (Section 20-3)

\[
\text{RCOCR} + \text{H₂O} \rightarrow 2 \text{RCOH}
\]

Carboxylic acid

11. Alcohols (Section 20-3)

\[
\text{RCOCR} + \text{R’OH} \rightarrow \text{RCOR’} + \text{RCOH}
\]

Ester

Reactions of Esters

12. Amines (Section 20-3)

\[
\text{RCOCR} + \text{R’NH₂} \rightarrow \text{RCNHR’} + \text{RCOH}
\]

Amide

13. Water (Ester Hydrolysis) (Sections 19-9 and 20-4)

Acid catalysis

\[
\text{RCOR’} + \text{H₂O} \xrightarrow{\text{Catalytic H}^+} \text{RCOH} + \text{R’OH}
\]

Carboxylic acid

Base catalysis

\[
\text{RCOR’} + \text{−OH} \xrightarrow{\text{H₂O}} \text{RCO}^- + \text{R’OH}
\]

1 equivalent Carboxylate ion

14. Alcohols (Transesterification) and Amines (Section 20-4)

\[
\text{RCOR’} + \text{R’OH} \xrightarrow{\text{H}^+ \text{ or OR’}} \text{RCOR}'' + \text{R’OH}
\]

Ester

\[
\text{RCOR’} + \text{R’NH₂} \xrightarrow{\Delta} \text{RCNHR’} + \text{R’OH}
\]

Amide
15. Organometallic Reagents (Section 20-4)

\[
\text{RCOR}'' \xrightarrow{1. \text{2 R' MgX, (CH}_3\text{CH}_2\text{O}} \xrightarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{RCOR'} + \text{R''OH} \quad \text{Tertiary alcohol}
\]

Methyl formate

\[
\text{HCOCH}_3 \xrightarrow{1. \text{2 R' MgX, (CH}_3\text{CH}_2\text{O}} \xrightarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{RCOR'} + \text{CH}_3\text{OH} \\
\quad \text{Secondary alcohol}
\]

16. Hydrides (Section 20-4)

\[
\text{RCOR'} \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2\text{O})} \text{RCH}_2\text{OH} \quad \text{Alcohol}
\]

\[
\text{RCOR'} \xrightarrow{1. \text{(CH}_3\text{CHCH}_2\text{AlH, toluene, -60}^\circ\text{C}} \xrightarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{RCH} \quad \text{Aldehyde}
\]

17. Enolates (Section 20-4)

\[
\text{LDA, THF} \quad \text{RCH}_2\text{COR'} \xrightarrow{\text{RCHCOR'}} \text{Ester enolate ion}
\]

Reactions of Amides

18. Water (Section 20-6)

\[
\text{RCNHR'} + \text{H}_2\text{O} \xrightarrow{\text{H}^+, \Delta} \text{RCOH} + \text{R'NH}_3 \quad \text{Carboxylic acid}
\]

\[
\text{RCNHR'} + \text{H}_2\text{O} \xrightarrow{\text{HO}^+, \Delta} \text{RCO}^- + \text{R'NH}_2
\]

19. Hydrides (Section 20-6)

\[
\text{RCNHR'} \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2\text{O})} \text{RCH}_2\text{NHR'} \quad \text{Amine}
\]

\[
\text{RCNHR'} \xrightarrow{1. \text{(CH}_3\text{CHCH}_2\text{AlH, (CH}_3\text{CH}_2\text{O})} \xrightarrow{2. \text{H}^+, \text{H}_2\text{O}} \text{RCH} \quad \text{Aldehyde}
\]

20. Enolates and Amidates (Section 20-7)

\[
\text{RCH}_2\text{CNHR'} \xrightarrow{\text{Base}} \text{RCH}_2\text{C}==\text{NR'} \quad \text{Amide enolate ion}
\]

\[
\text{RCH}_2\text{CNHR'} \xrightarrow{\text{Base}} \text{RCH}_2\text{C}==\text{NR'} \quad \text{Amidate ion}
\]
21. Hofmann Rearrangement (Section 20-7)

\[
\text{RCNH}_2 + \text{Br}_2, \text{NaOH}, \text{H}_2\text{O}, 75^\circ \text{C} \rightarrow \text{RNH}_2 + \text{CO}_2
\]

**Reactions of Nitriles**

22. Water (Section 20-8)

\[
\text{RC} \equiv \text{N} + \text{H}_2\text{O} \xrightarrow{\text{H}^+ \text{ or HO}^-, \Delta} \text{RCNH}_2 \rightarrow \text{RCNHOH} \rightarrow \text{RCO}_2\text{H}
\]

23. Organometallic Reagents (Section 20-8)

\[
\text{RC} \equiv \text{N} \xrightarrow{1. \text{R'}MgX \text{ or R'Li} \ 2. \text{H}^+, \text{H}_2\text{O}} \xrightarrow{\text{O}} \text{RCR'}
\]

24. Hydrides (Section 20-8)

\[
\text{RC} \equiv \text{N} \xrightarrow{1. \text{LiAlH}_4 \ 2. \text{H}^+, \text{H}_2\text{O}} \xrightarrow{\text{O}} \text{RCH}_2\text{NH}_2
\]

25. Catalytic Hydrogenation (Section 20-8)

\[
\text{RC} \equiv \text{N} \xrightarrow{\text{H}_2, \text{PtO}_2, \text{CH}_3\text{CH}_2\text{OH}} \xrightarrow{\text{O}} \text{RCH}_2\text{NH}_2
\]

**Important Concepts**

1. The \textit{electrophilic reactivity} of the carbonyl carbon in \textit{carboxylic acid derivatives} is weakened by good electron-donating substituents. This effect, measurable by IR spectroscopy, is responsible not only for the decrease in the reactivity with nucleophiles and acid, but also for the increased basicity along the series: acyl halides–anhydrides–esters–amides. Electron donation by resonance from the nitrogen in amides is so pronounced that there is \textit{hindered rotation} about the amide bond on the NMR time scale.

2. \textit{Carboxylic acid derivatives} are named as \textit{acyl halides}, \textit{carboxylic anhydrides}, \textit{alkyl alkanoates}, \textit{alkanamides}, and \textit{alkanenitriles}, depending on the functional group.

3. \textit{Carbonyl stretching frequencies} in the IR spectra are diagnostic of the carboxylic acid derivatives: Acyl chlorides absorb at 1790–1815 cm\(^{-1}\), anhydrides at 1740–1790 and 1800–1850 cm\(^{-1}\), esters at 1735–1750 cm\(^{-1}\), and amides at 1650–1690 cm\(^{-1}\).

4. Carboxylic acid derivatives generally react with \textit{water} (under acid or base catalysis) to hydrolyze to the corresponding carboxylic acid; they combine with \textit{alcohols} to give esters and with \textit{amines} to furnish amides. With \textit{Grignard} and other \textit{organometallic reagents}, they form ketones; esters may react further to form the corresponding alcohols. Reduction by \textit{hydrides} gives products in various oxidation states: aldehydes, alcohols, or amines.

5. Long-chain esters are the constituents of animal and plant \textit{waxes}. Triesters of glycerol are contained in natural \textit{oils} and \textit{fats}. Their hydrolysis gives \textit{soaps}. \textit{Triglycerides} containing phosphoric acid ester subunits belong to the class of \textit{phospholipids}. Because they carry a highly polar head group and hydrophobic tails, phospholipids form \textit{micelles} and \textit{lipid bilayers}.

6. \textit{Transesterification} can be used to convert one ester into another.
7. The functional group of nitriles is somewhat similar to that of the alkynes. The two component atoms are \( sp \) hybridized. The IR stretching vibration appears at about 2250 cm\(^{-1}\). The hydrogens next to the cyano group are deshielded in \(^1H\) NMR. The \(^{13}C\) NMR absorptions for nitrile carbons are at relatively low field (\( \delta \sim 112–126 \text{ ppm} \)), a consequence of the electronegativity of nitrogen.

**Problems**

30. Name (IUPAC system) or draw the structure of each of the following compounds.

(a) ![Structure](image-a)
(b) ![Structure](image-b)
(c) ![Structure](image-c)
(d) ![Structure](image-d)
(e) ![Structure](image-e)
(f) ![Structure](image-f)
(g) ![Structure](image-g)
(h) ![Structure](image-h)
(i) ![Structure](image-i)
(j) ![Structure](image-j)
(k) ![Structure](image-k)
(l) ![Structure](image-l)

31. Name each of the following compounds according to IUPAC or Chemical Abstracts rules. Pay attention to the order of precedence of the functional groups.

(a) ![Structure](image-a)
(b) ![Structure](image-b)
(c) ![Structure](image-c)
(d) ![Structure](image-d)

32. (a) Use resonance forms to explain in detail the relative order of acidity of carboxylic acid derivatives, as presented in Section 20-1. (b) Do the same, but use an argument based on inductive effects.

33. In each of the following pairs of compounds, decide which possesses the indicated property to the greater degree. (a) Length of C–X bond: acetyl fluoride or acetyl chloride. (b) Acidity of the boldface H: \( \text{CH}_3\text{COCH}_3 \) or \( \text{CH}_3\text{COOCH}_3 \). (c) Reactivity toward addition of a nucleophile: (i) an amide or (ii) an imide (as shown in the margin). (d) High-energy infrared carbonyl stretching frequency: ethyl acetate or ethenyl acetate.

34. Give the product(s) of each of the following reactions.

(a) ![Reaction](image-a)
(b) ![Reaction](image-b)
(c) ![Reaction](image-c)
(d) ![Reaction](image-d)
(e) ![Reaction](image-e)
35. Formulate a mechanism for the reaction of acetyl chloride with 1-propanol shown on p. 932.

36. Give the product(s) of the reactions of acetic anhydride with each of the following reagents. Assume in all cases that the reagent is present in excess.
   (a) (CH₃)₂CHOH  
   (b) NH₃  
   (c) MgBr, THF; then H⁺, H₂O  
   (d) LiAlH₄, (CH₃CH₂)₂O; then H⁺, H₂O

37. Give the product(s) of the reaction of butanedioic (succinic) anhydride with each of the reagents in Problem 36.

38. Formulate a mechanism for the reaction of butanedioic (succinic) anhydride with methanol shown on p. 935.

39. Give the product(s) of reaction of methyl pentanoate with each of the following reagents under the conditions shown.
   (a) NaOH, H₂O, heat; then H⁺, H₂O  
   (b) (CH₃)₂CHCH₂CH₂OH (excess), H⁺  
   (c) (CH₃CH₂)₂NH, heat  
   (d) CH₃MgI (excess), (CH₃CH₂)₂O; then H⁺, H₂O  
   (e) LiAlH₄, (CH₃CH₂)₂O; then H⁺, H₂O  
   (f) [(CH₃)₂CHCH₂]₂AlH, toluene, low temperature; then H⁺, H₂O

40. Give the products of reaction of γ-valerolactone (5-methyloxao-2-cyclopentanone, Section 20-4) with each of the reagents in Problem 39.

41. Draw the structure of each of the following compounds: (a) β-butyrolactone; (b) β-valerolactone; (c) δ-valerolactone; (d) β-propiolactam; (e) α-methyl-δ-valerolactam; (f) N-methyl-γ-butyrolactam.

42. Formulate a mechanism for the acid-catalyzed transesterification of ethyl 2-methylpropanoate (ethyl isobutyrate) into the corresponding methyl ester. Your mechanism should clearly illustrate the catalytic role of the proton.

43. Formulate a mechanism for the reaction of methyl 9-octadecenoate with 1-dodecanamine shown on p. 939.

44. Reaction review. Suggest reagents to convert each of the following starting materials into the indicated product: (a) hexanoyl chloride into acetic hexanoic anhydride; (b) methyl hexanoate into N-methylhexanamide; (c) hexanoyl chloride into hexanal; (d) hexanenitrile into hexanoic acid; (e) hexanamide into hexanamine; (f) hexanamide into pentanamine; (g) ethyl hexanoate into 3-ethyl-3-octanol; (h) hexanenitrile into 1-phenyl-1-hexanone [C₆H₅CO(CH₂)₄CH₃].

45. Give the product of each of the following reactions.

(a) \[COOCH₃\] \[\rightarrow\] \[\text{KOH, H₂O} \rightarrow \] \[\text{H⁺, H₂O}\]

(b) \[\text{H₂C} \rightarrow \] \[\text{(CH₃)₂CHNH₂, CH₃OH, H⁺, H₂O}\]

(c) \[\text{O} \rightarrow \] \[\text{MgBr, THF; then H⁺, H₂O}\]

(d) \[\text{CH₃COCH₃} \rightarrow \] \[\text{LDA, THF, −78°C} \rightarrow \] \[\text{CH₃, HMPA}\]

(e) \[\text{CH₃COOCH₃} \rightarrow \] \[\text{(CH₃)₂CHNH₂, CH₃OH, H⁺, H₂O}\]

46. For each of the naturally occurring lactones below, draw the structure of the compound that would result from hydrolysis using aqueous base.

(a) Sedanenolide, major contributor to the flavor of celery
(b) O

(b) O

(c) \(\text{CH}_3\text{COCH}_2\text{CH}_2\text{COOH}\)

(c) \(\text{CH}_3\text{COCH}_2\text{CH}_2\text{COOH}\)

\[\text{A novel “green” process converts levulinic acid (4-oxopentanoic acid, CH}_3\text{COCH}_2\text{CH}_2\text{COOH},\]

\[\text{which is readily obtained from waste biomass, into \(\gamma\)-valerolactone by treatment with gaseous H}_2\text{ in the presence of a special hydrogenation catalyst. Speculate on how this reaction may take place.}\]

47. \(N,N\)-Diethyl-3-methylbenzamide (\(N,N\)-diethyl-\(m\)-toluamide), marketed as DEET, is perhaps the most widely used insect repellent in the world and is especially effective in interrupting the transmission of diseases by mosquitoes and ticks. Propose one or more preparations of DEET (see structure, margin) from the corresponding carboxylic acid and any other appropriate reagents.

48. Like many chiral pharmaceuticals, Ritalin, widely used to treat attention deficit disorder, is synthesized and marketed as a racemic mixture. In 2003, a new and potentially practical synthetic route to the active enantiomer (see structure, margin) was described. The first step is shown below, the reaction of dimethyl sulfate with a six-membered ring lactam. Propose a mechanism for this reaction.

\[\text{CH}_3\text{SO}_2\text{CH}_3\]

\[\text{CH}_3\text{SO}_2\text{CH}_3\]

\[\text{N}_2\text{H}\]

\[\text{N}_2\text{H}\]

49. Formulate a mechanism for the formation of acetamide, \(\text{CH}_3\text{CNH}_2\), from methyl acetate and ammonia.

50. Give the products of the reactions of pentanamide with the reagents given in Problem 39(a, e, f). Repeat for \(N,N\)-dimethylpentanamide.

51. Formulate a mechanism for the acid-catalyzed hydrolysis of 3-methylpentanamide shown on p. 948. (Hint: Use as a model the mechanism for general acid-catalyzed addition–elimination presented in Section 19-7.)

52. What reagents would be necessary to carry out the following transformations? (a) Cyclohexanecarbonyl chloride \(\rightarrow\) pentanoylcyclohexane; (b) 2-butenedioic (maleic) anhydride \(\rightarrow\) (Z)-2-butene-1,4-diol; (c) 3-methylbutanoyl bromide \(\rightarrow\) 3-methylbutanal; (d) benzamide \(\rightarrow\) 1-phenylmethanamine; (e) propanenitrile \(\rightarrow\) 3-hexanone; (f) methyl propanoate \(\rightarrow\) 4-ethyl-4-heptanol.

53. Nylon-6,6 was the first completely synthetic fiber, initially prepared in the mid-1930s at DuPont. It is a copolymer whose subunits are alternating molecules of 1,6-hexanediame and hexanedioic (adipic) acid, linked by amide functions. (a) Write a structural representation of Nylon-6,6. \(\text{Hexanedinitrile (adiponitrile)}\) may be used as a common precursor to both \(N,N\)-hexanediame and hexanedioic acid. Show the reactions necessary to convert the dinitrile into both the diamine and the diacid. (c) Formulate a mechanism for the conversion into the diacid under the reaction conditions that you chose in (b).

54. Upon treatment with strong base followed by protonation, compounds A and B undergo cis-trans isomerization, but compound C does not. Explain.
55. 2-Aminobenzoic (anthranilic) acid is prepared from 1,2-benzenedicarboxylic anhydride (phthalic anhydride) by using the two reactions shown here. Explain these processes mechanistically.

\[
\begin{align*}
\text{1,2-Benzenedicarboxylic anhydride} & \xrightarrow{\text{NH}_3, 300^\circ \text{C}} \text{1,2-Benzenedicarboximide} \\
& \xrightarrow{1. \text{NaOH, Br}_2, 80^\circ \text{C}, 2. \text{H}^+, \text{H}_2\text{O}} \text{2-Aminobenzoic acid}
\end{align*}
\]

56. On the basis of the reactions presented in this chapter, write reaction summary charts for esters and amides similar to the chart for acyl halides (Figure 20-1). Compare the number of reactions for each of the compound classes. Is this information consistent with your understanding of the relative reactivity of each of the functional groups?

57. Show how you might synthesize chlorpheniramine, a powerful antihistamine used in several decongestants, from each of carboxylic acids A and B. Use a different carboxylic amide in each synthesis.

\[
\begin{align*}
\text{A} & : \text{CHCH}_2\text{COOH} \\
\text{B} & : \text{CHCH}_2\text{CH}_2\text{COOH} \\
& : \text{CHCH}_2\text{CH}_2\text{N(CH}_3\text{)}_2 \\
& : \text{Chlorpheniramine}
\end{align*}
\]

58. Although esters typically have carbonyl stretching frequencies at about 1740 cm\(^{-1}\) in the infrared spectrum, the corresponding band for lactones can vary greatly with ring size. Three examples are shown in the margin. Propose an explanation for the IR bands of these smaller ring lactones.

59. Upon completing a synthetic procedure, every chemist is faced with the job of cleaning glassware. Because the compounds present may be dangerous in some way or have unpleasant properties, a little serious chemical thinking is often beneficial before “doing the dishes.” Suppose that you have just completed a synthesis of hexanoyl chloride, perhaps to carry out the reaction in Problem 34(b); first, however, you must clean the glassware contaminated with this acyl halide. Both hexanoyl chloride and hexanoic acid have terrible odors. (a) Would cleansing the glassware with soap and water be a good idea? Explain. (b) Suggest a more pleasant alternative, based on the chemistry of acyl halides and the physical properties (particularly the odors) of the various carboxylic acid derivatives.

60. **CHALLENGE** Show how you would carry out the following transformation in which the ester function at the lower left of the molecule is converted into a hydroxy group but that at the upper right is preserved. (**Hint:** Do not try ester hydrolysis. Look carefully at how the ester groups are linked to the steroid and consider an approach based on transesterification.)
61. The removal of the C17 side chain of certain steroids is a critical element in the synthesis of a number of hormones, such as testosterone, from steroids in the relatively readily available pregnane family.

How would you carry out the comparable transformation, shown in the margin, of acetylcyclopentane into cyclopentanol? (Note: In this and subsequent synthetic problems, you may need to use reactions from several areas of carbonyl chemistry discussed in Chapters 17–20.)

62. Propose a synthetic sequence to convert carboxylic acid A into the naturally occurring sesquiterpene α-curcumene.

63. Propose a synthetic scheme for the conversion of lactone A into amine B, a precursor to the naturally occurring monoterpene C.

64. [CHALLENGE] Propose a synthesis of β-selinene, a member of a very common family of sesquiterpenes, beginning with the alcohol shown here. Use a nitrile in your synthesis. Inspection of a model may help you choose a way to obtain the desired stereochemistry. (Is the 1-methylethenyl group axial or equatorial?)

65. Give the structure of the product of the first of the following reactions, and then propose a scheme that will ultimately convert it into the methyl-substituted ketone at the end of the scheme. This example illustrates a common method for the introduction of methyl groups into synthetically prepared steroids. (Hint: It will be necessary to protect the carbonyl function.)
Spectroscopic data for two carboxylic acid derivatives are given in NMR-A and NMR-B. Identify these compounds, which may contain C, H, O, N, Cl, and Br but no other elements. (a) $^1$H NMR: spectrum A (one signal has been amplified to reveal all peaks in the multiplet). IR: 1728 cm$^{-1}$. High-resolution mass spectrum: $m/z$ for the molecular ion is 116.0837. See table for important MS fragmentation peaks. (b) $^1$H NMR: spectrum B, IR: 1739 cm$^{-1}$. High-resolution mass spectrum: The intact molecule gives two peaks with almost equal intensity: $m/z = 179.9786$ and 181.9766. See table for important MS fragmentation peaks.

![1H NMR spectra](image)

### Team Problem

67. Friedel-Crafts acylations are best carried out with acyl halides, but other carboxylic acid derivatives undergo this process, too, such as carboxylic anhydrides or esters. These reagents may have some drawbacks, however, the subject of this problem.

Before you start, discuss as a group the mechanisms for forming acylium ions from acyl halides and carboxylic anhydrides in Section 15-13. Then divide your group in two and analyze the outcome of the following two reactions. Use the NMR spectral data given to confirm your product assignments. (Hint: D is formed via C.)

$$
	ext{C}_6	ext{H}_5 + 	ext{O} = 	ext{C} = 	ext{O} \xrightleftharpoons[\text{AlCl}_3]{300\text{MHz}} \text{A (C}_3\text{H}_5\text{O)} + \text{B (C}_{10}\text{H}_{12}\text{O)}
$$

$$
	ext{C}_6	ext{H}_5 + \text{O} = \text{C} \xrightleftharpoons[\text{AlCl}_3]{300\text{MHz}} \text{A (C}_3\text{H}_5\text{O)} + \text{C (C}_3\text{H}_{10}\text{)} + \text{D (C}_{10}\text{H}_{12}\text{O)}
$$

Compound C: $^1$H NMR: $\delta$ 1.20 (t, 3H), 2.64 (q, 2H), 7.10–7.30 (m, 5H).

Compound D: $^1$H NMR: $\delta$ 1.25 (t, 3H), 2.57 (s, 3H), 2.70 (q, 2H), 7.20 (d, 2H), 7.70 (d, 2H).
Reconvene to share your solutions. Then specifically address the nature of the complications ensuing when using the reagents shown. Finally, all together, consider the following reaction sequence. Again, use a mechanistic approach to arrive at the structures of the products.

\[
\text{C}_10\text{H}_{10}\text{O}_3 + \text{AlCl}_3 \rightarrow \text{C}_{10}\text{H}_{10}\text{O}_3
\]

\[
\text{Zn(Hg), HCl, } \Delta \rightarrow \text{C}_{10}\text{H}_{12}\text{O}_2
\]

\[
\text{SOCl}_2 \rightarrow \text{C}_{10}\text{H}_{11}\text{ClO}
\]

\[
\text{AlCl}_3 \rightarrow \text{C}_{10}\text{H}_{10}\text{O}
\]

**Preprofessional Problems**

68. What is the IUPAC name of the compound shown in the margin? (a) Isopropyl 2-fluoro-3-methylbutanoate; (b) 2-fluoroisobutanoyl 2-propanoate; (c) 1-methylethyl 2-fluorobutyrate; (d) 2-fluoroisopropyl isopropanoate; (e) 1-methylethyl 2-fluoro-2-methylpropanoate.

69. Saponification of \((\text{CH}_3)_2\text{CHC}^{18}\text{OCH}_2\text{CH}_2\text{CH}_3\) with aqueous NaOH will give

(a) \((\text{CH}_3)_2\text{CHC}^{18}\text{O}^- + \text{CH}_3\text{CH}_2\text{CH}_2^{18}\text{OH};

(b) \((\text{CH}_3)_2\text{CHC}^{18}\text{O}^- + \text{CH}_3\text{CH}_2\text{CH}_2\text{OH};

(c) \((\text{CH}_3)_2\text{CHC}^{18}\text{OCH}_2\text{CH}_2\text{CH}_3 + \text{C}^{18}\text{O};

(d) \((\text{CH}_3)_2\text{CHCHO} + \text{CH}_3\text{CH}_2\text{CH}_2^{18}\text{OH}.

70. The best description for compound A (see margin) is (a) an amide; (b) a lactam; (c) an ether; (d) a lactone.

71. Which of the three compounds below would be the most reactive toward hydrolysis with aqueous base?

(a) \[
\text{O} \quad \text{COCH}_3
\]

(b) \[
\text{O} \quad \text{CCl}
\]

(c) \[
\text{O} \quad \text{CNH}_2
\]
Our atmosphere consists of about one-fifth oxygen, O\textsubscript{2}, and nearly four-fifths nitrogen, N\textsubscript{2}. We are fully aware of the importance of the oxygen part: We need it to breathe and nature uses it abundantly in water, alcohols, ethers, and many other organic and inorganic molecules. What about the nitrogen component? Unlike O\textsubscript{2}, which is ultimately the reactive ingredient in biological oxidations, N\textsubscript{2} itself is relatively inert. However, in its reduced form of ammonia, NH\textsubscript{3}, and its organic derivatives, the amines, it plays as active a role in nature as oxygen. Thus, amines and other nitrogen-bearing compounds are among the most abundant organic molecules. As components of the amino acids, peptides, proteins, and alkaloids, they are essential to biochemistry. Many amines, such as the neurotransmitters, possess powerful physiological activity; related substances have found medicinal uses as decongestants, anesthetics, sedatives, and stimulants (Chemical Highlight 21-1). Similar activity is found in cyclic amines in which nitrogen is part of a ring, the nitrogen heterocycles (Chapter 25).

In many respects, the chemistry of the amines is analogous to that of the alcohols and ethers (Chapters 8 and 9). For example, all amines are basic (although primary and secondary amines can also behave as acids), they form hydrogen bonds, and they act as nucleophiles in substitution reactions. However, there are some differences in reactivity, because nitrogen is less electronegative than oxygen. Thus, primary and secondary amines are less acidic and form weaker hydrogen bonds than alcohols, and they are more basic and more nucleophilic. This chapter will show that these properties underlie their physical and chemical characteristics and give us a variety of ways to synthesize amines.
**21-1 Naming the Amines**

Amines are derivatives of ammonia, in which one, two, or three of the hydrogens have been replaced by alkyl or aryl groups. Therefore, amines are related to ammonia in the same sense as ethers and alcohols are related to water. Note, however, that the designations primary, secondary, and tertiary (see below) are used in a different way. In alcohols, ROH, the nature of the R group defines this designation; in amines, the number of R substituents on nitrogen determines the amine classification.

![Chemical structures of ammonia, primary amine, secondary amine, and tertiary amine](image)

The system for naming amines is confused by the variety of common names in the literature. Probably the best way to name aliphatic amines is that used by *Chemical Abstracts*—that is, as alkanamines, in which the name of the alkane stem is modified by replacing the ending -e by -amine. The position of the functional group is indicated by a prefix designating the carbon atom to which it is attached, as in the alcohols (Section 8-1).

![Chemical structures of methanamine, 1,4-butenediamine, and 1,5-pentanediame](image)

Substances with two amine functions are diamines, two examples of which are 1,4-butenediamine and 1,5-pentanediame. Their contribution to the smell of dead fish and rotting flesh leads to their descriptive common names, putrescine and cadaverine, respectively.

![Chemical structures of 1,4-butenediamine, 1,5-pentanediame, and benzenamine](image)

The aromatic amines, or anilines, are called benzenamines (Section 15-1). For secondary and tertiary amines, the largest alkyl substituent on nitrogen is chosen as the alkanamine stem, and the other groups are named by using the letter N-, followed by the name of the additional substituent(s).
An alternative way to name amines treats the functional group, called *amino-*, as a substituent of the alkane stem. This procedure is analogous to naming alcohols as hydroxyalkanes. It is also used when other functional groups are present in the molecule, because the amine function has the lowest order of precedence of all functional groups discussed in this text (Section 19-1).

Many common names are based on the term alkylamine (see margin), as in the naming of alkyl alcohols.

### Exercise 21-1
Name each of the following molecules twice, first as an alkanamine, then as an alkyl amine.

(a) \( \text{CH}_3\text{CHCH}_2\text{CH}_3 \)
(b) \( \text{N(CH}_3)_2 \)
(c) \( \text{Br} - \text{CH}_3\text{CH}_2\text{NH}_2 \)

### Exercise 21-2
Draw structures for the following compounds (common name in parentheses): (a) 2-propynamine (propargylamine); (b) \( N\text{-2-propenyl} \)phenylmethanamine (\( N\text{-allyl} \)benzylamine); (c) \( N,2\text{-dimethyl-2-propanamine} \) (\( \text{tert} \)-butylmethylamine).

### In Summary
There are several systems for naming amines. *Chemical Abstracts* uses names of the type alkanamine and benzenamine. Alternatives for alkanamine are the terms amino-alkane and alkylamine. The common name for benzenamine is aniline.

**21-2 Structural and Physical Properties of Amines**

Nitrogen often adopts a tetrahedral geometry, similar to carbon, but with one lone electron pair instead of a fourth bond. Thus, amines generally have tetrahedral shapes around the heteroatom. However, this arrangement is not rigid because of a rapid isomerization process called inversion. Nitrogen is not as electronegative as oxygen, so while amines form hydrogen bonds, they are weaker than the hydrogen bonds formed by alcohols. As a result, amines have relatively low boiling points compared to alcohols.

**The alkanamine nitrogen is tetrahedral**

In contrast to amides (Section 20-1), the nitrogen orbitals in amines are very nearly \( sp^3 \) hybridized (see Section 1-8), forming an approximately tetrahedral arrangement. Three vertices of the tetrahedron are occupied by the three substituents, the fourth by the lone electron pair. As we shall see, it is this electron pair that is the source of the basic and nucleophilic properties of the amines. The term *pyramidal* is often used to describe the geometry adopted by the nitrogen and its three substituents. Figure 21-1 depicts the structure of methanamine (methylamine).
CHEMICAL HIGHLIGHT 21-1

Physiologically Active Amines and Weight Control

A large number of physiologically active compounds owe their activity to the presence of amino groups. Several simple examples are well-known prescription or illegal drugs, such as adrenaline, Benzedrex, Urotropine, amphetamine, mescaline, and Effexor (see Chapter Opening). A recurring pattern in many (but not all) of these compounds is the 2-phenylethanamine (β-phenethylamine) unit—that is, a nitrogen connected by a two-carbon chain to a benzene nucleus (highlighted below in green where applicable). This structural feature appears to be crucial for the binding to brain receptor sites responsible for neurotransmitter action at certain nerve terminals. Such amines can affect a wide variety of behavior, from controlling appetite and muscular activity to creating potentially addictive euphoric stimulation.

The problem of selective targeting of these sites by molecular design has played a major role in the development of drugs that control weight and combat obesity. This effort has taken several directions. Thus, whereas many of the “diet pills” rely on their anorectic (appetite-suppressing) effect, newer products, such as sibutramine (approved by the FDA in 1997), which has no stimulating side effects, act by increasing satiety. In other words, you feel hungry, but you are more quickly satisfied after you start eating, or feel full longer. A recent compound, rimonabant, works on a different principle, and its discovery illustrates one of the ways chosen by researchers to find new drugs. It is known that smoking cannabis (marijuana; Sections 9-11 and 20-6) can induce hunger pangs (“the munchies”). Therefore, it was hypothesized that blocking the corresponding cannabinoid receptors in the brain would eliminate such craving. Such an effect then could be useful in weight control. Indeed, extensive screening showed that rimonabant is very active in this respect, and the drug entered the European market in 2006. However, the U.S. FDA refused approval in 2007, because of concerns over potential depressive side effects. In 2008 the drug was pulled off the European market and several companies discontinued developing related compounds, putting a stop to this promising approach, at least for now.

Another approach to controlling weight is to increase metabolic rate (and hence body temperature), a goal most simply and commonly attained by exercising. An arguably...
less taxing alternative is a thermogenic drug. Caffeine is such a compound, but its enhancing effect on the metabolic rate is short-lived and is followed by a period of actually depressing it.

Whereas thermogenic drugs help control body weight by “burning off fat,” the exact opposite—namely, inhibition of caloric intake by preventing metabolism—is being attempted with yet another class of drugs. An example is orlistat (approved by the FDA in 1999), a molecule that retards the enzymatic breakdown of fat in the gut, thus allowing food to be excreted undigested. Initially sold only by prescription, the FDA approved an over-the-counter formulation in 2007 (marketed under the name alli™), a first for a weight-loss drug.

Amines are not the only agents that are being investigated for their potential in weight control. For example, the completely nondigestible fat olestra contains no nitrogens, and its development is based on the finding that molecules with more than five ester functions (recall that “normal” fats are triglycerides; Section 20-5) are not metabolized by the body’s enzymes. Although the structure of olestra looks forbidding, it is actually a simple octaester of common table sugar, sucrose (shown in green; Chapter 24). Olestra is currently used in some foods, especially savory snacks such as potato chips, cheese puffs, and crackers.

You may question the validity of this type of drug research, because it appears to cater to the glutton or the “fashionable” in the search of the perfect body. Not so. Do not forget that obesity is a major health hazard, causing chronic diseases, such as cardiovascular and respiratory problems, hypertension, diabetes, and certain cancers, and that it shortens the life span of those afflicted. It appears to be mostly the result of a metabolic (perhaps in some cases genetic) disposition that cannot otherwise be controlled.
The tetrahedral geometry around an amine nitrogen suggests that it should be chiral if it bears three different substituents, the lone electron pair serving as the fourth. The image and mirror image of such a compound are not superimposable, by analogy with carbon-based stereocenters (Section 5-1). This fact is illustrated with the simple chiral alkanamine $N$-methylethanamine (ethylmethylamine).

However, samples of the amine prove not to be optically active. Why? Amines are not configurationally stable at nitrogen, because of rapid isomerization by a process called inversion. The molecule passes through a transition state incorporating an $sp^3$-hybridized nitrogen atom, as illustrated in Figure 21-2. This transition state is similar to that depicted in Figure 6-4 for the inversion observed in $S_n2$ reactions (Section 6-5). The barrier to this motion in ordinary small amines has been measured spectroscopically and found to be between 5 and 7 kcal mol$^{-1}$ (ca. 20–30 kJ mol$^{-1}$). It is therefore impossible to keep an enantiomerically pure, simple di- or trialkylamine from racemizing at room temperature when the nitrogen atom is the only stereocenter.

Amines form weaker hydrogen bonds than alcohols do

Because alcohols readily form hydrogen bonds (Section 8-2), they have unusually high boiling points. In principle, so should amines, and indeed Table 21-1 bears out this ascending

Exercise 21-3
The bonds to nitrogen in methanamine (methylamine; see Figure 21-1) are slightly longer than the bonds to oxygen in the structure of methanol (Figure 8-1). Explain. (Hint: See Table 1-2.)
expectation. However, because amines form weaker hydrogen bonds than alcohols do, their boiling points are lower and their solubility in water less. In general, the boiling points of the amines lie between those of the corresponding alkanes and alcohols. The smaller amines are soluble in water and in alcohols because they can form hydrogen bonds to the solvent. If the hydrophobic part of an amine exceeds six carbons, the solubility in water decreases rapidly; the larger amines are essentially insoluble in water.

**In Summary** Amines adopt an approximately tetrahedral structure in which the lone electron pair occupies one vertex of the tetrahedron. They can, in principle, be chiral at nitrogen but are difficult to maintain in enantiomerically pure form because of fast inversion at the nitrogen. Amines have boiling points higher than those of alkanes of similar size. Their boiling points are lower than those of the analogous alcohols because of weaker hydrogen bonding, and their water solubility is between that of comparable alkanes and alcohols.

### 21-3 Spectroscopy of the Amine Group

Primary and secondary amines can be recognized by infrared spectroscopy because they exhibit a characteristic broad N–H stretching absorption in the range between 3250 and 3500 cm\(^{-1}\). Primary amines show two strong peaks in this range, whereas secondary amines give rise to only a single line (see also IR spectra of amides, Section 20-1). Primary amines also show a band near 1600 cm\(^{-1}\) that is due to a scissoring motion of the NH\(_2\) group (Section 11-8, Figure 11-17, and margin). Tertiary amines do not give rise to such signals, because they do not have a hydrogen that is bound to nitrogen. Figure 21-3 shows the infrared spectrum of cyclohexanamine.

Nuclear magnetic resonance spectroscopy also may be useful for detecting the presence of amino groups. Amine hydrogens often resonate to give broadened peaks, like the OH signal in the NMR spectra of alcohols. Their chemical shift depends mainly on the rate of exchange of protons with water in the solvent and the degree of hydrogen bonding.

---

*Whereas all amines can act as proton acceptors in hydrogen bonding, only primary and secondary amines can function as proton donors, because tertiary amines lack such protons.*

Amine and Their Derivatives

Figure 21-3 (A) Infrared spectrum of cyclohexanamine. The molecule exhibits two strong peaks between 3250 and 3500 cm \(^{-1}\), characteristic of the N–H stretching absorptions of the primary amine functional group. The broad band near 1600 cm \(^{-1}\) results from scissoring motions of the N–H bonds. (B) N-Methylcyclohexanamine shows only one N–H peak at 3300 cm \(^{-1}\). (C) N,N-Dimethylcyclohexanamine has no peaks between 3250 and 3500 cm \(^{-1}\).

Figure 21-4 shows the \(^1\)H NMR spectrum of azacyclohexane (piperidine), a cyclic secondary amine. The amine hydrogen peak appears at \(\delta = 1.22\) ppm, and there are two other sets of signals, multiplets at \(\delta = 1.34\) and 2.61 ppm. The absorption at lowest field can be assigned to the hydrogens neighboring the nitrogen, which are deshielded by the effect of its electronegativity.

Exercise 21-4

Would you expect the hydrogens next to the heteroatom in an amine, \(\text{RCH}_2\text{NH}_2\), to be more or less deshielded than those in an alcohol, \(\text{RCH}_2\text{OH}\)? Explain. (Hint: See Exercise 21-3.)

The \(^{13}\)C NMR spectra of amines show a similar trend: Carbons bound directly to nitrogen resonate at considerably lower field than do the carbon atoms in alkanes. However, as in \(^1\)H NMR (Exercise 21-4), nitrogen is less deshielding than oxygen.
Mass spectrometry readily establishes the presence of nitrogen in an organic compound. Unlike carbon, which is tetravalent, nitrogen is trivalent. Because of these valence requirements and because nitrogen has an even atomic weight (14), molecules incorporating one nitrogen (or any odd number of nitrogens) have an odd molecular weight (review Exercise 11-21). You can readily verify this count by considering that the molecular formula for an amine containing a nitrogen is \( C_nH_{2n+1}N \).

The mass spectral fragmentation patterns of amines also aid in structural assignments. For example, the mass spectrum of \( N,N \)-diethylethanamine (triethylamine) shows the peak for the molecular ion at \( m/z = 101 \) (Figure 21-5). More prominent, however, the base peak is at \( m/z = 86 \) and is caused by the loss of a methyl group by \( \alpha \)-cleavage (Section 11-10). Such fragmentation is favored because it results in a resonance-stabilized iminium ion.

**Mass-Spectral Fragmentation of \( N,N \)-Diethylethanamine**

\[
\begin{align*}
(CH_3CH_2)_2NCH_2\text{CH}_3 & \quad \rightarrow \quad CH_3^+ \quad + \quad (CH_3CH_2)_2N\equiv CH_2 \quad \leftrightarrow \quad (CH_3CH_2)_2N\equiv CH_2
\end{align*}
\]

The rupture of the C–C bond next to nitrogen is frequently so easy that the molecular ion cannot be observed. For example, in the mass spectrum of 1-hexanamine, the molecular ion \( (m/z = 101) \) is barely visible; the dominating peak corresponds to the methyleneiminium fragment \([CH_2\equiv NH_2]^+ (m/z = 30)\).
Figure 21-5 Mass spectrum of \( N,N\text{-diethylethanamine} \) (triethylamine), showing a molecular ion peak at \( m/z = 101 \). In general, molecules incorporating one nitrogen atom have an odd molecular weight. The base peak is due to loss of a methyl group, resulting in an iminium ion with \( m/z = 86 \).

Exercise 21-5

Working with the Concepts: Assigning the Structure of an Amine

A compound with the molecular formula \( C_8H_{11}N \) exhibited the following spectral data: Mass spectrum: \( m/z \) (relative intensity) = 121 (M\(^+\), 6), 91 (15), 30 (100). \(^1\)H NMR: \( \delta = 1.16 \) (s, 2 H), 2.73 (t, \( J = 7 \) Hz, 2 H), 2.93 (t, \( J = 7 \) Hz, 2 H), 7.20 (m, 5 H) ppm. \(^{13}\)C NMR: \( \delta = 40.2 \) (CH\(_2\)), 43.6 (CH\(_2\)), 126.1 (CH), 128.4 (CH), 128.8 (CH), 139.9 (C_quaternary) ppm. IR (neat): selected \( \nu = 3366, 3284, 3062, 3026, 2932, 2850, 1603, 746, 700 \) cm\(^{-1}\).

What is it?

Strategy

The combined spectral data give us more than enough information to elucidate the structure of this unknown. The following analyzes them in order of appearance in the question, starting with the mass and \(^1\)H NMR spectra to reach a tentative assignment. The remaining data are then used to support it. However, in problems like this, you can start with whatever spectral information you deem most relevant, jump from one type of spectroscopy to another, and piece together the solution that way.

Solution

• The mass spectrum shows a molecular ion \( (m/z = 121) \), which corresponds to the molecular formula (as it should), \( C_8H_{11}N \).

• More instructive are the fragment peaks: the first, at \( m/z = 91 \), signifies the loss of a piece with mass = 30, exactly the value of the second fragment ion. In other words, the molecule breaks up very efficiently into two segments of \( m/z = 91 \) and 30. How do we dissect \( C_8H_{11}N \) to provide such fragments? It should not take you long to realize that \( m/z = 30 \) must be due to \( \text{[CH}_2\text{NH}_2] \), as there is no other sensible alternative. (The only other molecule with this mass that can be written is \( C_2H_6 \), ethane.) Therefore, \( m/z = 91 \) has the composition \( C_6H_7N \).

• Subtracting the \( C_2H_6 \) from \( C_8H_{11}N \) leaves \( C_6H_7N \) for \( A \) and \( B \).

• Finally, we observe an aromatic multiplet of 5 H at \( \delta = 7.20 \) ppm, strongly indicative of a phenyl group, \( C_6H_5 \). If this group were \( A \), then \( B \) would have to be \( \text{NH}_2 \), and a possible structure would be 2-phenylethanamine, \( C_6H_5CH_2CH_2NH_2 \). Such a solution would certainly be in accord with the
In Summary

The IR stretching absorption of the N–H bond ranges between 3250 and 3500 cm\(^{-1}\); the corresponding \(^1\)H NMR peak is often broad and can be found at variable \(\delta\).

- The electron-withdrawing nitrogen deshields neighboring carbons and hydrogens, although to a lesser extent than the oxygen in alcohols and ethers. The mass spectra of simple alkanamines that contain only one nitrogen atom have odd-numbered molecular ion peaks, because of the trivalent character of nitrogen. Fragmentation occurs in such a way as to produce resonance-stabilized iminium ions.

21-4 Acidity and Basicity of Amines

Like the alcohols (Section 8-3), amines are both basic and acidic. Because nitrogen is less electronegative than oxygen, the acidity of amines is about 20 orders of magnitude less than that of comparable alcohols. Conversely, the lone pair is much more available for protonation, thereby causing amines to be better bases.

<table>

</tr>
</tbody>
</table>

Amines are very weak acids

We have seen evidence that amines are much less acidic than alcohols: Amide ions, \(R_2N^-\), are used to deprotonate alcohols (Section 9-1). The equilibrium of this proton transfer lies strongly to the side of the alkoxide ion. The high value of the equilibrium constant, about \(10^{20}\), is due to the strong basicity of amide ions, which is consistent with the low acidity of amines. The p\(K_a\) of ammonia and alkanamines is of the order of 35.
The deprotonation of amines requires extremely strong bases, such as alkyl lithium reagents. For example, lithium diisopropylamide, the sterically hindered base used in some bimolecular elimination reactions (Section 7-8), is made in the laboratory by treatment of \( N-(1\text{-methyl})-2\text{-propanamine} \) (diisopropylamine) with butyllithium.

**Preparation of LDA**

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{CH}_3 \\
\text{CH}_3\text{CHNCHCH}_3 & \\
\text{H} & \\
\text{N-(1-Methyl)2-propanamine (Diisopropylamine)} & \\
\text{Li}^+ & \\
\text{H}_3\text{C} & \quad \text{CH}_3 \\
\text{CH}_3\text{CHNCHCH}_3 & \\
\text{Lithium diisopropylamide, LDA}
\end{align*}
\]

An alternative synthesis of amide ions is the treatment of amines with alkali metals. Alkali metals dissolve in amines (albeit relatively slowly) with the evolution of hydrogen and the formation of amine salts (much as they dissolve in water and alcohol, furnishing \( \text{H}_2 \) and metal hydroxides or alkoxides, Section 9-1). For example, sodium amide can be made in liquid ammonia from sodium metal in the presence of catalytic amounts of \( \text{Fe}^{3+} \), which facilitates electron transfer to the amine. In the absence of such a catalyst, sodium simply dissolves in ammonia (labeled “Na, liquid \( \text{NH}_3 \)”) to form a strongly reducing solution (Section 13-6).

**Amines are moderately basic, ammonium ions are weakly acidic**

Amines deprotonate water to a small extent to form ammonium and hydroxide ions. Thus, amines are more strongly basic than alcohols but not nearly as basic as alkoxides. Protonation occurs at the site of the free electron pair as pictured in the electrostatic potential map of \( N,N\text{-dimethylmethanamine} \) (trimethylamine) in the margin.

**Basicity of Amines**

\[
\begin{align*}
\text{RNH}_2 & + \text{H}^+ + \text{OH}^- \rightleftharpoons \text{RNH}_3^+ + \text{H}_2\text{O}^- \\
\text{Ammonium ion} & \\
\text{Amine} & \\
\text{RNH}_2 & \\
\text{H} & \\
\text{RNH}_3^+ & \\
\text{Primary ammonium chloride} & \\
\text{R}_2\text{NH}_2 \text{Br}^- & \\
\text{Secondary ammonium bromide} & \\
\text{R}_3\text{NH}^+ \text{I}^- & \\
\text{Tertiary ammonium iodide}
\end{align*}
\]

The resulting ammonium salts can be primary, secondary, or tertiary, depending on the number of substituents on nitrogen.
Ammonium salts are named by attaching the substituent names to the ending -ammonium followed by the name of the anion.

It is useful to view the basicity of the amines as a measure of the acidity of their conjugate acids (Section 2-2), the ammonium ions. These species are stronger acids than water ($pK_a = 15.7$; Table 2-2) or alcohols but much weaker than carboxylic acids ($pK_a = 4-5$; Section 19-4).

Any factor, such as substituents or hybridization, that increases the electron density of the amine nitrogen increases the basicity of the amine and therefore the $pK_a$ of the corresponding ammonium salt. Conversely, decreasing the electron density of the amine nitrogen decreases its basicity and the $pK_a$ of the corresponding ammonium salt. For example, alkylammonium salts are slightly less acidic than ammonium ion, $\text{NH}_4^+$, and therefore the corresponding amines are more basic. The reason is the electron-donating character of alkyl groups (Sections 7-5 and 16-1). However, as shown below, the $pK_a$ values do not increase in a regular way with increasing alkyl substitution. In fact, tertiary amines are typically less basic than secondary systems. Solvation is responsible for this observation. Thus, increasing the number of alkyl groups on the amine nitrogen increases unfavorable steric disruption of the solvent shell (Section 8-3). At the same time, it decreases the number of hydrogens attached to the nitrogen capable of entering into favorable hydrogen bonds (Section 21-2). Both phenomena counteract the inductive donor properties of the alkyl groups in solution. Indeed, in the gas phase, in which there is no solvent, the trend is as expected: ($pK_a$) $\text{NH}_4^+ < \text{CH}_3\text{NH}_3 < (\text{CH}_3)_2\text{NH} < (\text{CH}_3)_3\text{N}$.

</tbody>
</table>

*The $pK_a$ value of an ammonium ion is actually 35.
The nitrogen lone pairs in arenamines, carboxamides, and imines are less available for protonation.

In contrast to the effect of alkyl groups, the basicity of amines is decreased by electron-withdrawing substituents on the nitrogen. For example, the $pK_a$ of 2-[bis(2-hydroxyethyl)amino]ethanol is only 7.75, a consequence of the presence of three inductively...
solution by acidification with strong mineral acid, such as HCl. Next, the organic solution that remains is treated with acid, thus converting any amine present into the corresponding water-soluble ammonium salt, which moves into the water phase. Separation of the layers gives an organic solution, which contains the neutral substances. The amine is removed from water solution by treatment with strong base, such as NaOH.

**Separation of Acidic (Carboxylic Acid), Basic (Amine), and Neutral (Haloalkane) Organic Compounds by Aqueous Extraction**

Electron-withdrawing oxygens. Similarly, benzenamine (aniline) is considerably less basic ($pK_a = 4.63$) than its saturated analog cyclohexanamine ($pK_a = 10.66$) and other primary amines. There are two reasons for this effect. One is the $sp^2$ hybridization of the aromatic carbon attached to the nitrogen in benzenamine, which renders that carbon relatively electron withdrawing (Sections 11-3 and 13-2), in this way making the nitrogen lone pair less available for protonation. The second reason is the resonance stabilization of the system by delocalization of the electron pair into the aromatic $\pi$ system (Section 16-1). This resonance is lost upon protonation. A similar example is acetamide, in which the appended acetyl group ties up the nitrogen lone pair by induction (the carbonyl carbon is positively polarized) and resonance (Section 20-1).

As might be expected, the hybridization at nitrogen itself also drastically affects basicity, in the order $:NH_2 > R_2C==NR' > RC==N$: a phenomenon that we already encountered in the discussion of the relative acidity of alkanes, alkenes, and alkynes (Section 13-2). Thus, iminium ions (Section 17-9) have $pK_a$ values estimated to be of the order of 7 to 9; $N$-protonated nitriles (Section 20-8) are even more acidic ($pK_a < -5$). Table 21-2 summarizes the $pK_a$ values of the conjugate acids of some representative amines.

**Exercise 21-7**

Explain the decreasing $pK_a$ values of the following (protonated) amines:

$pK_a = 10.7 
9.5 
8.2$
In Summary  Amines are poor acids and require alkyllithium reagents or alkali metal treatment to form amide ions. In contrast, they are moderately good bases, leading to the relatively weakly acidic ammonium salts.

21-5 Synthesis of Amines by Alkylation

Amines can be synthesized by alkylating nitrogen atoms. Several such procedures take advantage of an important property of the nitrogen in many compounds: It is nucleophilic.

Amines can be derived from other amines

As nucleophiles, amines react with haloalkanes to give ammonium salts (Section 6-2). Unfortunately, this reaction is not clean, because the resulting amine product usually undergoes further alkylation. How does this complication arise?

Consider the alkylation of ammonia with bromomethane. When this transformation is carried out with equimolar quantities of starting materials, the weakly acidic product (methylammonium bromide), as soon as it is formed, (reversibly) donates a proton to the starting, weakly basic ammonia. The small quantities of methanamine generated in this way then compete effectively with the ammonia for the alkylating agent, and this further methylation generates a dimethylammonium salt.

The process does not stop there, either. This salt can donate a proton to either of the other two nitrogen bases present, furnishing N-methylmethanamine (dimethylamine). This compound constitutes yet another nucleophile competing for bromomethane; its further reaction leads to N,N-dimethylmethanamine (trimethylamine) and, eventually, to tetramethylammonium bromide, a quaternary ammonium salt. The final outcome is a mixture of alkylammonium salts and alkanamines.

\[ \text{CH}_3\text{Br} \xrightarrow{\text{Amine hydrobromide}} (\text{CH}_3)_2\text{N}^+ \quad \text{N}_2\text{N-Dimethylmethanamine (Trimethylamine)} \]

\[ \text{CH}_3\text{Br} \xrightarrow{\text{Tetramethylammonium bromide}} \text{Tetramethylammonium hydrobromide} \]

The mixture of products obtained upon treatment of haloalkanes with ammonia or amines is a serious drawback that limits the usefulness of direct alkylation in synthesis. As a result, indirect alkylation methods are frequently applied, particularly in the preparation of primary amines.

Exercise 21-8

Like other amines, benzenamine (aniline) can be benzylated with chloromethylbenzene (benzyl chloride), \( \text{C}_6\text{H}_5\text{CH}_2\text{Cl} \). In contrast with the reaction with alkanamines, which proceeds at room temperature, this transformation requires heating to between 90 and 95°C. Explain. (Hint: See Section 21-4.)

Indirect alkylation leads to primary amines

The synthesis of primary amines requires a nitrogen-containing nucleophile that will undergo reaction only once and that can be converted subsequently into the amino group. For example, cyanide ion, \( \text{CN}^- \), turns primary and secondary haloalkanes into nitriles, which are then reduced to the corresponding amines (Section 20-8). This sequence allows the conversion \( \text{RX} \to \text{RCH}_2\text{NH}_2 \). Note, however, that this method introduces an additional carbon into the haloalkane framework, because cyanide is alkylated at carbon and not nitrogen.

Conversion of a Haloalkane into the Homologous Amine by Cyanide Displacement–Reduction

\[ \text{RX} + \text{CN}^- \xrightarrow{\text{LiAlH}_4 \text{ or } \text{H}_2, \text{metal catalyst}} \text{RC≡N} + \text{X}^- \]

\[ \text{RC≡N} \xrightarrow{\text{H}_2, \text{Raney Ni, 100 atm}} \text{RCH}_2\text{NH}_2 \]

\[ \text{CH}_3(\text{CH}_2)_3\text{Br} + \text{NaCN} \xrightarrow{\text{DMSO}} \text{CH}_3(\text{CH}_2)_3\text{CN} \xrightarrow{\text{H}_2, \text{Raney Ni, 100 atm}} \text{CH}_3(\text{CH}_2)_3\text{CH}_2\text{NH}_2 \]

1-Bromononane Decanenitrile 1-Decanamine

93% 92%

To transform a haloalkane selectively into the corresponding amine without additional carbons requires a modified nitrogen nucleophile that is unreactive after the first alkylation. Such a nucleophile is the azide ion, \( \text{N}_3^- \), which reacts with haloalkanes to furnish alkyl azides. These azides in turn are reduced by catalytic hydrogenation (Pd–C) or by lithium aluminum hydride to the primary amines.

Azide Displacement–Reduction

\[ \text{Br} + \text{Na}^+ \text{N}=\text{N}=\text{N}^- \xrightarrow{\text{CH}_3\text{CH}_2\text{OH}} \text{S} \to 2 \text{ reaction} \]

\[ \text{N}=\text{N}=\text{N}^- \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O}} \text{2. } \text{H}^+, \text{H}_2\text{O} \]

3-Cyclopentylpropyl azide 3-Cyclopentylpropanamine

91% 89%
A nonreductive approach to synthesizing primary amines uses the (commercially available) anion of 1,2-benzenedicarboximide (phthalimide), the imide of 1,2-benzenedicarboxylic (phthalic) acid. This process is also known as the **Gabriel synthesis**. Because the nitrogen in the imide is adjacent to two carbonyl functions, the acidity of the NH group ($pK_a = 8.3$) is much greater than that of an ordinary amide ($pK_a = 22$, Section 20-7). Deprotonation can therefore be achieved with as mild a base as carbonate ion, the resulting anion being monoalkylated in good yield. The amine subsequently can be liberated by acidic hydrolysis, initially as the ammonium salt. Base treatment of the salt then produces the free amine.

**Exercise 21-9**

The cleavage of an N-alkyl-1,2-benzenedicarboximide (N-alkyl phthalimide) is frequently carried out with base or with hydrazine, $\text{H}_2\text{NNH}_2$. The respective products of these two treatments are the 1,2-benzenedicarboxylate A or the hydrazide B. Write mechanisms for these two transformations. (Hint: Review Section 20-6.)

---

*Professor Siegmund Gabriel (1851–1924), University of Berlin.*
In Summary  Amines can be made from ammonia or other amines by simple alkylation, but this method gives mixtures and poor yields. Primary amines are better made in stepwise fashion, employing nitrile and azide groups, or protected systems, such as 1,2-benzenedicarboxylic imide (phthalimide) in the Gabriel synthesis.

21-6 Synthesis of Amines by Reductive Amination

A more general method of amine synthesis, called reductive amination of aldehydes and ketones, allows the construction of primary, secondary, and tertiary amines. In this process, the carbonyl compound is exposed to an amine containing at least one N – H bond (NH₃, primary, secondary amines) and a reducing agent to furnish a new alkylated amine directly (a primary, secondary, or tertiary amine, respectively). The new C – N bond is formed to the carbonyl carbon of the aldehyde or ketone.

General Reductive Amination

The sequence begins by the initial condensation of the amine with the carbonyl component (Section 17-9) to produce the corresponding imine (for NH₃ and primary amines) or iminium ion (secondary amines). Similar to the carbon–oxygen double bond in aldehydes and ketones, the carbon–nitrogen double bond in these intermediates is then reduced by simultaneous catalytic hydrogenation or by added special hydride reagents.

Reductive Amination of a Ketone with a Primary Amine

This reaction succeeds because of the selectivity of the reducing agents: either hydrogen gas in the presence of a catalyst (Section 12-2) or sodium cyanoborohydride, Na⁺–BH₃CN. Both react faster with the imine double bond than with the carbonyl group under the conditions employed. With Na⁺–BH₃CN, the conditions are relatively acidic (pH = 2–3), activating the imine double bond by protonation on nitrogen and thus facilitating hydride attack at carbon. As shown in the margin, the relative stability of the modified borohydride reagent

Exercise 21-10

Show how you would apply the Gabriel method to the synthesis of each of the following amines: (a) 1-hexanamine; (b) 3-methylpentanamine; (c) cyclohexanamine; (d) H₂NCH₂CO₂H, the amino acid glycine. (Caution: In the synthesis of glycine, you need to watch out for the carboxylic acid function. Can you see why?) For each of these four syntheses, would the azide displacement–reduction method be equally good, better, or worse?

ANIMATION

ANIMATED MECHANISM: Reductive amination

Diminished ability of H to leave as :H⁻, hence reagent is less sensitive to H⁺.
Amine Synthesis by Reductive Amination

\[
\text{Benzaldehyde} + \text{NH}_3 \rightarrow \text{Phenylmethanamine (Benzylamine)}
\]

\[
\text{Cyclohexanone} + \text{CH}_3\text{NH}_2 \rightarrow \text{N-Methylcyclohexanamine}
\]

Similarly, reductive aminations with secondary amines give tertiary amines.

Secondary amines cannot form imines with aldehydes and ketones, but are in equilibrium with the corresponding \(N,N\)-dialkyliminium ions (Section 17-9), which are reduced by addition of \(H^+\) from cyanoborohydride.

Exercise 21-11

Formulate a mechanism for the reductive amination with the secondary amine shown in the preceding example.
Exercise 21-12

Working with the Concepts: Applying Reductive Amination

Explain the following transformation by a mechanism.

\[
\text{O} \quad \text{H} \quad \text{NH}_2 \quad \text{H} \quad \overset{\text{NaBH}_3\text{CN, CH}_3\text{OH}}{\rightarrow} \quad \text{O} \quad \text{H} \\
\]

**Strategy**
As usual, you need to take an inventory of the functionalities present in the starting material, the reagent, and the product (an amine). The result is that we are dealing with an intramolecular variant of reductive animation. This realization should be the starting point for retrosynthetic analysis.

**Solution**
- First, write down the generic process retrosynthetically:

\[
\begin{align*}
\text{C} - \text{N} & \quad \Rightarrow \quad \text{C} = \text{O} + \text{H} - \text{N} \\
\end{align*}
\]

- Thus, the retrosynthetic disconnection from the product is

\[
\begin{align*}
\text{O} & \quad \text{CH} \quad \text{H} \\
\end{align*}
\]

- The mechanism of the forward reaction follows accordingly (not all intermediates are shown):

Exercise 21-13

Try It Yourself

Treatment of aldehyde A with the modified sodium cyanoborohydride reagent shown gave the natural product bufavine, a bioactive constituent of the bulbs of the *Boophane flava* plant from southern Africa. Its mass spectral molecular ion occurs at \( m/z = 283 \). Suggest a structure.
In Summary  Reductive amination furnishes alkanamines by reductive condensation of amines with aldehydes and ketones.

21-7 Synthesis of Amines from Carboxylic Amides

Carboxylic amides can be versatile precursors of amines by reduction of the carbonyl unit (Section 20-6). Since amides are in turn readily available by reaction of acyl halides with amines (Section 20-2), the sequence acylation–reduction constitutes a controlled mono-alkylation of amines.

![Utility of Amides in Amine Synthesis]

Primary amides can also be turned into amines by oxidation with bromine or chlorine in the presence of sodium hydroxide—in other words, by the Hofmann rearrangement (Section 20-7). Recall that in this transformation the carbonyl group is extruded as carbon dioxide, so the resulting amine bears one carbon less than the starting material.

![Amines by Hofmann Rearrangement]

Exercise 21-14

Suggest synthetic methods for the preparation of \(N\)-methylhexanamine from hexanamine (two syntheses) and from \(N\)-hexylmethanamide (\(N\)-hexylformamide).

In Summary  Amides can be reduced to amines by treatment with lithium aluminum hydride. The Hofmann rearrangement converts amides into amines with loss of the carbonyl group.

21-8 Reactions of Quaternary Ammonium Salts: Hofmann Elimination

Much like the protonation of alcohols, which turns the –OH into the better leaving group \(\dfrac{-OH_2}{-OH}\) (Section 9-2), protonation of amines might render the resulting ammonium salts subject to nucleophilic attack. In practice, however, amines are not sufficiently good leaving groups (they are more basic than water) to partake in substitution reactions. Nevertheless, they can function as such in the Hofmann* elimination, in which a tetraalkylammonium salt is converted to an alkene by a strong base.

Section 21-5 described how complete alkylation of amines leads to the corresponding quaternary alkylammonium salts. These species are unstable in the presence of strong base, because of a bimolecular elimination reaction that furnishes alkenes (Section 7-7). The base attacks the hydrogen in the \(\beta\)-position with respect to the nitrogen, and a trialkylamine departs as a neutral leaving group.

*This is the Hofmann of the Hofmann rule for E2 reactions (Section 11-6) and the Hofmann rearrangement (Section 20-7).
Bimolecular Elimination of Quaternary Ammonium Ions

In the procedure of Hofmann elimination, the amine is first completely methylated with excess iodomethane (exhaustive methylation) and then treated with wet silver oxide (a source of HO\(^{-}\)) to produce the ammonium hydroxide. Heating degrades this salt to the alkene. When more than one regioisomer is possible, Hofmann elimination, in contrast to most E2 processes, tends to give less substituted alkenes as the major products. Recall that this result adheres to Hofmann’s rule (Section 11-6) and appears to be caused by the bulk of the ammonium group, which directs the base to the less hindered protons in the molecule.

Hofmann Elimination of 1-Butanamine

Exercise 21-15

Give the structures of the possible alkene products of the Hofmann elimination of (a) \(N\)-ethylpropanamine (ethylpropylamine) and (b) 2-butanamine. (Caution: In the Hofmann elimination of 2-butanamine, you need to consider several products. Hint: Review Section 11-6).

Exercise 21-16

Why is exhaustive methylation and not, say, ethylation used in Hofmann eliminations for structure elucidation? (Hint: Look for other possible elimination pathways.)
In Summary Quaternary methyl ammonium salts, synthesized by amine methylation, undergo bimolecular elimination in the presence of base to give alkenes.

21-9 Mannich Reaction: Alkylation of Enols by Iminium Ions

In the aldol reaction, an enolate ion attacks the carbonyl group of an aldehyde or ketone (Section 18-5) to furnish a $\beta$-hydroxycarbonyl product. A process that is quite analogous is the Mannich* reaction. Here, however, it is an enol that functions as the nucleophile and an iminium ion, derived by condensation of a second carbonyl component with an amine, as the substrate. The outcome is a $\beta$-aminocarbonyl product.

To differentiate the reactivity of the three components of the Mannich reaction, it is usually carried out with (1) a ketone or aldehyde; (2) a relatively more reactive aldehyde (often formaldehyde, CH$_2$==O, see Section 17-6); and (3) the amine, all in an alcohol solvent containing HCl. These conditions give the hydrochloride salt of the product. The free amine, called a Mannich base, can be obtained upon treatment with base.

The mechanism of this process starts with iminium ion formation between the aldehyde (e.g., formaldehyde) and the amine, on the one hand, and enolization of the ketone, on the other. The electrostatic potential maps in the margin (p. 995) illustrate the electron deficiency of the iminium ion (blue) and the contrasting relative electron abundance (red and yellow) of the enol. One can also recognize that the electron density is greater at the $\alpha$-carbon (yellow) next to the hydroxy-bearing carbon (green). As soon as the enol is formed, it undergoes nucleophilic attack on the electrophilic iminium carbon, and the resulting species converts to the Mannich salt by proton transfer from the carbonyl oxygen to the amino group.

*Professor Carl U. F. Mannich (1877–1947), University of Berlin.
Mechanism of the Mannich Reaction

**Step 1.** Iminium ion formation

\[ \text{CHO} + (\text{CH}_3)_2\text{NH}_2\text{Cl}^- \rightarrow \text{CHO}^+ \text{(CH}_3)_2\text{Cl}^- + \text{H}_2\text{O} \]

**Step 2.** Enolization

**Step 3.** Carbon–carbon bond formation

**Step 4.** Proton transfer

The following example shows the Mannich reaction in natural product synthesis. In this instance, one ring is formed by condensation of the amino group with one of the two carbonyl functions. Mannich reaction of the resulting iminium salt with the enol form of the other carbonyl function follows. The product has the framework of retronecine (see margin), an alkaloid that is present in many shrubs and is hepatotoxic (causes liver damage) to grazing livestock.

**Mannich Reaction in Synthesis**

**Exercise 21-18**

**Working with the Concepts: Practicing the Mannich Reaction**

Write the product of the Mannich reaction of ammonia, formaldehyde, and cyclopentanone.

**Strategy**

The Mannich reaction starts by condensation of the amine with the more reactive carbonyl component. We have to identify this constituent and convert it into the iminium species. We then couple the iminium intermediate with the enol form of the less reactive carbonyl component.
**In Summary**  Condensation of aldehydes (e.g., formaldehyde) with amines furnishes iminium ions, which are electrophilic and may be attacked by the enols of ketones (or other aldehydes) in the Mannich reaction. The products are $\beta$-aminocarbonyl compounds.

### 21-10 Nitrosation of Amines

Amines react with nitrous acid, through nucleophilic attack on the nitrosyl cation, $\text{NO}^+$. The product depends very much on whether the reactant is an alkanamine or a benzenamine (aniline) and on whether it is primary, secondary, or tertiary. This section deals with alkanamines; aromatic amines will be considered in the next chapter.

To generate $\text{NO}^+$, we must first prepare the unstable nitrous acid by the treatment of sodium nitrite with aqueous HCl. In such an acid solution, an equilibrium is established with the nitrosyl cation. (Compare this sequence with the preparation of the nitronium cation from nitric acid; Section 15-10.)
Nitrosyl Cation from Nitrous Acid

Na\(^+\)\(\overset{\text{O}}{\text{O}}\)\(\overset{\text{N}}{\text{O}}\)\(\overset{\text{O}}{\text{O}}\) + HCl \(\rightarrow\) H\(\overset{\text{+}}{\text{N}}\)\(\overset{\text{O}}{\text{O}}\)\(\overset{\text{N}}{\text{O}}\)\(\overset{\text{O}}{\text{O}}\) \(\rightarrow\) \[ \overset{\text{+}}{\text{N}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}} \] + H\(\overset{\text{2}}{\text{O}}\)

Sodium nitrite Nitrous acid Nitrosyl cation

The nitrosyl cation is electrophilic and is attacked by amines to form an \(N\)-nitrosammonium salt.

\[ \overset{\text{N}}{\text{N}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}} \rightarrow \overset{\text{N}}{\text{N}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}} \]

\(N\)-Nitrosammonium salt

The course of the reaction now depends on whether the amine nitrogen bears zero, one, or two hydrogens. *Tertiary* \(N\)-nitrosammonium salts are stable only at low temperatures and decompose upon heating to give a mixture of compounds. *Secondary* \(N\)-nitrosammonium salts are simply deprotonated to furnish the relatively stable \(N\)-nitrosamines as the major products.

\((\text{CH}_3)_2\text{NH} + \text{NaNO}_2, \text{HCl, H}_2\text{O, 0°C}} \rightarrow (\text{CH}_3)_2\text{N}^+\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{Cl}^-}{\text{N}} \rightarrow (\text{CH}_3)_2\text{N}^+\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{Cl}^-}{\text{N}} - \text{HCl} \rightarrow \text{H}_3\text{C}\overset{\text{N}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}_3\text{C}}{\text{N}} \rightarrow \text{H}_3\text{C}\overset{\text{N}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}_3\text{C}}{\text{N}} \rightarrow \text{88–90%} \}

\(N\)-Nitrosodimethylamine

Similar treatment of *primary* amines initially gives the analogous monoalkyl-\(N\)-nitrosamines. However, these products are unstable because of the remaining proton on the nitrogen. By a series of hydrogen shifts, they first rearrange to the corresponding diazohydroxides. Then protonation, followed by loss of water, gives highly reactive diazonium ions, \(R – N_2^+\). When \(R\) is a secondary or a tertiary alkyl group, these ions lose molecular nitrogen, \(N_2\), and form the corresponding carbocations, which may rearrange, deprotonate, or undergo nucleophilic trapping (Section 9-3) to yield the observed mixtures of compounds.

**Mechanism of Decomposition of Primary \(N\)-Nitrosamines**

**Step 1.** Rearrangement to a diazohydroxide

\(\overset{\text{N}}{\text{N}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{N}}{\text{N}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{OH}}{\text{N}} \)

Diazohydroxide

**Step 2.** Loss of water to give a diazonium ion

\(\overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{OH}}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{OH}}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \)

Diazonium cation

**Step 3.** Nitrogen loss to give a carbocation

\(\overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \)

Pure \(R\) enantiomer

\(\overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \rightarrow \overset{\text{R}}{\text{N}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{N}}{\text{O}}\overset{\text{O}}{\text{O}}\overset{\text{H}^-}{\text{N}} \)

Pure \(S\) enantiomer
CHEMICAL HIGHLIGHT 21-3

N-Nitrosodialkanamines and Cancer

N-Nitrosodialkanamines are notoriously potent carcinogens in a variety of animals. Although there is no direct evidence, they are suspected of causing cancer in humans as well. Most nitrosamines appear to cause liver cancer, but some of them are very organ specific in their carcinogenic potential (bladder, lungs, esophagus, nasal cavity, etc.). Their mode of carcinogenic action appears to begin with enzymatic oxidation of one of the \( \alpha \)-carbons to a hemiaminal (Section 17-9), which allows eventual formation of an unstable monoalkyl-N-nitrosamine, as shown here for \( N \)-nitrosodiethylamine:

\[
\begin{align*}
\text{Enzymatic oxidation} & \\
\begin{align*}
N & \text{NO} & \rightarrow & \text{HO} & \text{NO} & \rightarrow & \text{O} & \text{H} & + & \text{HN} & \text{NO}
\end{align*}
\end{align*}
\]

Monoalkyl-\( N \)-nitrosamines are sources of carbocations, as described in this section. Carbocations are powerful electrophiles that are thought to attack one of the bases in DNA to inflict the kind of genetic damage that seems to lead to cancerous cell behavior.

In the early 1970s, farm animals in Norway that had been fed herring meal preserved using relatively large doses of sodium nitrite began to show a high incidence of liver disorders, including cancer. Fish meal contains amines (for example, trimethylamine is primarily responsible for its odor) and it did not take long to realize that these amines reacted with the added nitrite to produce nitrosamines. This finding was disturbing because amines also occur in meats, and sodium nitrite is often added during the meat-curing process. Sodium nitrite inhibits the growth of bacteria that cause botulism, retards the development of rancidity and off-odors during storage, and preserves the flavor of added spices and smoke (if the meat is smoked). In addition, it gives meat an appetizing pink coloration and special flavor. The color has its origin in nitrite-derived nitric oxide, NO, which forms a red complex with the iron in myoglobin. (The oxygen complex of myoglobin gives blood its characteristic color; see Section 26-8).

Does the practice of curing meat lead to nitrosamine contamination? The answer is yes: Nitrosamines have been detected in a variety of cured meats, such as smoked fish, frankfurters (\( N \)-nitrosodimethylamine), and fried bacon (\( N \)-nitrosoazacyclopentane (\( N \)-nitrosopyrrolidine); see Exercise 25-7). This finding poses an environmental dilemma: Removing sodium nitrite as a food additive would prevent it from becoming a source of nitrosamines, but it would also cause a significant rise in botulism poisoning. Moreover, human exposure to nitrosamines occurs not only through meat; nitrosamines are also present in beer, nonfat dry milk, tobacco products, rubber, some cosmetics, and the gastric juices of the stomach. Their occurrence in the stomach can be called “natural,” as it is traced to bacteria in the mouth that reduce nitrate (which is, in turn, prevalent in vegetables such as spinach, beets, radishes, celery, and cabbages) to nitrite, which then reacts with amines present in other foods we ingest.

Because of the potential carcinogenicity of nitrosamines in humans, the level of nitrite in foods is closely regulated (<200 ppm). During the past 20 years, a number of measures, such as the use of additives that inhibit nitrosamine formation in curing (for example, vitamin C; Section 22-9) or changes in production processes (for example, the making of beer), have helped to significantly reduce human exposure to nitrosamines, estimated to be about 0.1 \( \mu g \) per day. It can be argued that we have evolved to tolerate such small quantities, but definitive data are still lacking (see also Chemical Highlight 25-4, on natural pesticides).
The nitrosyl cation also attacks the nitrogen of N-methylamides. The products, N-methyl-N-nitrosamides, are precursors to useful synthetic intermediates.

**Nitrosation of an N-Methylamide**

\[
\begin{align*}
\text{N-Methylamide} & \rightarrow \text{N-Methyl-N-nitrosamide} \\
\end{align*}
\]

**Exercise 21-22**

**Working with the Concepts: Applying Basic Principles: A New Reaction of NO\(^+\)**

The ketone shown below undergoes nitrosation to the corresponding oxime (for oximes, see Section 17-9). Explain by a mechanism.

\[
\begin{align*}
\text{O} & \text{O} \\
& \text{OH} \\
\end{align*}
\]

**Strategy**

This is a new reaction, not discussed in the text. To try to understand it, you need to identify the changes that have occurred in going from starting material to product and to recall the function of the reagent.

**Solution**

- Topologically, we have attached the NO unit to the \(\alpha\)-position of the starting ketone. This becomes clearer if we consider the tautomer of the product:

\[
\begin{align*}
\text{O} & \text{N} \\
& \text{H} \\
\end{align*}
\]

- Turning to the reagent, this section has shown that sodium nitrite in the presence of acid is a source of the electrophilic nitrosyl cation. In our example, it appears that attack has occurred to the carbonyl function. Do we know anything about how electrophiles might attack ketones in this manner? Or, to put it differently, how do we make the \(\alpha\)-carbonyl carbon nucleophilic?

- Recall from Chapter 18 that ketones are in equilibrium with their enol tautomers, an equilibrium that is established rapidly in the presence of catalytic acid. These enols feature electron-rich double bonds that are ready targets for electrophiles, such as iminium ions (Mannich reaction, Section 21-9) or halogens (Section 18-3). Let us formulate a similar attack by NO\(^+\).

\[
\begin{align*}
\text{:O:} & \text{H} \\
\text{O} & \text{N} \\
\end{align*}
\]

- We have now established the connectivity of the final product. To form it, all we need is to deprotonate the carbonyl function and tautomerize the nitrosyl part to the oxime.

For the follow-up Exercise 21-23, see p. 1002.
Amines in Industry: Nylon

In addition to their significance in medicine (Chemical Highlight 21-1), the amines have numerous industrial applications. An example is 1,6-hexanedi­amine (hexamethylenediamine, HMDA), needed in the manufacture of nylon. The amine is polycondensed with hexanedioic (adipic) acid to produce Nylon 6,6, out of which hosiery, gears, and millions of tons of textile fiber are made.

**Polycondensation of Adipic Acid with HMDA**

\[
\begin{align*}
\text{Hexanedioic acid (Adipic acid)} & \quad + \\
\text{1,6-Hexanedi­amine (Hexamethylenediamine)} & \quad \rightarrow \\
\text{Double salt} & \quad \rightarrow \quad 270^\circ C, 250 \text{ psi} \\
& \quad \text{Polymerization} \\
\text{Nylon 6,6} & \quad \rightarrow \quad \text{Hexanedioic acid (Adipic acid)}
\end{align*}
\]

The high demand for nylon has stimulated the development of several ingenious cheap syntheses of the monomeric precursors. Thus, hexanedioic (adipic) acid is currently produced from benzene by three different multistep routes, all culminating in the last step in the salt-catalyzed oxidation of cyclohexanol (or cyclohexanol/cyclohexanone mixtures) with nitric acid. A “green” approach was disclosed in 2006 by chemists at Rhodia Chimie, France, in which air is used as the oxidizing agent instead of the toxic and corrosive (and more expensive) HNO₃.

**Adipic Acid Production**

- **Current industrial process**
  - OH → HNO₃, 60°C, V, Cu salts → COOH
  - Hexanedioic acid (Adipic acid)
- **A “green” synthesis**
  - Air, 120°C, Mn, Co salts → COOH

The left leg of movie star Marie Wilson (who can be seen dangling from a crane) advertising Nylon stockings (Hollywood, 1949).
In the mid-1960s, Monsanto developed a process that uses a more expensive starting material but takes just one step: the electrolytic hydrodimerization of propenenitrile (acrylonitrile).

**Hexanediamine from Adipic Acid**

![Chemical equation]

Later, a still shorter hexanedinitrile synthesis was discovered that used 1,3-butadiene as a starting material. Chlorination of butadiene furnished a mixture of 1,2- and 1,4-dichlorobutene (Section 14-6). This mixture can be converted directly into only the required 3-hexenedinitrile with sodium cyanide in the presence of cuprous cyanide. Selective hydrogenation of the alkenyl double bond then furnishes the desired product.

**Hexanedinitrile (Adiponitrile) from 1,3-Butadiene**

![Chemical equation]

In the mid-1960s, Monsanto developed a process that uses a more expensive starting material but takes just one step: the electrolytic hydrodimerization of propenenitrile (acrylonitrile).

**Electrolytic Hydrodimerization of Propenenitrile (Acrylonitrile)**

![Chemical equation]

To counter Monsanto’s challenge, du Pont devised yet another synthesis, again starting with 1,3-butadiene, but now eliminating the consumption of chlorine, removing the toxic-waste problems of the disposal of copper salts, and using cheaper hydrogen cyanide rather than sodium cyanide. The synthesis is based on the conceptually simplest approach: direct regioselective anti-Markovnikov addition of two molecules of hydrogen cyanide to butadiene. A transition-metal catalyst, such as iron, cobalt, or nickel, is needed to effect this regiocontrol.

**Hydrogen Cyanide Addition to 1,3-Butadiene**

![Chemical equation]

Base treatment of \(N\)-methyl-\(N\)-nitrosamides gives diazomethane

\(N\)-Methyl-\(N\)-nitrosamides are converted into diazomethane, \(\text{CH}_2\text{N}_2\), upon treatment with aqueous base.

Diazomethane is used in the synthesis of methyl esters from carboxylic acids. However, it is exceedingly toxic and highly explosive in the gaseous state (b.p. \(-24^\circ\text{C}\)) and in concentrated solutions. It is therefore usually generated in dilute ether solution and immediately allowed to react with the acid. This method is very mild and permits esterification of molecules possessing acid- and base-sensitive functional groups, as shown in the following example.

When it is irradiated or exposed to catalytic amounts of copper, diazomethane evolves nitrogen to generate the reactive carbene methylene, \(\text{H}_2\text{C}=:\). Methylene reacts with alkenes by addition to form cyclopropanes stereospecifically (Section 12-9).

---

**Exercise 21-23**

**Try It Yourself**

The following reaction has been explored as a possible first step in the preparation of acetaminophen (Chapter 16 Opening). What is its mechanism and what is the mechanistic connection to the process described in Exercise 21-22?

![Reaction](image)

**Base treatment of \(N\)-methyl-\(N\)-nitrosamides gives diazomethane**

\(N\)-Methyl-\(N\)-nitrosamides are converted into \text{diazomethane}, \(\text{CH}_2\text{N}_2\), upon treatment with aqueous base.

Diazomethane is used in the synthesis of methyl esters from carboxylic acids. However, it is exceedingly toxic and highly explosive in the gaseous state (b.p. \(-24^\circ\text{C}\)) and in concentrated solutions. It is therefore usually generated in dilute ether solution and immediately allowed to react with the acid. This method is very mild and permits esterification of molecules possessing acid- and base-sensitive functional groups, as shown in the following example.

When it is irradiated or exposed to catalytic amounts of copper, diazomethane evolves nitrogen to generate the reactive carbene methylene, \(\text{H}_2\text{C}=:\). Methylene reacts with alkenes by addition to form cyclopropanes stereospecifically (Section 12-9).

---

**Exercise 21-24**

Formulate a mechanism for the methyl esterification by diazomethane. (**Hint:** Review the resonance structures for \(\text{CH}_2\text{N}_2\) in Section 1-5.)

---

**In Summary** Nitrous acid attacks amines, thereby causing \(N\)-nitrosation. Secondary amines give \(N\)-nitrosamines, which are notorious for their carcinogenicity. \(N\)-Nitrosamines derived
from primary amines decompose through $S_N1$ or $S_N2$ processes to a variety of products. $N$-Nitrosation of $N$-methylamides results in the corresponding $N$-nitrosamides, which liberate diazomethane upon treatment with hydroxide. Diazomethane is a reactive substance used in the methylesterification of carboxylic acids and as a source of methylene for the cyclopropanation of alkenes.

THE BIG PICTURE

We have seen the role of the amine function as a base or nucleophile at various points of the text. As early as in Sections 1-3 and 1-8, we learned about its valence electron count and hybridization, using $\text{NH}_3$ as an example. In Section 2-2, we saw its first use as a base or nucleophile, and a resulting practical application in the resolution of ammonium tartrates was featured in Section 5-8. Amine nucleophilicity was an essential part of Chapters 6 and 7, elaborated in its synthetic aspects in Sections 17-9, 18-4, 18-9, 19-10, 20-6, and 20-7.

The present chapter summarizes, reinforces, and extends this material. In particular, it points out the similarities and differences between the amines and the alcohols. Thus, nitrogen is located immediately to the left of oxygen in the periodic table. It therefore has one valence electron less and, correspondingly, lesser positive nuclear charge. Hence, it is trivalent, and not divalent, and less electronegative. However, chemically, it shows many similarities, and the amine–imine functionalities strongly resemble their oxygen counterparts—namely, the alcohol–carbonyl functionalities. In the laboratory, as well as in nature, the two systems complement each other, as described in several Chemical Highlights and problems. Once again, the similarities and differences in how these systems function can be traced back to the similarities and differences in their electronic structures.

We have now completed our survey of the basic organic chemistry compound classes, as defined by simple functional groups. In the remainder of the book, we shall examine compounds with multiple functional groups, whether they be the same or different. We shall see the amino group and amine derivatives again in these chapters, particularly when studying heterocycles, proteins, and nucleic acids. We shall learn that the combination of the amino and carbonyl groups underlies the molecular structure of life itself.

CHAPTER INTEGRATION PROBLEMS

21-25. On the basis of the synthetic methods for amines provided in this chapter, carry out retrosynthetic analyses of the antidepressant Prozac, with 4-trifluoromethylphenol and benzene as your starting materials.

![Diagram]

SOLUTION

As for any synthetic problem, you can envisage many possible solutions. However, the constraints of given starting materials, convergence, and practicality rapidly narrow the number of available options. Thus, it is clear that the 4-trifluoromethylphenoxyl group is best introduced by Williamson ether synthesis (Section 9-6) with an appropriate benzylic halide, compound A (Section 22-1), with the use of our first starting compound, 4-trifluoromethylphenol.
Retrosynthetic Step to A

The task therefore reduces to devising routes to A, utilizing the second starting material, benzene, and suitable building blocks. We know that the best way to introduce an alkyl chain into benzene is by Friedel-Crafts acylation (Section 15-13). This reaction would also supply a carbonyl function, as in compound B, which could be readily transformed [by reduction to the alcohol (Section 8-6) and conversion of the hydroxy into a good leaving group, X (Chapter 9)] into compound A (or something similar). On paper, an attractive acylating reagent would be ClCCH₂CH₂NHCH₃. However, this reagent carries two functional groups that would react with each other either intermolecularly to produce a polyamide (see Chemical Highlight 21-4) or intramolecularly to produce a β-lactam (Section 20-6). This problem could be circumvented by using a leaving group in place of the amino function, the latter to be introduced by one of the methods in Section 21-5.

Retrosynthesis of A

Consideration of cyanide as a building block (Section 21-5) opens up another avenue of retrosynthetic disconnection of compound B (and therefore compound A) through compound C.

Retrosynthesis of B

The required compound D could be envisaged to arise from acetylbenzene (made by Friedel-Crafts acetylation of benzene), followed by acid-catalyzed halogenation of the ketone (Section 18-3). Reduction of the nitrile group in compound C could be carried out with concomitant carbonyl conversion to give a primary amine version of compound A, namely, E. N-Methylation might be most conveniently accomplished by reductive amination (although, as we shall see in Chapter 22, the benzylic position may be sensitive to the reductive conditions employed).

Retrosynthesis of E
Intermediate E can be approached by using nucleophilic cyanide in a different manner—namely, by attack at the less hindered position of phenyloxacyclopropane. The latter would arise from phenylethene (styrene) by oxacyclopropanation (Section 12-10), and phenylethene could in turn be readily made from acetylene by reduction—dehydration.

Inspection of the synthetic methods described in Sections 21-5 through 21-8 may give you further ideas about how to tackle the synthesis of Prozac, but they are all variations on the schemes formulated so far. However, consideration of the Mannich reaction (Section 21-9) provides a more fundamental alternative, attractive because of its more highly convergent nature to a derivative of compound B with the intact amino function in place. Indeed, this is the commercial route used by Eli Lilly to the final drug.

**Retro-Mannich Synthesis of B (X—CH$_3$NH)**

\[
\begin{align*}
\text{B} & \quad \text{CH}_2=\text{O} + \text{CH}_3\text{NH}_2 \\
& \quad \text{CH}_3\text{NH}
\end{align*}
\]

21-26. Formulate a mechanism for the following reaction.

![Reaction Diagram](image)

**SOLUTION**

As always, let us first analyze what is given, before delving into a possible solution. We note that C$_8$H$_{13}$N on the left turns into the same on the right: We are dealing with an isomerization. There are no reagents, only a catalytic amount of water (a proton source). The topology of a seven-membered ring changes to that of a five-membered one, and the functionality of a (di)enamine (Section 17-9) is transformed into that of an $\alpha,\beta$-unsaturated imine (Section 18-8). Our task is to find a way by which water will open the seven-membered ring and eventually close some acyclic intermediate to the five-membered ring product.

What does an enamine do in the presence of water? *Answer:* it hydrolyzes (Section 17-9).

**Mechanism of Hydrolysis**

\[
\begin{align*}
\text{A} & \quad \text{H}_2\text{O} \quad \Delta \quad \text{B} \\
& \quad \text{C} \quad \text{D} \quad \text{E} \quad \text{F}
\end{align*}
\]

Let us formulate the mechanism of this step as applied to our starting material A. Crucial in dealing with enamines is the increased basicity (and nucleophilicity) of the $\beta$-carbon, which leads to its preferred protonation (Section 17-9) [and alkylation (Section 18-4)]. Thus, protonation of A gives B,
which is attacked by hydroxide to furnish C, thus completing the initial hydration sequence in enamine hydrolysis (Section 17-9). The next step, breaking the C–N bond, has a “quirk” in our system: The nitrogen, usually activated to leave by direct protonation, is part of an enamine unit, which is (again) protonated at carbon to generate D containing an iminium leaving group. Ring opening therefore proceeds through E to F.

Now that we have accomplished ring opening, what is next? Simply looking at the topology of F and the desired B, we can see that we need to form a (double) bond between the β-carbon of the imine and the carbonyl carbon. If the imine were a ketone, we would accomplish this by an intramolecular aldol condensation (Section 18-7). Here, we utilize the imine as a masked ketone, via its enamine form G as the nucleophile. The individual steps are completely analogous.

An “Imine Version” of the Intramolecular Aldol Condensation

Note that the rapid imine F to enamine G conversion obviates an alternative pathway of an intramolecular Mannich reaction (Section 21-9). Formulate this alternative!

New Reactions

1. Acidity of Amines and Amide Formation (Section 21-4)

\[
\text{RNH}_2 + \text{H}_2\text{O} \rightleftharpoons \text{RNH} + \text{H}_3\text{O}^+ \quad K_a \approx 10^{-35}
\]

\[
\text{R}_2\text{NH} + \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Li} \rightleftharpoons \text{R}_2\text{N}^+\text{Li}^+ + \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3
\]

Lithium dialkylamide

\[
2 \text{NH}_3 + 2 \text{Na} \xrightarrow{\text{Catalytic Fe}^+} 2 \text{NaNH}_2 + \text{H}_2
\]

2. Basicity of Amines (Section 21-4)

\[
\text{RNH}_2 + \text{H}_2\text{O} \rightleftharpoons \text{RNH}_3 + \text{HO}^-
\]

\[
\text{RNH}_3 + \text{H}_2\text{O} \rightleftharpoons \text{RNH}_2 + \text{H}_3\text{O}^+ \quad K_a \approx 10^{-10}
\]
Salt formation

\[
RNH_2 + HCl \rightarrow RNH_3Cl^-
\]

Alkylammonium chloride

General for primary, secondary, and tertiary amines

Preparation of Amines

3. Amines by Alkylation (Section 21-5)

\[
RNH_2 + R'X \rightarrow RNH_2X^-
\]

General for primary, secondary, and tertiary amines

Drawback: Multiple alkylation

\[
RNH_2X^- + R'X \rightarrow \rightarrow \rightarrow RNHR'\_X^-
\]

4. Primary Amines from Nitriles (Section 21-5)

\[
RX + CN_{DMSO} \rightarrow RCN_{LiAlH_4, or \ H_2, catalyst} \rightarrow RCH_2NH_2
\]

R limited to methyl, primary, and secondary alkyl groups

5. Primary Amines from Azides (Section 21-5)

\[
RX + N_3_{CH_3CH_2OH} \rightarrow RN_3_{LiAlH_4, \ (CH_3CH_2)_2O} \rightarrow RCH_2NH_2
\]

R limited to methyl, primary, and secondary alkyl groups

6. Primary Amines by Gabriel Synthesis (Section 21-5)

\[
O \quad \begin{array}{c}
1. K_2CO_3, H_2O \\
2. RX, DMF
\end{array} \quad \begin{array}{c}
O \\
1. H_2SO_4, H_2O, 120^\circ C \\
2. NaOH, H_2O
\end{array} \quad \begin{array}{c}
O \\
1. K_2CO_3, H_2O \\
2. RX, DMF
\end{array} \quad \begin{array}{c}
NH_2 \\
R \quad R'
\end{array} = R \quad H
\]

R limited to methyl, primary, and secondary alkyl groups

7. Amines by Reductive Amination (Section 21-6)

\[
R_2NH + CH_2==O \quad \begin{array}{c}
\text{NH}_2, \text{NaBH}_3CN, \text{H}_2O \text{ or alcohol}
\end{array} \quad \begin{array}{c}
\text{NH}_2 \\
R \quad R'
\end{array}
\]

Reductive methylation with formaldehyde

\[
R_2NH + CH_2==O \quad \begin{array}{c}
\text{NaBH}_3CN, \text{CH}_3OH
\end{array} \quad \begin{array}{c}
\text{R}_2\text{NCH}_3
\end{array}
\]
8. Amines from Carboxylic Amides (Section 21-7)

\[
\begin{align*}
\text{RCN} & \xrightarrow{1. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)\text{O}} \text{RCH}_2\text{N}R'' \\
\text{H}_2\text{O} & \xrightarrow{2. \text{H}_2\text{O}} \text{RCH}_2\text{N}R''
\end{align*}
\]

9. Hofmann Rearrangement (Section 21-7)

\[
\text{RCNH}_2 \xrightarrow{\text{Br}_2, \text{NaOH, H}_2\text{O}} \text{RNH}_2 + \text{CO}_2
\]

Reactions of Amines

10. Hofmann Elimination (Section 21-8)

\[
\text{RCH}_2\text{CH}_2\text{NH}_2 \xrightarrow{\text{Excess CH}_3\text{I, K}_2\text{CO}_3} \text{RCH}_2\text{CH}_2\text{N}^+(\text{CH}_3)_3 \xrightarrow{\text{Ag}_2\text{O, H}_2\text{O}} \text{RCH}==\text{CH}_2 + \text{N}(\text{CH}_3)_3 + \text{H}_2\text{O}
\]

11. Mannich Reaction (Section 21-9)

\[
\text{RCOR} + \text{CH}_2==\text{O} + (\text{CH}_3)_2\text{NH} \xrightarrow{1. \text{HCl}} \text{RCH}==\text{CH}_2 + \text{N}(\text{CH}_3)_2 + \text{H}_2\text{O}
\]

12. Nitrosation of Amines (Section 21-10)

Tertiary amines

\[
\text{R}_3\text{N} \xrightarrow{\text{NaNO}_2, \text{H}^+ X^-} \text{Tertiary N-nitrosammonium salt}
\]

Secondary amines

\[
\text{RNH}_2 \xrightarrow{\text{NaNO}_2, \text{H}^+} \text{N-N=O}
\]

Primary amines

\[
\text{RNH}_2 \xrightarrow{\text{NaNO}_2, \text{H}^+} \text{RN==NO} \xrightarrow{\text{H}^+/\text{H}_2\text{O}} \text{RN}_2^+ \xrightarrow{-\text{N}_2} \text{R}^+ \xrightarrow{-\text{N}_2} \text{mixture of products}
\]

13. Diazomethane (Section 21-10)

\[
\text{CH}_2\text{NCR} \xrightarrow{\text{KOH}} \text{CH}_2==\text{N==N}^- + \text{N}_2
\]

Esterification with diazomethane

\[
\text{RCOH} + \text{CH}_2\text{N}_2 \xrightarrow{-\text{N}_2} \text{RCOCH}_3 + \text{N}_2
\]
Important Concepts

1. **Amines** can be viewed as derivatives of ammonia, just as ethers and alcohols can be regarded as derivatives of water.

2. *Chemical Abstracts* names amines as alkamines (and benzenamines), alkyl substituents on the nitrogen being designated as N-alkyl. Another system is based on the label aminoalkane. Common names are based on the label alkylamine.

3. The nitrogen in amines is $sp^3$ hybridized, the nonbonding electron pair functioning as the equivalent of a substituent. This tetrahedral arrangement **inverts rapidly** through a planar transition state.

4. The lone electron pair in amines is less tightly held than in alcohols and ethers, because nitrogen is less electronegative than oxygen. The consequences are a diminished capability for hydrogen bonding, higher basicity and nucleophilicity, and lower acidity.

5. Infrared spectroscopy helps to differentiate between primary and secondary amines. **Nuclear magnetic resonance** spectroscopy indicates the presence of nitrogen-bound hydrogens; both hydrogen and carbon atoms are deshielded in the vicinity of the nitrogen. **Mass spectra** are characterized by iminium ion fragments.

6. Indirect methods, such as displacements with azide or cyanide, or reductive amination, are superior to direct alkylation of ammonia for the synthesis of amines.

7. The NR$_3$ group in a quaternary amine, R’=NR$_3$, is a **good leaving group** in E2 reactions; this enables the Hofmann elimination to take place.

8. The nucleophilic reactivity of amines manifests itself in reactions with electrophilic carbon, as in haloalkanes, aldehydes, ketones, and carboxylic acids and their derivatives.

Problems

27. Give at least two names for each of the following amines.

(a) \( \text{NH}_2 \)

(b) \( \text{N} \)

(c) \( \text{Cl} \)

(d) \( \text{CH}_3 \)

(e) \( \text{N} \)

(f) \( \text{O} \)

(g) \( \text{Cl} \)

(h) \( \text{(CH}_3\text{CH}_2\text{)}_2\text{NCH}_2\text{CH}==\text{CH}_2 \)

28. Give structures that correspond to each of the following names.

(a) \( N,N\)-Dimethyl-3-cyclohexenamine; (b) \( N \)-ethyl-2-phenylethylamine; (c) 2-aminoethanol; (d) \( m \)-chloroaniline.

29. Name each of the following compounds pictured in Chemical Highlight 21-1 according to IUPAC or Chemical Abstracts. Pay attention to the order of precedence of the functional groups.

(a) Propylhexedrine; (b) amphetamine; (c) mescaline; (d) epinephrine.

30. As mentioned in Section 21-2, the inversion of nitrogen requires a change of hybridization.

(a) What is the approximate energy difference between pyramidal nitrogen (\( sp^3 \) hybridized) and trigonal planar nitrogen (\( sp^2 \) hybridized) in ammonia and simple amines? (**Hint:** Refer to the \( E_a \) of inversion.) (b) Compare the nitrogen atom in ammonia with the carbon atom in each of the following species: methyl cation, methyl radical, and methyl anion. Compare the most stable geometries and the hybridizations of each of these species. Using fundamental notions of orbital energies and bond strengths, explain the similarities and differences among them.
31. Use the following NMR- and mass-spectral data to identify the structures of two unknown compounds, A and B.

A: $^1$H NMR: δ = 0.92 (t, J = 6 Hz, 3 H), 1.32 (broad s, 12 H), 2.28 (broad s, 2 H), and 2.69 (t, J = 7 Hz, 2 H) ppm. Mass spectrum $m/z$ (relative intensity) = 129(0.6) and 30(100).

B: $^1$H NMR: δ = 1.00 (s, 9 H), 1.17 (s, 6 H), 1.28 (s, 2 H), and 1.42 (s, 2 H) ppm. Mass spectrum $m/z$ (relative intensity) = 129(0.05), 114(3), 72(4), and 58(100).

32. The following spectroscopic data ($^{13}$C NMR and IR) are for several isomeric amines of the formula C$_6$H$_{15}$N. Propose a structure for each compound.

(a) $^{13}$C NMR: δ = 23.7 (CH$_3$) and 45.3 (CH) ppm. IR: 3300 cm$^{-1}$.

(b) $^{13}$C NMR: δ = 12.6 (CH$_3$) and 46.9 (CH$_2$) ppm. IR: no bands in 3250–3500 cm$^{-1}$.

(c) $^{13}$C NMR: δ = 12.0 (CH$_3$), 23.9 (CH$_2$), and 52.3 (CH$_2$) ppm. IR: 3280 cm$^{-1}$.

(d) $^{13}$C NMR: δ = 14.2 (CH$_3$), 27.1 (CH$_2$), 32.3 (CH$_2$), 34.6 (CH$_2$), and 42.7 (CH$_2$) ppm. IR: 1600 (broad), 3280, and 3365 cm$^{-1}$.

(e) $^{13}$C NMR: δ = 25.6 (CH$_3$), 38.7 (CH$_3$), and 53.2 (C quaternary) ppm. IR: no bands in 3250–3500 cm$^{-1}$.

33. The following mass-spectral data are for two of the compounds in Problem 32. Match each mass spectrum with one of them.

(a) $m/z$ (relative intensity) = 101(8), 86(11), 72(79), 58(10), 44(40), and 30(100).

(b) $m/z$ (relative intensity) = 101(3), 86(30), 58(14), and 44(100).

34. Is a molecule whose conjugate acid has a high pK$_a$ value a stronger or a weaker base than a molecule whose conjugate acid has a low pK$_a$ value? Explain using a general equilibrium equation.

35. In which direction would you expect each of the following equilibria to lie?

(a) NH$_3$ + $^+$OH $\rightleftharpoons$ NH$_2^-$ + H$_2$O

(b) CH$_3$NH$_2$ + H$_2$O $\rightleftharpoons$ CH$_3$NH$_3^+$ + $^+$OH

(c) CH$_3$NH$_2$ + (CH$_3$)$_2$N$^+$ $\rightleftharpoons$ CH$_3$NH$_3^+$ + (CH$_3$)$_3$N

36. How would you expect the following classes of compounds to compare with simple primary amines as bases and acids?

(a) Carboxylic amides; for example, CH$_3$CONH$_2$

(b) Imines; for example, CH$_3$CONHCOCH$_3$

(c) Enamines; for example, CH$_2$==CHN(CH$_3$)$_2$

(d) Benzenamines; for example, [Structure]

37. Several functional groups containing nitrogen are considerably stronger bases than are ordinary amines. One is the amidine group found in DBN and DBU, both of which are widely used as bases in a variety of organic reactions.

Another unusually strong organic base is guanidine, H$_2$NCNH$_2$. Indicate which nitrogen in each of these bases is the one most likely to be protonated and explain the enhanced strength of these bases relative to simple amines.

38. Reaction review: Without consulting the Reaction Road Map on page 1009, suggest reagents that convert each of the following starting materials into the indicated product:

(a) (chloromethyl)-benzene (benzyl chloride) into phenylmethanamine (benzylamine); (b) benaldehyde into phenylmethanamine (benzylamine); (c) benzaldehyde into N-ethylphenylmethanamine (benzylethylamine); (d) (chloromethyl)benzenes (benzyl chloride) into 2-phenylethanamine (phenethylamine); (e) benaldehyde into N,N-dimethylphenylmethanamine (benzylmethylamine); (f) 1-phenylethanone (acetophenone) into 3-amino-1-phenyl-1-propanone; (g) benzonitrile into phenylmethanamine (benzylamine); (h) 2-phenylacetamide into phenylmethanamine (benzylamine).
Chapter 21

39. The following syntheses are proposed for amines. In each case, indicate whether the synthesis will work well, poorly, or not at all. If a synthesis will not work well, explain why.

(a) \[ \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl} \xrightarrow{1. \text{KCN, CH}_3\text{CH}_2\text{OH}} \xrightarrow{2. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2 \]

(b) \[ (\text{CH}_3)_3\text{CCl} \xrightarrow{1. \text{NaN}_3, \text{DMSO}} \xrightarrow{2. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O}} (\text{CH}_3)_3\text{CNH}_2 \]

(c) \[ \text{CONH}_2 \xrightarrow{\text{Br}_2, \text{NaOH, H}_2\text{O}} \text{CH}_3\text{CH}_2\text{NH}_2 \]

(d) \[ \text{BrCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2 \xrightarrow{\text{CH}_3\text{NH}_2} \text{NHCH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2 \]

(e) \[ \text{CONH}_2 \xrightarrow{\text{Br}_2, \text{NaOH, H}_2\text{O}} \text{NH}_2 \]

(f) \[ \text{COCl} \xrightarrow{1. \text{CH}_3\text{NH}_2, \text{H}_2\text{O}} \xrightarrow{2. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O}} \]

(g) \[ \text{CHO} \xrightarrow{1. (\text{CH}_3)_3\text{CNH}_2} \xrightarrow{2. \text{NaBH}_3\text{CN, CH}_3\text{CH}_2\text{OH}} \text{CH}_2\text{NH}(\text{CH}_3)_3 \]

(h) \[ \text{H}_2\text{NCH}_2\text{CH}_2\text{CHO} \xrightarrow{\text{NaBH}_3\text{CN, CH}_3\text{CH}_2\text{OH}} \]

(i) \[ \text{Br} \xrightarrow{1. \text{HNO}_3, \text{H}_2\text{SO}_4} \xrightarrow{2. \text{Fe, H}^+} \text{NH}_2 \]

(j) \[ \text{OH} \xrightarrow{1. \text{NaH, THF}} \xrightarrow{2. \text{CH}_3\text{I}} \xrightarrow{3. \text{LiAlH}_4, (\text{CH}_3\text{CH}_2)_2\text{O}} \text{NCH}_3 \]

40. For each synthesis in Problem 39 that does not work well, propose an alternative synthesis of the final amine, starting either with the same material or with a material of similar structure and functionality.

41. Give the structures of all possible nitrogen-containing organic products that might be expected to form on reaction of chloroethane with ammonia. (Hint: Consider multiple alkylations.)

42. Phenylpropanolamine (PPA) has long been an ingredient in many cold remedies and appetite suppressants. In late 2000, the FDA asked manufacturers to remove products containing this compound from the market because of evidence of an increased risk of hemorrhagic stroke. This action has caused a switch to the safer pseudoephedrine as the active component of such medications.

![Phenylpropanolamine and Pseudoephedrine structures]
Suppose that you are the director of a major pharmaceutical laboratory with a huge stock of phenylpropanolamine on hand and the president of the company issues the order, “Pseudoephedrine from now on!” Analyze all your options, and propose the best solution that you can find for the problem.

43. Apetinil, an appetite suppressant (i.e., diet pill; see Chemical Highlight 21-1), has the structure shown in the margin. Is it a primary, a secondary, or a tertiary amine? Propose an efficient synthesis of Apetinil from each of the following starting materials. Try to use a variety of methods.

(a) $\text{C}_6\text{H}_5\text{CH}_2\text{COCH}_3$
(b) $\text{C}_6\text{H}_5\text{CH}_2\text{CHCH}_3$
(c) $\text{C}_6\text{H}_5\text{CH}_2\text{CHCOOH}$

44. Suggest the best syntheses that you can for the following amines, beginning each with any organic compounds that do not contain nitrogen. (a) Butanamine; (b) $N$-methylbutanamine; (c) $N,N$-dimethylbutanamine.

45. Give the structures of the possible alkene products of Hofmann elimination of each of the following amines. If a compound can be cycled through multiple eliminations, give the products of each cycle.

(a) $\text{CH}_3\text{CHCH}_2\text{CH}_3$
(b) $\text{CH}_3\text{C}_3\text{H}_8\text{N}$
(c) $\text{H}_2\text{C}==\text{N}$
(d) $\text{H}_2\text{C}\text{N}$
(e) $\text{H}_2\text{C}==\text{N}$

46. What primary amine(s) would give each of the following alkenes or alkene mixtures upon Hofmann elimination? (a) 3-Heptene; (b) mixture of 2- and 3-heptene; (c) 1-heptene; (d) mixture of 1- and 2-heptene.

47. Formulate a detailed mechanism for the Mannich reaction between 2-methylpropanal, formaldehyde, and methanamine shown on page 994.

48. Reaction of the tertiary amine tropinone with (bromomethyl)benzene (benzyl bromide) gives not one but two quaternary ammonium salts, $A$ and $B$.

\[ \text{Tropinone (C}_9\text{H}_{12}\text{NO)} + \text{CH}_2\text{Br} \rightarrow \text{A} + \text{B} + \text{[C}_9\text{H}_{12}\text{NO}_x\text{Br}^{-)} \]

Compounds $A$ and $B$ are stereoisomers that are interconverted by base; that is, base treatment of either pure isomer leads to an equilibrium mixture of the two. (a) Propose structures for $A$ and $B$. (b) What kind of stereoisomers are $A$ and $B$? (c) Suggest a mechanism for the equilibration of $A$ and $B$ by base. (Hint: Think “reversible Hofmann elimination.”)

49. Attempted Hofmann elimination of an amine containing a hydroxy group on the $\beta$-carbon gives an oxacyclopropane product instead of an alkene.

\[ \text{HO} \quad \text{NH}_2 \quad \text{H}_2\text{C}==\text{CH}_2 \quad 1. \text{Excess CH}_3\text{I} \quad 2. \text{Ag}_2\text{O, H}_2\text{O} \quad 3. \Delta \quad \text{H}_2\text{C}==\text{CH}_2 + (\text{CH}_3)_2\text{N} \]
(a) Propose a sensible mechanism for this transformation. (b) Pseudoephedrine (see Problem 42) and ephedrine are closely related, naturally occurring compounds, as the similar names imply. In fact, they are stereoisomers. From the results of the following reactions, deduce the precise stereochemistries of ephedrine and pseudoephedrine.

50. Show how each of the following molecules might be synthesized by Mannich or Mannich-like reactions. \( \text{Hint: Work backward, identifying the bond made in the Mannich reaction.} \)

(a) \( \text{O} \quad \text{N} \quad \text{N} \quad \text{O} \)

(b) \( \text{O} \quad \text{N} \quad \text{C} \quad \text{H}_2 \text{C} \quad \text{C} \quad \text{H}_2 \text{C} \quad \text{N} \quad \text{H}_2 \text{C} \quad \text{C} \quad \text{O} \)

(c) \( \text{H}_2 \text{C} \quad \text{C} \quad \text{H}_2 \text{C} \quad \text{N} \quad \text{H}_2 \text{C} \quad \text{C} \quad \text{O} \)

(d) \( \text{O} \quad \text{N} \quad \text{N} \quad \text{O} \)

(e) \( \text{O} \quad \text{N} \quad \text{C} \quad \text{H}_2 \text{C} \quad \text{C} \quad \text{H}_2 \text{C} \quad \text{N} \quad \text{H}_2 \text{C} \quad \text{C} \quad \text{O} \)

51. Tropinone (Problem 48) was first synthesized by Sir Robert Robinson (famous for the Robinson annulation reaction; Section 18-11), in 1917, by the following reaction. Show a mechanism for this transformation.

52. Illustrate a method for achieving the transformation shown in the margin, using combinations of reactions presented in Sections 21-8 and 21-9.

53. Give the expected product(s) of each of the following reactions.

(a) \( \text{H}_3 \text{C} \quad \text{CH} \quad \text{NH}_2 \quad \text{NaNO}_2, \text{HCl}, \text{H}_2\text{O} \)

(b) \( \text{N} \quad \text{H} \quad \text{NaNO}_2, \text{HCl}, 0^\circ \text{C} \)

54. Tertiary amines add readily as nucleophiles to carbonyl compounds, but, lacking a hydrogen on nitrogen, they cannot deprotonate to give a stable product. Instead, their addition gives an intermediate that is highly reactive toward other nucleophiles. Thus, tertiary amines are occasionally used as catalysts for the addition of weak nucleophiles to carboxylic acid derivatives.

(a) Fill in the missing structures in the scheme below.

\[
\begin{align*}
\text{(CH}_3\text{)}_3\text{N} + \text{CH}_2\text{COCl} & \rightleftharpoons \text{Intermediate A} \\
& \rightleftharpoons \text{Intermediate B} \\
& \text{(CH}_3\text{H}_2\text{CNO)}^+ \\
& \text{(C}_2\text{H}_4\text{NO})^+ 
\end{align*}
\]
(b) Intermediate B readily enters into reactions with weak nucleophiles such as phenol (margin). Formulate the mechanism for this process and give the structure of the product.

55. **CHALLENGE** Tertiary amines undergo reversible conjugate addition to \( \alpha,\beta \)-unsaturated ketones (see Chapter 18). This process is the basis for the Baylis-Hillman reaction, which is catalyzed by tertiary amines, that resembles a crossed aldol reaction. An example is shown below.

(a) Formulate a mechanism for this process. Begin with conjugate addition of the amine to the enone. Give the products of each of the following Baylis-Hillman reactions:

\[
\begin{array}{c}
\text{(b)} \quad \text{CH}_3\text{CHO} + \quad \text{O} \quad \xrightarrow{(\text{CH}_3)_3\text{N}} \\
\text{(c)} \quad \text{CH}_2\text{CH}=\text{CH}_2 + \quad \text{O} \quad \xrightarrow{(\text{CH}_3)_3\text{N}} \\
\end{array}
\]

56. **CHALLENGE** Reductive amination of *excess* formaldehyde with a primary amine leads to the formation of a dimethylated tertiary amine as the product (see the following example). Propose an explanation.

\[
\begin{array}{c}
\text{(CH}_3\text{)}_3\text{CCH}_2\text{NH}_2 + 2 \text{CH}_2=\text{O} \xrightarrow{\text{NaBH}_3\text{CN, CH}_3\text{OH}} (\text{CH}_3)_3\text{CCH}_2\text{N}(\text{CH}_3)_2 \\
\text{2,2-Dimethylpropanamine} \quad N,N,2,2-\text{Tetramethylpropanamine} \quad 84\%
\end{array}
\]

57. Several of the natural amino acids are synthesized from 2-oxocarboxylic acids by an enzyme-catalyzed reaction with a special coenzyme called pyridoxamine. Use electron-pushing arrows to describe each step in the following synthesis of phenylalanine from phenylpyruvic acid.
58. **Challenge** From the following information, deduce the structure of coniine, a toxic amine found in poison hemlock, which, deservedly, has a very bad reputation. IR: 3330 cm\(^{-1}\). \(^1\)H NMR: \(\delta = 0.91\) (t, \(J = 7\) Hz, 3 H), 1.33 (s, 1 H), 1.52 (m, 10 H), 2.70 (t, \(J = 6\) Hz, 2 H), and 3.0 (m, 1 H) ppm. Mass spectrum: \(m/z\) (relative intensity) = 127 (M\(^+\), 43), 84(100), and 56(20).

![Diagram of coniine synthesis](image)

59. Pethidine, the active ingredient in the narcotic analgesic Demerol, was subjected to two successive exhaustive methylations with Hofmann eliminations, and then ozonolysis, with the following results:

![Diagram of pethidine synthesis](image)

(a) Propose a structure for pethidine based on this information.

(b) Propose a synthesis of pethidine that begins with ethyl phenylacetate and cis-1,4-dibromo-2-butene. (Hint: First prepare the dialdehyde ester shown in the margin, and then convert it into pethidine.)

60. Skytanthine is a monoterpene alkaloid with the following properties. Analysis: C\(_{11}\)H\(_{21}\)N. \(^1\)H NMR: two CH\(_3\) doublets (\(J = 7\) Hz) at \(\delta = 1.20\) and 1.33 ppm; one CH\(_3\) singlet at \(\delta = 2.32\) ppm; other hydrogens give rise to broad signals at \(\delta = 1.3\)–2.7 ppm. IR: no bands \(\geq 3100\) cm\(^{-1}\). Deduce the structures of skytanthine and degradation products A, B, and C from this information.

![Diagram of skytanthine degradation](image)

61. Many alkaloids are synthesized in nature from a precursor molecule called norlaudanosoline, which in turn appears to be derived from the condensation of amine A with aldehyde B. Formulate a mechanism for this transformation. Note that a carbon–carbon bond is formed in the process. Name a reaction presented in this chapter that is closely related to this carbon–carbon bond formation.

![Diagram of norlaudanosoline synthesis](image)
**Team Problem**

62. Quaternary ammonium salts catalyze reactions between species dissolved in two immiscible phases, a phenomenon called phase-transfer catalysis. For example, heating a mixture of 1-chlorooctane dissolved in decane with aqueous sodium cyanide shows no sign of the $S_N2$ product, nonanenitrile. On the other hand, addition of a small amount of (phenylmethyl)triethylammonium chloride results in a rapid, quantitative reaction.

\[
\text{CH}_3\text{(CH}_2\text{)}_7\text{Cl} + \text{Na}^+\text{CN} \xrightarrow{\text{1-Chlorooctane}} \text{CH}_3\text{(CH}_2\text{)}_7\text{CN} + \text{Na}^+\text{Cl}^- \quad 100\%
\]

As a team, discuss possible answers to the following questions:
(a) What is the solubility of the catalyst in the two solvents?
(b) Why is the $S_N2$ reaction so slow without catalyst?
(c) How does the ammonium salt facilitate the reaction?

**Preprofessional Problems**

63. One of the following four amines is tertiary. Which one? (a) Propanamine; (b) $N$-methylthalamine; (c) $N,N$-dimethylthalamine; (d) $N$-methylpropanamine.

64. Identify the best conditions for the following transformation:

\[
\text{O} \quad \text{CH}_3\text{CH}_2\text{CNH}_2 \xrightarrow{\text{H}_2, \text{metal catalyst}} \text{CH}_3\text{CH}_2\text{NH}_2 + \text{CO}_2
\]

(a) $H_2$, metal catalyst; (b) excess $\text{CH}_3\text{I}$, $K_2\text{CO}_3$; (c) $\text{Br}_2$, $\text{NaOH}$, $\text{H}_2\text{O}$; (d) $\text{LiAlH}_4$, ether; (e) $\text{CH}_3\text{N}_2$, ether.

65. Rank the basicities of the following three nitrogen-containing compounds (most basic first):

- $\text{NH}_3$
- $\text{CH}_3\text{NH}_2$
- $(\text{CH}_3)_2\text{N}^+\text{NO}_3^-$

(a) $A > B > C$; (b) $B > C > A$; (c) $C > A > B$; (d) $C > B > A$; (e) $B > A > C$.

66. Which of the following formulas best represents diazomethane?

(a) $\text{CH}_2\overset{+}{\equiv}\text{N}=\overset{+}{\equiv}\text{N}$
(b) $\overset{-}{\equiv}\text{N}=\overset{-}{\equiv}\text{C}=\overset{-}{\equiv}\text{N}=\overset{-}{\equiv}\text{H}$
(c) $\overset{-}{\equiv}\text{N}=\overset{-}{\equiv}\text{C}=\overset{-}{\equiv}\text{N}=\overset{-}{\equiv}\text{H}$
(d) $\overset{-}{\equiv}\text{CH}_2\overset{+}{\equiv}\text{N}=\overset{+}{\equiv}\text{N}$
(e) $\overset{-}{\equiv}\text{CH}_2\overset{+}{\equiv}\text{N}$

67. Use the following partial IR- and mass-spectral data to identify one of the structures among the selection given. IR spectrum: 3300 and 1690 cm$^{-1}$; mass spectrum: $m/z = 73$ (parent ion).

(a) $\overset{-}{\equiv}\text{HCN(\text{CH}_3)}/\text{O}$
(b) $\overset{-}{\equiv}\text{NHCH}_3$
(c) $\overset{-}{\equiv}\text{H}_2\text{NCH}_2\text{C}\equiv\text{CCH}_2\text{NH}_2$

(d) $\overset{-}{\equiv}\text{CH}_3\text{CH}_2\text{CNH}_2$
(e) $\overset{-}{\equiv}\text{NH}_2$
Chemistry of Benzene Substituents

Alkylbenzenes, Phenols, and Benzenamines

Benzene (Chapter 15) used to be a common laboratory solvent until OSHA (U.S. Occupational Safety and Health Administration) placed it on its list of carcinogens. Chemists now use methylbenzene (toluene) instead, which has very similar solvating power but is not carcinogenic. Why not? The reason is the relatively high reactivity of the benzylic hydrogens that renders methylbenzene subject to fast metabolic degradation and extrusion from the body, unlike benzene, which can survive many days embedded in fatty and other tissues. Thus, the benzene ring, though itself quite unreactive because of its aromaticity, appears to activate neighboring bonds or, more generally, affects the chemistry of its substituents. You should not be too surprised by this finding, because it is complementary to the conclusions of Chapter 16. There we saw that substituents affect the behavior of benzene. Here we shall see the reverse.

How does the benzene ring modify the behavior of neighboring reactive centers? This chapter takes a closer look at the effects exerted by the ring on the reactivity of alkyl substituents, as well as of attached hydroxy and amino functions. We shall see that the behavior of these groups (introduced in Chapters 3, 8, and 21) is altered by the occurrence of resonance. After considering the special reactivity of aryl-substituted (benzylic) carbon atoms, we turn our attention to the preparation and reactions of phenols and benzenamines (anilines). These compounds are found widely in nature and are used in synthetic procedures as precursors to substances such as aspirin, dyes, and vitamins.
**22-1 Reactivity at the Phenylmethyl (Benzyl) Carbon: Benzylic Resonance Stabilization**

Methylbenzene is readily metabolized because its methyl C–H bonds are relatively weak with respect to homolytic and heterolytic cleavage. When one of these methyl hydrogens has been removed, the resulting phenylmethyl (benzyl) group, C₆H₅CH₂ (see margin), may be viewed as a benzene ring whose π system overlaps with an extra p orbital located on an attached alkyl carbon. This interaction, generally called benzylic resonance, stabilizes adjacent radical, cationic, and anionic centers in much the same way that overlap of a π bond and a third p orbital stabilizes 2-propenyl (allyl) intermediates (Section 14-1). However, unlike allylic systems, which may undergo transformations at either terminus and give product mixtures (in the case of unsymmetrical substrates), benzylic reactivity is regioselective and occurs only at the benzylic carbon. The reason for this selectivity lies in the disruption of aromaticity that goes with attack on the benzene ring.

**Benzylic radicals are reactive intermediates in the halogenation of alkylbenzenes**

We have seen that benzene will not react with chlorine or bromine unless a Lewis acid is added. The acid catalyzes halogenation of the ring (Section 15-9).

\[
\text{No reaction} \quad \text{Br–Br} \quad \text{FeBr}_3 \quad \text{HBr} \quad \text{Br} \\
\text{In contrast, heat or light allows attack by chlorine or bromine on methylbenzene (toluene) even in the absence of a catalyst. Analysis of the products shows that reaction takes place at the methyl group, not at the aromatic ring, and that excess halogen leads to multiple substitution.}
\]

Each substitution yields one molecule of hydrogen halide as a by-product.

As in the halogenation of alkanes (Sections 3-4 through 3-6) and the allylic halogenation of alkenes (Section 14-2), the mechanism of benzylic halogenation proceeds through radical intermediates. Heat or light induces dissociation of the halogen molecule into atoms. One of them abstracts a benzylic hydrogen, a reaction giving HX and a phenylmethyl (benzyl) radical. This intermediate reacts with another molecule of halogen to give the product, a (halomethyl)benzene, and another halogen atom, which propagates the chain process.
What explains the ease of benzylic halogenation? The answer lies in the stabilization of the phenylmethyl (benzyl) radical by the phenomenon called benzylic resonance (Figure 22-1). As a consequence, the benzylic C–H bond is relatively weak ($\Delta H^\circ = 87$ kcal mol$^{-1}$, 364 kJ mol$^{-1}$); its cleavage is relatively favorable and proceeds with a low activation energy.

Inspection of the resonance structures in Figure 22-1 reveals why the halogen attacks only the benzylic position and not an aromatic carbon: Reaction at any but the benzylic carbon would destroy the aromatic character of the benzene ring.

Benzylic cations delocalize the positive charge

Reminiscent of the effects encountered in the corresponding allylic systems (Section 14-3), benzylic resonance can affect strongly the reactivity of benzylic halides and sulfonates in nucleophilic displacements. For example, the 4-methylbenzenesulfonate (tosylate) of 4-methoxyphenylmethanol (4-methoxybenzyl alcohol) reacts with solvent ethanol rapidly via an $S_N1$ mechanism. This reaction is an example of solvolysis, specifically ethanolysis, which we described in Chapter 7.
The reason is the delocalization of the positive charge of the benzylic cation through the benzene ring, allowing for relatively facile dissociation of the starting sulfonate.

Mechanism of Benzylic Unimolecular Nucleophilic Substitution

Several benzylic cations are stable enough to be isolable. For example, the X-ray structure of the 2-phenyl-2-propyl cation (as its SbF$_6$ salt) was obtained in 1997 and shows the phenyl–C bond (1.41 Å) to be intermediate in length between those of pure single (1.54 Å) and double bonds (1.33 Å), in addition to the expected planar framework and trigonal arrangement of all $sp^2$ carbons (Figure 22-2), as expected for a delocalized benzylic system.

Exercise 22-2

Which one of the two chlorides will solvolyze more rapidly: (1-chloroethyl)benzene, C$_6$H$_5$CHCl, or chloro(diphenyl)methane, (C$_6$H$_5$)$_2$CHCl? Explain your answer.

The above $S_{N}1$ reaction is facilitated by the presence of the para methoxy substituent, which allows for extra stabilization of the positive charge. In the absence of this substituent, $S_{N}2$ processes may dominate. Thus, the parent phenylmethyl (benzyl) halides and sulfonates undergo preferential and unusually rapid $S_{N}2$ displacements, even under solvolytic conditions, and particularly in the presence of good nucleophiles. As in allylic $S_{N}2$ reactions (Section 14-3), two factors contribute to this acceleration. One is that the benzylic carbon is made relatively more electrophilic by the neighboring $sp^2$-hybridized phenyl carbon.
as opposed to \(sp^3\)-hybridized ones; Section 13-2). The second is stabilization of the \(S_N2\) transition state by overlap with the benzene \(\pi\) system (Figure 22-3).

\[
\text{CH}_2\text{Br} + \text{HCN} \xrightarrow{S_N2} \text{CH}_2\text{CN} + \text{Br}^-
\]

(Bromomethyl)benzene (Benzyl bromide) Phenylenethanenitrile (Phenylacetonitrile)

\((\sim 100\) times faster than \(S_N2\) reactions of primary bromoalkanes)

**Exercise 22-3**

Phenylmethanol (benzyl alcohol) is converted into (chloromethyl)benzene in the presence of hydrogen chloride much more rapidly than ethanol is converted into chloroethane. Explain.

**Resonance in benzylic anions makes benzylic hydrogens relatively acidic**

A negative charge adjacent to a benzene ring, as in the phenylmethyl (benzyl) anion, is stabilized by conjugation in much the same way that the corresponding radical and cation are stabilized. The electrostatic potential maps of the three species (rendered in the margin at an attenuated scale for optimum contrast) show the delocalized positive (blue) and negative (red) charges in the cation and anion, respectively, in addition to the delocalized electron (yellow) in the neutral radical.

**Resonance in Benzylic Anions**

\[
\begin{align*}
\text{CH}_3 & \Rightarrow \text{CH}_2 \leftrightarrow \text{CH}_2 \leftrightarrow \text{CH}_2 \leftrightarrow \text{CH}_2 + \text{H}^+ \\
pK_a \approx 41
\end{align*}
\]

The acidity of methylbenzene (toluene; \(pK_a \approx 41\)) is therefore considerably greater than that of ethane (\(pK_a \approx 50\)) and comparable to that of propene (\(pK_a \approx 40\)), which is deprotonated to produce the resonance-stabilized 2-propenyl (allyl) anion (Section 14-4). Consequently, methylbenzene (toluene) can be deprotonated by butyllithium to generate phenylmethylolithium.

**Figure 22-3** The benzene \(\pi\) system overlaps with the orbitals of the \(S_N2\) transition state at a benzylic center. As a result, the transition state is stabilized, thereby lowering the activation barrier toward \(S_N2\) reactions of (halomethyl)benzenes.
Chapter 22 Chemistry of Benzene Substituents

Deprotonation of Methylbenzene

```
\[
\text{Methylbenzene (Toluene)} + \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Li} \rightarrow (\text{CH}_3)_2\text{NCH}_2\text{CH}_2\text{N}(-\text{CH}_3)_2, \text{THF, } \Delta \rightarrow \text{Phenylmethylolithium (Benzyllithium)} + \text{CH}_3\text{CH}_2\text{CH}_2\text{H}
\]
```

Exercise 22-4
Which molecule in each of the following pairs is more reactive with the indicated reagents, and why?

(a) \( (\text{C}_6\text{H}_5)_2\text{CH} \) or \( \text{C}_6\text{H}_5\text{CH}_3 \), with \( \text{CH}_3\text{CH}_2\text{CH}_2\text{Li} \)

(b) \( \text{OCH}_3 \) or \( \text{CH}_2\text{Br} \), with \( \text{NaOCH}_3 \) in \( \text{CH}_3\text{OH} \)

(c) \( \text{CH}_3\text{CHOH} \) or \( \text{CH}_2\text{COOH} \), with \( \text{HCl} \)

In Summary Benzyl radicals, cations, and anions are stabilized by resonance with the benzene ring. This effect allows for relatively easy radical halogenations, \( \text{S}_\text{N1} \) and \( \text{S}_\text{N2} \) reactions, and benzylic anion formation.

22-2 Benzylic Oxidations and Reductions

Because it is aromatic, the benzene ring is quite unreactive. While it does undergo electrophilic aromatic substitutions (Chapters 15 and 16), reactions that dismantle the aromatic six-electron circuit, such as oxidations and reductions, are much more difficult to achieve. In contrast, such transformations occur with comparative ease when taking place at benzylic positions. This section describes how certain reagents oxidize and reduce alkyl substituents on the benzene ring.

Oxidation of alkyl-substituted benzenes leads to aromatic ketones and acids

Reagents such as hot \( \text{KMnO}_4 \) and \( \text{Na}_2\text{Cr}_2\text{O}_7 \) may oxidize alkylbenzenes all the way to benzoic acids. Benzylcarbon–carbon bonds are cleaved in this process, which usually requires at least one benzylic C–H bond to be present in the starting material (i.e., tertiary alkylbenzenes are inert).

Complete Benzylic Oxidations of Alkyl Chains

```
\[
\text{1-Butyl-4-methylbenzene} \rightarrow \text{1,4-Benzenedicarboxylic acid (Terephthalic acid)}
\]
```

1. \( \text{KMnO}_4, \text{HO}^-, \Delta \)
2. \( \text{H}^+, \text{H}_2\text{O} \rightarrow -3 \text{CO}_2 \)

80%
The reaction proceeds through first the benzylic alcohol and then the ketone, at which stage it can be stopped under milder conditions (see margin and Section 16-5).

The special reactivity of the benzylic position is also seen in the mild conditions required for the oxidation of benzylic alcohols to the corresponding carbonyl compounds. For example, manganese dioxide, MnO₂, performs this oxidation selectively in the presence of other (nonbenzylic) hydroxy groups. (Recall that MnO₂ was used in the conversion of allylic alcohols into α,β-unsaturated aldehydes and ketones; see Section 17-4.)

Selectif Oxidation of a Benzylic Alcohol with Manganese Dioxide

\[
\begin{align*}
\text{CH₃} & \text{O} \quad \text{H} \quad \text{OH} \\
\text{CH₃O} \\
\text{MnO₂, acetone, 25°C, 5 h} \\
\text{CH₃O} & \quad \text{CH₃O} \\
\text{OH} & \quad \text{OH} \\
\end{align*}
\]

94%

Benzylic ethers are cleaved by hydrogenolysis

Exposure of benzylic alcohols or ethers to hydrogen in the presence of metal catalysts results in rupture of the reactive benzylic carbon–oxygen bond. This transformation is an example of hydrogenolysis, cleavage of a σ bond by catalytically activated hydrogen.

Cleavage of Benzylic Ethers by Hydrogenolysis

\[
\begin{align*}
\text{CH₂} & \quad \text{O} \quad \text{R} \\
\text{H₂, Pd–C, 25°C} \\
\text{CH₂H} & \quad \text{+} \quad \text{HOR} \\
\end{align*}
\]

Exercise 22-5

Write synthetic schemes that would connect the following starting materials with their products.

(a) \[ \text{CH₃CH₂CH₃} \quad \rightarrow \quad \text{CH₃} \]

(b) \[ \text{H₃C} \quad \text{CH₃} \quad \text{H₃C} \quad \text{CH₃} \quad \rightarrow \quad \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \]

Hydrogenolysis is not possible for ordinary alcohols and ethers. Therefore, the phenylmethyl (benzyl) substituent is a valuable protecting group for hydroxy functions. The following scheme shows its use in part of a synthesis of a compound in the eudesmane class of essential oils, which includes substances of importance in both medicine and perfumery.
Because the hydrogenolysis of the phenylmethyl (benzyl) ether in the final step occurs under neutral conditions, the tertiary alcohol function survives untouched. A tertiary butyl ether would have been a worse choice as a protecting group, because cleavage of its carbon–oxygen bond would have required acid (Section 9-8), which may cause dehydration (Section 9-2).

In Summary  Benzylic oxidations of alkyl groups take place in the presence of permanganate or chromate; benzylic alcohols are converted into the corresponding ketones by manganese dioxide. The benzylic ether function can be cleaved by hydrogenolysis in a transformation that allows the phenylmethyl (benzyl) substituent to be used as a protecting group for the hydroxy function in alcohols.

22-3 Names and Properties of Phenols

Arenes substituted by hydroxy groups are called phenols (Section 15-1). The π system of the benzene ring overlaps with an occupied p orbital on the oxygen atom, a situation resulting in delocalization similar to that found in benzylic anions (Section 22-1). As one result of this extended conjugation, phenols possess an unusual, enolic structure. Recall that enols are usually unstable: They tautomerize easily to the corresponding ketones because of the relatively strong carbonyl bond (Section 18-2). Phenols, however, prefer the enol to the keto form because the aromatic character of the benzene ring is preserved.
Phenols and their ethers are ubiquitous in nature; some derivatives have medicinal and herbicidal applications, whereas others are important industrial materials. This section first explains the names of these compounds. It then describes an important difference between phenols and alkanols—phenols are stronger acids because of the neighboring aromatic ring.

**Phenols are hydroxyarenes**

Phenol itself was formerly known as carbolic acid. It forms colorless needles (m.p. 41°C), has a characteristic odor, and is somewhat soluble in water. Aqueous solutions of it (or its methyl-substituted derivatives) are applied as disinfectants, but its main use is for the preparation of polymers (phenolic resins; Section 22-6). Pure phenol causes severe skin burns and is toxic; deaths have been reported from the ingestion of as little as 1 g. Fatal poisoning may also result from absorption through the skin.

Substituted phenols are named as phenols, benzenediols, or benzenetriols, according to the system described in Section 15-1, although some common names are accepted by IUPAC (Section 22-8). These substances find uses in the photography, dyeing, and tanning industries. The compound bisphenol A (shown in the margin; see also Chemical Highlight 22-1) is an important monomer in the synthesis of epoxyresins and polycarbonates, materials that are widely employed in the manufacture of durable plastic materials, food packaging, dental sealants, and coatings inside beverage cans (Chemical Highlight 22-1).

Phenols containing the higher-ranking carboxylic acid functionality are called hydroxybenzoic acids. Many have common names. Phenyl ethers are named as alkoxybenzenes. As a substituent, C₆H₅O is called phenoxy.

Many examples of phenol derivatives, particularly those exhibiting physiological activity, are depicted in this book (e.g., see Chemical Highlights 5-4, 9-1, 21-1, 22-1, and 22-2, and
Phenols are unusually acidic

Phenols have $pK_a$ values that range from 8 to 10. Even though they are less acidic than carboxylic acids ($pK_a = 3–5$), they are stronger than alkanols ($pK_a = 16–18$). The reason is resonance: The negative charge in the conjugate base, called the phenoxide ion, is stabilized by delocalization into the ring.

**Acidity of Phenol**

$$\text{Phenoxide ion}$$

Sections 4-7, 9-11, 15-1, 22-9, 24-12, 25-8, and 26-1). You are very likely to have ingested without knowing it the four phenol derivatives shown here.
The acidity of phenols is greatly affected by substituents that are capable of resonance. 4-Nitrophenol (\(p\)-nitrophenol), for example, has a \(pK_a\) of 7.15.

\[ \text{OH} \quad \rightarrow \quad \text{H}^+ + \quad \text{etc.} \]

\(pK_a = 7.15\)

The 2-isomer has similar acidity (\(pK_a = 7.22\)), whereas nitrosubstitution at C3 results in a \(pK_a\) of 8.39. Multiple nitration increases the acidity to that of carboxylic or even mineral acids. Electron-donating substituents have the opposite effect, raising the \(pK_a\).

\[ \text{OH} \quad \rightarrow \quad \text{H}^+ + \quad \text{etc.} \]

As Section 22-5 will show, the oxygen in phenol and its ethers is also weakly basic, in the case of ethers giving rise to acid-catalyzed cleavage.

**Exercise 22-6**

Why is 3-nitrophenol (\(m\)-nitrophenol) less acidic than its 2- and 4-isomers but more acidic than phenol itself?

**Exercise 22-7**

Rank in order of increasing acidity: phenol, A; 3,4-dimethylphenol, B; 3-hydroxybenzoic (\(m\)-hydroxybenzoic) acid, C; 4-(fluoromethyl)phenol \([p-(fluoromethyl)phenol]\), D.

**In Summary** Phenols exist in the enol form because of aromatic stabilization. They are named according to the rules for naming aromatic compounds explained in Section 15-1. Those derivatives bearing carboxy groups on the ring are called hydroxybenzoic acids. Phenols are acidic because the corresponding anions are resonance stabilized.
CHEMICAL HIGHLIGHT 22-1

Two Phenols in the News: Bisphenol A and Resveratrol

This section mentions two phenols as examples of chemicals to which you have potentially frequent exposure: bisphenol A (p. 1027) and resveratrol (p. 1028). Bisphenol A is the essential ingredient of the familiar polycarbonate plastics used in clear baby bottles, instant-formula cans, dental sealants, the linings of food and beverage containers, and reusable plastic bottles. More than 2 billion pounds are made each year in the United States alone, and three times as much are made worldwide. Yet there is continuing controversy surrounding this monomer, first made in 1891—a controversy that illustrates the difficulty of interpreting scientific data in terms of human risk assessment.

The problem is that bisphenol A behaves as an estrogen mimic in animals. The monomer has been found to leach from the plastic, at increasing rates when heated, such as in a microwave oven. For example, a study carried out in 2003 showed that even very low levels of bisphenol A (about 20 ppb) caused chromosome aberrations in developing mouse eggs. These amounts are in the same range as are encountered in human blood and urine. Because the processes through which human and mouse eggs are prepared for fertilization are very similar, the study is a cause for concern, although it does not prove that humans are at risk.

Moreover, in other studies carried out with adult rats, bisphenol A appeared to have no adverse effects on reproduction and development. A critique of these findings, dated 2008, pointed out that fetuses and newborns lack the liver enzyme needed to detoxify the chemical, again raising the specter of adverse effects on children. As a report by the National Institute of Environmental Health Sciences stresses, the discrepancies in studies of this type may be due to the use of different strains of animals, varying degrees of exposure and differing background levels of estrogenic pollutants, dosing regimens, and housing of the animals.

22-4 Preparation of Phenols: Nucleophilic Aromatic Substitution

Phenols are synthesized quite differently from the way in which ordinary substituted benzenes are made. Direct electrophilic addition of OH to arenes is difficult because of the scarcity of reagents that generate an electrophilic hydroxy group, such as HO⁻. Instead, phenols are prepared by formal nucleophilic displacement of a leaving group from the arene ring by hydroxide, HO⁻, reminiscent of, but mechanistically quite different from, the synthesis of alkanols from haloalkanes. This section considers the ways in which this transformation may be achieved.

Nucleophilic aromatic substitution may follow an addition–elimination pathway

Treatment of 1-chloro-2,4-dinitrobenzene with hydroxide replaces the halogen with the nucleophile, furnishing the corresponding substituted phenol. Other nucleophiles, such
(singly versus group). Remember that we are talking about extremely small concentrations of a biologically active compound (parts per billion!) that affect only a certain percentage of animals and to differing degrees. And then there are the big questions of the extent to which animal studies are relevant to humans and whether there is a threshold level of exposure that humans can tolerate because of the presence of evolutionary natural detoxification mechanisms. In 2007 and 2008, two government-convened groups reiterated that human exposure is at a level that causes adverse effects in humans and that there is concern about prenatal and early-childhood exposure. As a result, both Canada and the U.S. Congress began moving toward a ban of bisphenol A in children’s products, and some retailers, such as Wal-Mart and Toys”R”Us, are phasing out their sale. Concurrently, industrial producers are replacing polycarbonate plastics with other polymers.

The issues surrounding the potentially harmful effects of chemicals in the environment are equally relevant with respect to their potentially beneficial effects. An example is resveratrol. This compound has been used in traditional medicine to treat conditions of the heart and liver, and recently scientists took an interest in its physiological properties. It is present in various plants and foods, such as eucalyptus, lily, mulberries, peanuts, and, most prominently, in the skin of white and, especially, red grapes, where it is found in concentrations of 50–100 μg/g. The compound is a chemical weapon against invading organisms, such as fungi. Grapes are used for wine making, so resveratrol occurs in red wine, at levels of up to 160 μg per ounce. Studies have suggested that the regular consumption of red wine reduces the incidence of coronary heart disease, a finding described as the “French paradox,” namely, the low incidence of heart problems in France despite the relatively high-fat diet.

Resveratrol may be the active species, as recent research has indicated its potentially beneficial cardiovascular effects, including its action as an antioxidant, which inhibits lipid peroxidation (Section 22-9), and as an antiplatelet agent (Chemical Highlight 22-2), which prevents atherosclerosis. Other investigations have shown that the molecule is also an active antitumor agent, involved in retarding the initiation, promotion, and progression of certain cancers, with seemingly minimal toxicity. Perhaps most interesting, it was discovered that resveratrol significantly extended the lifespan of certain species of yeast, worm, the fruit fly, and fish. Along similar lines, it canceled the life-shortening effects of a high-fat diet in mice. As a result of these promising discoveries, resveratrol has been hailed by manufacturers as the “French paradox in a bottle” and pushed for wide-scale consumption. However, experts advise caution. For example, little is known about its metabolism and how it affects the liver, the above results are derived in large part from in vitro experiments, and, like bisphenol A, it has estrogen-like physiological effects, enhancing the growth of breast cancer cells. For the time being, an occasional glass of red wine may be the best course of action, if any!

Resveratrol protects grapes from fungus, such as that shown here.

as alkoxides or ammonia, may be similarly employed, forming alkoxyarenes and arenamines, respectively. Processes such as these, in which a group other than hydrogen is displaced from an aromatic ring, are called ipso substitutions (ipso, Latin, on itself). The products of these reactions are intermediates in the manufacture of useful dyes.
The transformation is called **nucleophilic aromatic substitution**. The key to its success is the presence of one or more strongly electron-withdrawing groups on the benzene ring located ortho or para to the leaving group. Such substituents stabilize an intermediate anion by resonance. In contrast with the $S_N2$ reaction of haloalkanes, substitution in these reactions takes place by a **two-step mechanism**, an addition–elimination sequence similar to the mechanism of substitution of carboxylic acid derivatives (Sections 19-7 and 20-2).

**Mechanism of Nucleophilic Aromatic Substitution**

**Step 1.** Addition (facilitated by resonance stabilization)

The negative charge is strongly stabilized by resonance involving the ortho- and para-NO$_2$ groups.
Step 2. Elimination (only one resonance structure is shown)

\[
\begin{align*}
\text{Nu} & \quad \text{Cl} \\
\text{O}_2\text{N} & \quad \text{NO}_2 \\
\text{O}_2\text{N} & \quad \text{NO}_2
\end{align*}
\]

In the first and rate-determining step, ipso attack by the nucleophile produces an anion with a highly delocalized charge, for which several resonance structures may be written, as shown. Note the ability of the negative charge to be delocalized into the electron-withdrawing groups. In contrast, such delocalization is not possible in 1-chloro-3,5-dinitrobenzene, in which these groups are located meta; so this compound does not undergo ipso substitution under the conditions employed.

\[
\begin{align*}
\text{Nu} & \quad \text{Cl} \\
\text{O}_2\text{N} & \quad \text{NO}_2 \\
\text{O}_2\text{N} & \quad \text{NO}_2
\end{align*}
\]

Meta-NO\textsubscript{2} groups do not provide resonance stabilization of the negative charge.

In the second step, the leaving group is expelled to regenerate the aromatic ring. The reactivity of haloarenes in nucleophilic substitutions increases with the nucleophilicity of the reagent and the number of electron-withdrawing groups on the ring, particularly if they are in the ortho and para positions.

Exercise 22-8

Write the expected product of reaction of 1-chloro-2,4-dinitrobenzene with NaOCH\textsubscript{3} in boiling CH\textsubscript{3}OH.

Exercise 22-9

Working with the Concepts: Using Nucleophilic Aromatic Substitution in Synthesis

Ofloxacin, an antibiotic of the quinolone class (Section 25-7), is used in the treatment of infections of the respiratory and urinary tract, the eyes, the ears, and skin tissue. The quinolone antibiotics are another alternative in the ongoing battle against penicillin (and other drug)-resistant bacteria. The final three steps in the synthesis of ofloxacin are shown below, the last of which is a simple ester hydrolysis (Section 20-4). Formulate mechanisms for the other two transformations from A to B and then to C.
Strategy
Taking an inventory of the topological changes and of the nature of the bonds formed and bonds broken, we note that B and C are the result of two successive intra- and one intermolecular nucleophilic aromatic substitutions, respectively. The first steps are ring closures and therefore especially favored for entropic and enthalpic reasons. (Formation of six-membered rings is a favorable reaction, see Sections 9-6 and 17-7.) The aromatic ring in A should be highly activated with respect to nucleophilic attack, because it bears four inductively electron-withdrawing fluorine substituents, in addition to the resonance-based electron-withdrawing carbonyl group. To propose a mechanism, let's look at the individual steps.

Solution
• In the conversion of A to B, the strong base Na"H" is employed. Where are the acidic sites in A? Most obvious is the hydroxy function (pK_a 15–16, Section 8-3, Table 8-2), which will certainly be deprotonated.
• What about the amino group? Closer inspection of structure A shows that the nitrogen is connected via a double bond to two carbonyl moieties. Thus, the function is resonance stabilized in much the same way as an ordinary amide (but more so):

   ![Resonance in A](image)

   Consequently, it should be relatively acidic, even more acidic than an amide (pK_a 22, Section 20-7). It is therefore likely that A is doubly deprotonated before attacking the benzene nucleus. Nucleophilic aromatic substitution is then readily formulated to assemble the first new ring. In the scheme below, only one—the dominating—resonance form of the anion resulting from nucleophilic attack on the arene is shown, that in which the negative charge is delocalized onto the carbonyl oxygen.

   ![First Ring Closure](image)

   The second nucleophilic substitution by alkoxide is unusual, inasmuch as it has to occur at a position meta to the carbonyl function. Therefore, the intermediate anion is not stabilized by resonance, but solely by inductive effects. The regioselectivity is controlled by strain: The alkoxide cannot “reach” the more favorable carbon para to the carbonyl.

   ![Second Ring Closure to B](image)

   The conversion of B to C features an intermolecular substitution with an amine nucleophile. Of the two carbons bearing the potential fluoride leaving groups, the one para to the carbonyl is picked, because of the resonance stabilization of the resulting intermediate anion. The initial product is formed as the ammonium salt, from which the free base C is liberated by basic work-up (Chemical Highlight 21-2).

   ![B to C](image)
Haloarenes undergo substitution through benzyne intermediates

Haloarenes devoid of electron-withdrawing substituents do not undergo simple ipso substitution. Nevertheless, when haloarenes are treated with nucleophiles that are also strong bases, if necessary at highly elevated temperatures, they convert to products in which the halide has been replaced by the nucleophile. For example, if exposed to hot sodium hydroxide followed by neutralizing work-up, chlorobenzene furnishes phenol.

\[
\text{Cl} \quad \text{CH}_2 = \text{SO}_2 - \text{Ph} \quad \xrightarrow{\text{1. NaOH, H}_2\text{O, 340°C, 150 atm}} \quad \text{OH} \\
\text{Chlorobenzene} \quad + \quad \text{Phenol} \quad + \quad \text{NaCl}
\]

Treatment with potassium amide results in benzenamine (aniline).

\[
\text{Cl} \quad \text{CH}_2 = \text{SO}_2 - \text{Ph} \quad \xrightarrow{\text{1. KNH}_2, \text{liquid NH}_3} \quad \text{NH}_2 \\
\text{Benzenamine (Aniline)} \quad + \quad \text{KCl}
\]

It is tempting to assume that these substitutions follow a mechanism similar to that formulated for nucleophilic aromatic ipso substitution earlier in this section. However, when the last reaction is performed with radioactively labeled chlorobenzene (\(^{14}\text{C}\) at C1), a very curious result is obtained: Only half of the product is substituted at the labeled carbon; in the other half, the nitrogen is at the neighboring position.
Direct substitution does not seem to be the mechanism of these reactions. What, then, is the answer to this puzzle? A clue is the attachment of the incoming nucleophile only at the ipso or at the ortho position relative to the leaving group. This observation can be accounted for by an initial base-induced elimination of HX from the benzene ring, a process reminiscent of the dehydrohalogenation of haloalkenes to give alkynes (Section 13-4). In the present case, elimination is not a concerted process, but rather takes place in a sequential manner, deprotonation preceding the departure of the leaving group (step 1 of the mechanism shown). Both stages in step 1 are difficult, with the second being worse than the first. Why is that? With respect to the initial anion formation, recall (Section 11-3) that the acidity of $C_{sp^2}$-H is very low ($pK_a < 44$), and the same is true in general for phenyl hydrogens. The presence of the adjacent $\pi$ system of benzene does not help, because the negative charge in the phenyl anion resides in an $sp^2$ orbital that is perpendicular to the $\pi$ frame and is therefore incapable of resonance with the double bonds in the six-membered ring. Thus, deprotonation of the haloarene requires a strong base. It takes place ortho to the halogen, because the halogen’s inductive electron-withdrawing effect acidifies this position relative to the others.

Although deprotonation is not easy, the second stage of step 1, subsequent elimination of $X^-$, is even more difficult because of the highly strained structure of the resulting reactive species, called 1,2-dehydrobenzene or benzyne.

**Mechanism of Nucleophilic Substitution of Simple Haloarenes**

**Step 1.** Elimination occurs stepwise

![Mechanism of Nucleophilic Substitution of Simple Haloarenes](image)

**Step 2.** Addition occurs to both strained carbons

Why is benzyne so strained? Recall that alkynes normally adopt a linear structure, a consequence of the $sp$ hybridization of the carbons making up the triple bond (Section 13-2). Because of benzyne’s cyclic structure, its triple bond is forced to be bent, rendering it unusually reactive. Thus, benzyne exists only as a reactive intermediate under these conditions, being rapidly attacked by any nucleophile present. For example (step 2), amide ion or even ammonia solvent can add to furnish the product benzenamine (aniline). Because the two ends of the triple bond are equivalent, addition can take place at either carbon, explaining the label distribution in the benzenamine obtained from $^{14}C$-labeled chlorobenzene.

Benzyne is too reactive to be isolated and stored in a bottle, but it can be observed spectroscopically under special conditions. Irradiation of benzocyclobutenedione at 77 K
(−196°C) in frozen argon (m.p. = −189°C) produces a species whose IR and UV spectra are assignable to benzyne, formed by loss of two molecules of CO.

**Generation of Benzyne, a Reactive Intermediate**

\[
\text{O} \quad \text{hv, 77 K} \quad \text{O} \quad + \quad 2 \text{CO}
\]

Benzocyclobutene-1,2-dione

Although benzyne is usually represented as a cycloalkyne (Figure 22-4A), its triple bond exhibits an IR stretching frequency of 1846 cm\(^{-1}\), intermediate between the values for normal double (cyclohexene, 1652 cm\(^{-1}\)) and triple (3-hexyne, 2207 cm\(^{-1}\)) bonds. The \(^{13}\)C NMR values for these carbons (δ = 182.7 ppm) are also atypical of pure triple bonds (Section 13-3), indicating a considerable contribution of the cumulated triene (Section 14-5) resonance form (Figure 22-4B). The bond is weakened substantially by poor \(p\) orbital overlap in the plane of the ring.

![Figure 22-4](image)

**Exercise 22-11**

1-Chloro-4-methylbenzene (\(p\)-chlorotoluene) is not a good starting material for the preparation of 4-methylphenol (\(p\)-cresol) by direct reaction with hot NaOH, because it forms a mixture of two products. Why does it do so, and what are the two products?

**Exercise 22-12**

Explain the regioselectivity observed in the following reaction. (Hint: Consider the effect of the methoxy group on the selectivity of attack by amide ion on the intermediate benzyne.)

\[
\text{Br} \quad \text{OCH}_3 \quad \xrightarrow{\text{KNNH}_3, \text{liquid NH}_3} \quad \text{H}_2\text{N} \quad \text{OCH}_3 \quad + \quad \text{NH}_2 \quad \text{OCH}_3
\]

Major + Minor
Phenols are produced from arenediazonium salts

The most general traditional laboratory procedure for making phenols is from arenamines through their **arenediazonium salts**, \( \text{ArN}_2^+ \text{X}^- \). Recall that primary alkanamines can be \( \text{N} \)-nitrosated but that the resulting species rearrange to diazonium ions, which are unstable—they lose nitrogen to give carbocations (Section 21-10). In contrast, primary benzenamines (anilines) are attacked by cold nitrous acid, in a reaction called **diazotization**, to give relatively stable, isolable, although still reactive arenediazonium salts. Compared to their alkanediazonium counterparts, these species enjoy resonance stabilization and are prevented from undergoing immediate \( \text{N}_2 \) loss by the high energy of the resulting **aryl cations** (to be discussed in more detail in Section 22-10).

![Diazotization reaction](image)

When arenediazonium ions are gently heated in water, nitrogen is evolved and the resulting aryl cations are trapped extremely rapidly by the solvent to give phenols.

**Decomposition of Arenediazonium Salts in Water to Give Phenols**

![Decomposition reaction](image)

In these reactions, the “super” leaving group \( \text{N}_2 \) accomplishes what halides are only able to do when attached to a highly electron-deficient benzene nucleus (nucleophilic aromatic substitution) or under extreme conditions (through benzyne intermediates), namely, replacement by hydroxide. The three mechanisms are completely different. In nucleophilic aromatic substitution, the nucleophile attacks prior to departure of the leaving group. In the benzyne mechanism, the nucleophile acts initially as a base, followed by extrusion of the leaving group and subsequent nucleophilic attack on the strained triple bond. In the arenediazonium-ion decomposition, the leaving group exits first, followed by trapping by water.

The utility of this phenol synthesis is apparent when you recall that arenamines are derived from nitroarenes by reduction, and nitroarenes are made from other arenes by electrophilic aromatic substitution (Chapters 15 and 16). Therefore, retrosynthetically (Section 8-9), we can picture the hydroxy group in any position of a benzene ring that is subject to electrophilic nitration.
Retrosynthetic Connection of Phenols to Arenes

Two examples are depicted below.

Exercise 22-13

*ortho*-Benzenediazoniumcarboxylate A (made by diazotization of 2-aminobenzoic acid, Problem 20-59) is explosive. When warmed in solution with *trans*,*trans*-2,4-hexadiene, it forms compound B. Explain by a mechanism. ([Hint: Two other products are formed, both of which are gases.]

Exercise 22-14

Propose a synthesis of 4-(phenylmethyl)phenol (*p*-benzylphenol) from benzene. ([Caution: Remember that Friedel-Crafts reactions do not work with deactivated arenes.])
**Phenols can be made from haloarenes by Pd catalysis**

While we have seen that ordinary halobenzenes are resilient to reaction with hydroxide, they undergo such nucleophilic displacements in the presence of Pd salts and added phosphine ligands PR₃.

**Pd-Catalyzed Phenol Synthesis from Haloarenes**

\[
\text{X} \quad \text{KOH, Pd catalyst, PR₃, 100°C} \quad \text{OH}
\]

The reaction is general for substituted benzenes, providing a complement to the diazonium method described above.

**Mechanism of the Pd-Catalyzed Phenol Synthesis from Haloarenes**

The mechanism is related to that of the Heck and other Pd-catalyzed reaction (Section 13-9; Chemical Highlight 13-1). As shown in a simplified manner below, it begins by insertion of the metal into the aryl halide bond, exchange of the halide for hydroxide, and extrusion of the final product with regeneration of the catalyst.

**Similar substitutions can be carried out with alkoxides to give phenol ethers, and with amines, including ammonia, to furnish benzenamines.**

**3-Methoxy-N-(2-methylpropyl)benzenamine**

**3-Methoxy-N-(2-methylpropyl)aniline**

**2-(1-Methylethyl)benzenamine**

**3-Methoxy-(2-methylpropyl)benzenamine**

**(m-Hydroxyacetophenone)**

**4-Methoxyphenol**

**(p-Methoxyphenol)**

**1-(3-Hydroxyphenyl)ethanone**

**(m-Hydroxyacetophenone)**
Although the preceding methods are valuable in the preparation of specifically substituted phenols, the parent compound is made industrially by the air oxidation of (1-methylethyl)benzene (isopropylbenzene or cumene; see also Exercise 15-27) to the benzylic hydroperoxide and its subsequent decomposition with acid (margin). The “by-product” acetone is valuable in its own right and makes this process highly cost effective, quite apart from the environmentally benign use of air as an oxidant.

Exercise 22-15

How would you make the following phenols from the given starting materials? (Hint: Consult Chapters 15 and 16.)

(a) \( \text{CF}_3 \text{OH} \) from \( \text{CF}_3 \)
(b) \( \text{HO-NO}_2 \text{OCH}_3 \) from \( \text{NO}_2\text{OCH}_3 \)
(c) \( \text{OH} \) from \( \text{O} \)

In Summary  When a benzene ring bears enough strongly electron-withdrawing substituents, nucleophilic addition to give an intermediate anion with delocalized charge becomes feasible, followed by elimination of the leaving group (nucleophilic aromatic ipso substitution). Phenols result when the nucleophile is hydroxide ion, arenamines (anilines) when it is ammonia, and alkoxyarenes when alkoxides are employed. Very strong bases are capable of eliminating HX from haloarenes to form the reactive intermediate benzyynes, which are subject to nucleophilic attack to give substitution products. Phenols may also be prepared by decomposition of arenediazonium salts in water and by Pd-catalyzed hydroxylations of haloarenes.

22-5 Alcohol Chemistry of Phenols

The phenol hydroxy group undergoes several of the reactions of alcohols (Chapter 9), such as protonation, Williamson ether synthesis, and esterification.

The oxygen in phenols is only weakly basic

Phenols are not only acidic but also weakly basic. They (and their ethers) can be protonated by strong acids to give the corresponding phenyloxonium ions. Thus, as with the alkanols, the hydroxy group imparts amphoteric character (Section 8-3). However, the basicity of phenol is even less than that of the alkanols, because the lone electron pairs on the oxygen are delocalized into the benzene ring (Sections 16-1 and 16-3). The \( pK_a \) values for phenyloxonium ions are, therefore, lower than those of alkyloxonium ions.

\[
\begin{align*}
\text{CH}_3\text{O}^+ & \quad \text{CH}_3\text{OH} + H^+ \\
pK_a = -2.2 & \quad pK_a = -6.7
\end{align*}
\]
Unlike secondary and tertiary alkylloxonium ions derived from alcohols, phenyloxonium derivatives do not dissociate to form phenyl cations, because such ions have too high an energy content (see Section 22-10). The phenyl–oxygen bond in phenols is very difficult to break. However, after protonation of alkoxybenzenes, the bond between the alkyl group and oxygen is readily cleaved in the presence of nucleophiles such as Br$^-$ or I$^-$ (e.g., from HBr or HI) to give phenol and the corresponding haloalkane.

$$\text{COOH} \quad \text{HBr, } \Delta \quad \text{COOH} \quad + \quad \text{CH}_3\text{Br}$$

3-Methoxybenzoic acid (m-Methoxybenzoic acid) 3-Hydroxybenzoic acid (m-Hydroxybenzoic acid)

**Exercise 22-16**

Why does cleavage of an alkoxybenzene by acid not produce a halobenzene and the alkanol?

**Alkoxybenzenes are prepared by Williamson ether synthesis**

The Williamson ether synthesis (Section 9-6) permits easy preparation of many alkoxybenzenes. The phenoxide ions obtained by deprotonation of phenols (Section 22-3) are good nucleophiles. They can displace the leaving groups from haloalkanes and alkyl sulfonates.

$$\text{NaOH, H}_2\text{O} \quad \text{NaBr, } \text{HOH}$$

3-Chlorophenol (m-Chlorophenol) 1-Chloro-3-propoxybenzene (m-Chlorophenyl propyl ether)

**Esterification leads to phenyl alkanoates**

The reaction of a carboxylic acid with a phenol (Section 19-9) to form a phenyl ester is endothermic. Therefore, esterification requires an activated carboxylic acid derivative, such as an acyl halide or a carboxylic anhydride.

$$\text{NaOH, H}_2\text{O} \quad -\text{NaCl, } -\text{HOH}$$

4-Methylphenol (p-Cresol) Propanoyl chloride 4-Methylphenyl propanoate (p-Methylphenyl propanoate)

**Exercise 22-17**

Explain why, in the preparation of acetaminophen (Chemical Highlight 22-2), the amide is formed rather than the ester. (Hint: Review Section 6-8.)
In Summary

The oxygen in phenols and alkoxybenzenes can be protonated even though it is less basic than the oxygen in the alkanols and alkoxyalkanes. Protonated phenols and their derivatives do not ionize to phenyl cations, but the ethers can be cleaved to phenols and haloalkanes by HX. Alkoxybenzenes are made by Williamson ether synthesis, aryl alkoanoates by acylation.
22-6 Electrophilic Substitution of Phenols

The aromatic ring in phenols is also a center of reactivity. The interaction between the OH group and the ring strongly activates the ortho and para positions toward electrophilic substitution (Sections 16-1 and 16-3). For example, even dilute nitric acid causes nitration.

\[
\begin{align*}
\text{HNO}_3, \text{CHCl}_3, 15^\circ C & \quad \text{26\%} \\
\text{2-Nitrophenol} & \\
\text{OH} & \\
& \\
\text{OH} & \\
\text{NO}_2 & \\
\text{4-Nitrophenol} & \quad \text{61\%} \\
\end{align*}
\]

Ester formation, and is better carried out on ether derivatives of phenol (Section 16-5), as shown in the margin.

Phenols are halogenated so readily that a catalyst is not required, and multiple halogenations are frequently observed (Section 16-3). As shown in the following reactions, tribromination occurs in water at 20°C, but the reaction can be controlled to produce the monohalogenation product through the use of a lower temperature and a less polar solvent.

**Haloxygenation of Phenols**

Electrophilic attack at the para position is frequently dominant because of steric effects. However, it is normal to obtain mixtures resulting from both ortho and para substitutions, and their compositions are highly dependent on reagents and reaction conditions.

**Exercise 22-18**

Friedel-Crafts methylation of methoxybenzene (anisole) with chloromethane in the presence of AlCl₃ gives a 2:1 ratio of ortho:para products. Treatment of methoxybenzene with 2-chloro-2-methylpropane (tert-butyl chloride) under the same conditions furnishes only 1-methoxy-4-(1,1-dimethylethyl) benzene (p-tert-butylanisole). Explain. (Hint: Review Section 16-5.)

**Exercise 22-19**

**Working with the Concepts: Devising Synthetic Strategies Starting with Substituted Phenols**

Proparacaine is a local anesthetic that is used primarily to numb the eye before minor surgical procedures, such as the removal of foreign objects or stitches. Show how you would make it from 4-hydroxybenzenecarboxylic acid.

\[
\begin{align*}
\text{4-Hydroxybenzenecarboxylic acid} & \quad \text{H}_2\text{N} & \quad \text{NH}_2 \\
& \quad \text{OH} & \\
& \quad \text{O} & \\
\text{Proparacaine} & \\
\end{align*}
\]
Strategy

Inspection of the structures of both the starting material and the product reveals three structural modifications: (1) An amino group is introduced into the benzene core, suggesting a nitration-reduction sequence (Section 16-5) that relies on the ortho-directing effect of the hydroxy substituent; (2) the phenol function is etherified, best done by Williamson synthesis (Section 22-5); (3) the carboxy function is esterified with the appropriate amino alcohol (Section 20-2). What is the best sequence in which to execute these manipulations? To answer this question, consider the possible interference of the various functions with the suggested reaction steps.

Solution

• Modification 1 could be carried out with the starting material, resulting in the corresponding amino acid. However, “unmasking” the amino group (from its precursor nitro) early bodes trouble with steps 2 and 3, because amines are better nucleophiles than alcohols. Therefore, attempted etherification of the aminated phenol will lead to amine alkylation (Section 21-5). Similarly, attempts to effect ester formation in the presence of an amine function will give rise to amide generation (Section 19-10). However, early introduction of the nitro group and maintaining it as such until the other functions are protected looks good.

• For modification 2, Williamson ether synthesis in the presence of a carboxy group should be fine, because the carboxylate ion is a poorer nucleophile than phenoxide ion (Section 6-8).

• The preceding protection of the phenolic function is important to the success of modification 3, ester formation with the amino alcohol, especially if we want to activate the carboxy group as an acyl chloride.

• Putting it all together, a possible (and, indeed, the literature) synthesis of proparacaine is as follows:

Exercise 22-20

Try It Yourself

Device an alternative route to proparacaine from 4-hydroxybenzenecarboxylic acid, using Pd catalysis.

Under basic conditions, phenols can undergo electrophilic substitution, even with very mild electrophiles, through intermediate phenoxide ions. An industrially important application is the reaction with formaldehyde, which leads to o- and p-hydroxymethylation. Mechanistically, these processes may be considered enolate condensations, much like the aldol reaction (Section 18-5).
Hydroxymethylation of Phenol

The initial aldol products are unstable: They dehydrate on heating, giving reactive intermediates called quinomethanes.

Because quinomethanes are $\alpha,\beta$-unsaturated carbonyl compounds, they may undergo Michael additions (Section 18-11) with excess phenoxide ion. The resulting phenols can be hydroxymethylated again and the entire process repeated. Eventually, a complex phenol–formaldehyde copolymer, also called a phenolic resin (e.g., Bakelite), is formed. Their major uses are in plywood (45%), insulation (14%), molding compounds (9%), fibrous and granulated wood (9%), and laminates (8%).

Phenolic Resin Synthesis

polymer $+ n\ H_2O$
In the Kolbe*-Schmitt† reaction, phenoxide attacks carbon dioxide to furnish the salt of 2-hydroxybenzoic acid (o-hydroxybenzoic acid, salicylic acid, precursor to aspirin; see Chemical Highlight 22-2).

\[
\text{Phenol} + \text{CO}_2 \rightarrow \text{Salicylic Acid} + \text{Na}^+ \text{OH}^- \\
\text{C}_6\text{H}_5\text{OH} + \text{CO}_2 \rightarrow \text{C}_6\text{H}_5\text{COOH} + \text{Na}^+ \text{OH}^-
\]

**Exercise 22-21**

**Working with the Concepts: Recognizing Phenol as an Enol**

Formulate a mechanism for the Kolbe-Schmitt reaction.

**Strategy**

As always, we take an inventory of the components of the reaction: starting materials, other reagents and reaction conditions, and products. Phenol is an electron-rich arene (see this and Section 16-3) and also acidic. Carbon dioxide has an electrophilic carbon that is attacked by nucleophilic carbon atoms, such as in Grignard reagents (Section 19-6). The reaction conditions are strongly basic. Finally, the product looks like that of an electrophilic ortho substitution.

**Solution**

• Under basic conditions, phenol will exist as phenoxide, which, like an enolate ion (Section 18-1), can be described by two resonance forms (see margin).
• Enolate alkylations occur at carbon (Section 18-10). In analogy, you can formulate a phenoxide attack on the electrophilic carbon of CO\(_2\). Alternatively, you can think of this reaction as an electrophilic attack of CO\(_2\) on a highly activated benzene ring.
• Finally, deprotonation occurs to regenerate the aromatic arene.

As you will have noticed, the selectivity for ortho attack by CO\(_2\) in this process is exceptional. Although not completely understood, it may involve direction of the electrophile by the Na\(^+\) ion in the vicinity of the phenoxide negative charge.

**Exercise 22-22**

**Try It Yourself**

Phentolamine (as a water-soluble methanesulfonic acid salt) is an antihypertensive that has recently been introduced into dentistry: It cuts in half the time taken to recover from the numbing effect of local anesthetics. The key step in its preparation dates from 1886, the reaction shown below. What is its mechanism? (Caution: This is not a nucleophilic aromatic substitution. Hint: Think keto–enol tautomerism).

\[
\text{Phentolamine} \quad \text{Phentolamine} \\
\text{C}_6\text{H}_4\text{OH} + \text{CH}_3\text{NH}_2 \rightarrow \text{C}_6\text{H}_4\text{N}^+\text{CH}_3 + \text{H}_2\text{O} \\
\text{Phentolamine} + \text{H}_2\text{O} \rightarrow \text{Phentolamine} + \text{H}_2\text{O} \\
\text{Phentolamine} + \text{H}_2\text{O} \rightarrow \text{Phentolamine} + \text{H}_2\text{O}
\]

†Professor Rudolf Schmitt (1830–1898), University of Dresden, Germany.
In Summary The benzene ring in phenols is subject to electrophilic aromatic substitution, particularly under basic conditions. Phenoxide ions can be hydroxymethylated and carbonated.

22-7 An Electrocyclic Reaction of the Benzene Ring: The Claisen Rearrangement

At 200°C, 2-propenyloxybenzene (allyl phenyl ether) undergoes an unusual reaction that leads to the rupture of the allylic ether bond: The starting material rearranges to 2-(2-propenyl)phenol (o-allylphenol).

This transformation, called the Claisen* rearrangement, is another concerted reaction with a transition state that accommodates the movement of six electrons (Sections 14-8 and 15-3). The initial intermediate is a high-energy isomer, 6-(2-propenyl)-2,4-cyclohexadienone, which enolizes to the final product (Sections 18-2 and 22-3).

Mechanism of the Claisen Rearrangement

The Claisen rearrangement is general for other systems. With the nonaromatic 1-ethenyloxy-2-propene (allyl vinyl ether), it stops at the carbonyl stage because there is no driving force for enolization. This is called the aliphatic Claisen rearrangement.

*Professor Ludwig Claisen (1851–1930), University of Berlin, Germany.

\]

PROFESSIONAL INFORMATION

*Professor Arthur C. Cope (1909–1966), Massachusetts Institute of Technology, Cambridge.
**Strategy**

As always, we take an inventory of the components of the reaction: starting materials, other reagents and reaction conditions, and products. Here, this is straightforward: There are no reagents, we simply apply heat, and it appears that the reaction is an isomerization. You need to confirm this suspicion, by determining the molecular formulas of A and B. Indeed, it is C\textsubscript{10}H\textsubscript{16}O for both. What thermal reactions could you envisage for A?

**Solution**

• You note that A contains a diene unit connected to an isolated double bond. Hence, in principle, an intramolecular Diels-Alder reaction to C might be feasible (Section 14-8; Exercise 14-24):

  ![Potential Diels-Alder Reaction of A](image)

• It is apparent that this pathway is unfavorable for two reasons: (1) Both the diene and the dienophile are electron rich and therefore not good partners for cycloaddition (Section 14-8), and, even more obvious, (2) a strained ring is formed in C.

• An alternative is based on the recognition of a 1,5-hexadiene unit, the prerequisite for a Cope rearrangement. In A, this diene unit contains an oxygen, hence we can write a Claisen rearrangement to see where it leads us.

  ![Claisen Rearrangement of A](image)

• The product D contains a 1,5-diene substructure, capable of a Cope rearrangement, leading to citral B.

  ![Cope Rearrangement of D](image)

**Exercise 22-26**

**Try It Yourself**

The ether A provides B upon heating to 200°C. Formulate a mechanism. (Caution: The terminal alkenyl carbon cannot reach the para position of the benzene ring. Hint: Start with the first step of a Claisen rearrangement.)
In Summary 2-Propenyloxybenzene rearranges to 2-(2-propenyl)phenol (o-allylphenol) by an electrocyclic mechanism that moves six electrons (Claisen rearrangement). Similar concerted reactions are undergone by aliphatic unsaturated ethers (aliphatic Claisen rearrangement) and by hydrocarbons containing 1,5-diene units (Cope rearrangement).

22-8 Oxidation of Phenols: Benzoquinones

Phenols can be oxidized to carbonyl derivatives by one-electron transfer mechanisms, resulting in a new class of cyclic diketones, called benzoquinones.

Benzoquinones and benzenediols are redox couples

The phenols 1,2- and 1,4-benzenediol (for which the respective common names catechol and hydroquinone are retained by IUPAC) are oxidized to the corresponding diketones, ortho- and para-benzoquinone, by a variety of oxidizing agents, such as sodium dichromate or silver oxide. Yields can be variable when the resulting diones are reactive, as in the case of o-benzoquinone, which partly decomposes under the conditions of its formation.

The redox process that interconverts hydroquinone and p-benzoquinone can be visualized as a sequence of proton and electron transfers. Initial deprotonation gives a phenoxide ion, which is transformed into a phenoxy radical by one-electron oxidation. Proton
dissociation from the remaining OH group furnishes a \textit{semiquinone radical anion}, and a second one-electron oxidation step leads to the benzoquinone. All of the intermediate species in this sequence benefit from considerable resonance stabilization (two forms are shown for the semiquinone). We shall see in Section 22-9 that redox processes similar to those shown here occur widely in nature.

\begin{center}
\textbf{Redox Relation Between} \textit{p}-\textit{Benzoquinone and Hydroquinone}
\end{center}

\begin{center}
\begin{align*}
\text{Phenoxide} & \quad \overset{-H^+}{\leftrightarrow} \quad \overset{-e^-}{\leftrightarrow} \quad \overset{+H^+}{\leftrightarrow} \\
\text{Phenoxy} & \quad \overset{-H^+}{\leftrightarrow} \\
\text{radical} & \quad \overset{-e^-}{\leftrightarrow} \\

\text{anion} & \quad \overset{-e^-}{\leftrightarrow} \\
\end{align*}
\end{center}

\begin{center}
\textbf{Exercise 22-27}
\end{center}

Give a minimum of two additional resonance forms each for the phenoxide ion, phenoxy radical, and semiquinone radical anion shown in the preceding scheme.

\begin{center}
\textbf{The enone units in} \textit{p}-\textit{benzoquinones undergo conjugate and Diels-Alder additions}
\end{center}

\textit{p}-\textit{Benzoquinones function as reactive }\alpha,\beta\text{-unsaturated ketones in conjugate additions (see Section 18-9). For example, hydrogen chloride adds to give an intermediate hydroxy dienone that enolizes to the aromatic 2-chloro-1,4-benzenediol.}

\begin{center}
\begin{align*}
\text{\textit{p}-Benzoquinone} & \quad + \quad \text{HCl} & \quad \rightarrow & \quad \text{6-Chloro-4-hydroxy-2,4-cyclohexadienone} & \quad \rightarrow & \quad \text{2-Chloro-1,4-benzenediol}
\end{align*}
\end{center}

The double bonds also undergo cycloadditions to dienes (Section 14-8). The initial cycloadduct to 1,3-butadiene tautomerizes with acid to the aromatic system.

\begin{center}
\textbf{Diels–Alder Reactions of} \textit{p}-\textit{Benzoquinone}
\end{center}

\begin{center}
\begin{align*}
\text{\textit{p}-Benzoquinone} & \quad + \quad \text{1,3-Butadiene} & \quad \rightarrow \quad \text{1,4-Benzodienone} & \quad \rightarrow & \quad \text{2-Chloro-1,4-benzenediol}
\end{align*}
\end{center}
In Summary
Phenols are oxidized to the corresponding benzoquinones. The diones enter into reversible redox reactions that yield the corresponding diols. They also undergo conjugate additions and Diels-Alder additions to the double bonds.

22-9 Oxidation-Reduction Processes in Nature

This section describes some chemical processes involving hydroquinones and $p$-benzoquinones that occur in nature. We begin with an introduction to the biochemical reduction of $O_2$. Oxygen can engage in reactions that cause damage to biomolecules. Naturally occurring antioxidants inhibit these transformations, as do several synthetic preservatives.

Ubiquinones mediate the biological reduction of oxygen to water

Nature makes use of the benzoquinone–hydroquinone redox couple in reversible oxidation reactions. These processes are part of the complicated cascade by which oxygen is used in biochemical degradations. An important series of compounds used for this purpose are the ubiquinones (a name coined to indicate their ubiquitous presence in nature), also collectively called coenzyme Q (CoQ, or simply Q). The ubiquinones are substituted $p$-benzoquinone derivatives bearing a side chain made up of 2-methylbutadiene units (isoprene; Sections 4-7 and 14-10). An enzyme system that utilizes NADH (Chemical Highlights 8-1 and 25-2) converts CoQ into its reduced form ($QH_2$).
Ubiquinones \((n = 6, 8, 10)\) (Coenzyme Q)

\[
\text{Ubiquinones (} n = 6, 8, 10 \text{) (Coenzyme Q)}
\]

\[
\text{Reduced form of coenzyme Q (Reduced Q, or QH}_2\text{)}
\]

QH\(_2\) participates in a chain of redox reactions with electron-transporting iron-containing proteins called **cytochromes** (Chemical Highlight 8-1). The reduction of Fe\(^{3+}\) to Fe\(^{2+}\) in cytochrome \(b\) by QH\(_2\) begins a sequence of electron transfers involving six different proteins. The chain ends with reduction of O\(_2\) to water by addition of four electrons and four protons.

\[
\text{O}_2 + 4 \text{H}^+ + 4 \text{e}^- \rightarrow 2 \text{H}_2\text{O}
\]

**Phenol derivatives protect cell membranes from oxidative damage**

The biochemical conversion of oxygen into water includes several intermediates, including **superoxide**, \(\text{O}_2^-\), the product of one-electron reduction, and **hydroxy radical**, \(\cdot\text{OH}\), which arises from cleavage of \(\text{H}_2\text{O}_2\). Both are highly reactive species capable of initiating reactions that damage organic molecules of biological importance. An example is the phosphoglyceride shown here, a cell-membrane component derived from the unsaturated fatty acid \(\text{cis},\text{cis}-\text{octadeca-9,12-dienoic acid (linoleic acid).}\)

**Initiation step**

The doubly allylic hydrogens at C11 are readily abstracted by radicals such as \(\cdot\text{OH}\) (Section 14-2).

The resonance-stabilized pentadienyl radical combines rapidly with O\(_2\) in the first of two propagation steps. Reaction occurs at either C9 or C13 (shown here), giving either of two peroxy radicals containing conjugated diene units.

**Propagation step 1**
In the second propagation step this species removes a hydrogen atom from C11 of another molecule of phosphoglyceride, or more generally, lipid (Section 20-5), thereby forming a new dienyl radical and a molecule of lipid hydroperoxide. The dienyl radical may then reenter propagation step 1. In this way, a large number of lipid molecules may be oxidized following just a single initiation event.

Propagation step 2

Numerous studies have confirmed that lipid hydroperoxides are toxic, their products of decomposition even more so. For example, loss of \( \cdot \text{OH} \) by cleavage of the relatively weak O–O bond gives rise to an alkoxy radical, which may decompose by breaking a neighboring C–C bond (\( \beta \)-scission), forming an unsaturated aldehyde.

\( \beta \)-Scission of a Lipid Alkoxy Radical

Through related but more complex mechanisms, certain lipid hydroperoxides decompose to give unsaturated hydroxyaldehydes, such as \( \text{trans} \)-4-hydroxy-2-nonenal, as well as the dialdehyde propanedial (malondialdehyde). Molecules of these general types are partly responsible for the smell of rancid fats.

Both propanedial and the \( \alpha,\beta \)-unsaturated aldehydes are extremely toxic, because they are highly reactive toward the proteins that are present in close proximity to the lipids in cell membranes. For example, both dials and enals are capable of reacting with nucleophilic amino and mercapto groups from two different parts of one protein or from two different protein molecules, and these reactions produce cross-linking (Section 14-10). Cross-linking severely inhibits protein molecules from carrying out their biological functions (Chapter 26).

Cross-linking of Proteins by Reaction with Unsaturated Aldehydes

Processes such as these are thought by many to contribute to the development of emphysema, atherosclerosis (the underlying cause of several forms of heart disease and stroke), certain chronic inflammatory and autoimmune diseases, cancer, and, possibly, the process of aging itself.

Does nature provide the means for biological systems to protect themselves from such damage? A variety of naturally occurring antioxidant systems defend lipid molecules inside cell membranes from oxidative destruction. The most important is vitamin E, a collection
of eight compounds with very similar structures, commonly represented by one of them, \(\alpha\)-tocopherol (margin). They all possess a long hydrocarbon chain (see Problem 46 of Chapter 2), a feature that makes them lipid soluble. Their reducing qualities stem from the presence of the hydroquinone-like aromatic ring (Section 22-8). The corresponding phenoxide ion is an excellent electron donor. The protective qualities of vitamin E rest on its ability to break the propagation chain of lipid oxidation by the reduction of radical species.

**Reactions of Vitamin E with Lipid Hydroperoxy and Alkoxy Radicals**

In this process, lipid radicals are reduced and protonated. Vitamin E is oxidized to an \(\alpha\)-tocopheroxy radical, which is relatively unreactive because of extensive delocalization and the steric hindrance of the methyl substituents. Vitamin E is regenerated at the membrane surface by reaction with water-soluble reducing agents such as vitamin C.

**Regeneration of Vitamin E by Vitamin C**

The product of vitamin C oxidation eventually decomposes to lower-molecular-weight watersoluble compounds, which are excreted by the body.

**Exercise 22-29**

Vitamin C is an effective antioxidant because its oxidation product semidehydroascorbic acid is stabilized by resonance. Give other resonance forms for this species.
Benzoquinones consume glutathione, an intracellular reducing agent

Virtually all living cells contain the substance glutathione, a peptide that incorporates a mercapto functional group (see Sections 9-10 and 26-4). The mercapto function serves to reduce disulfide linkages in proteins to SH groups and to maintain the iron in hemoglobin in the 2+ oxidation state (Section 26-8). Glutathione also participates in the reduction of oxidants, such as hydrogen peroxide, H₂O₂, that may be present in the interior of the cell.

The molecule is converted into a disulfide (Section 9-10) in this process but is regenerated by an enzyme-mediated reduction.

\[
\text{2 Glutathione—SH} + \text{H}_2\text{O}_2 \xrightarrow{\text{Glutathione peroxidase}} \text{2 H}_2\text{O} + \text{glutathione—S—S—glutathione}
\]

Benzoquinones and related compounds react irreversibly with glutathione in the liver by conjugate addition. Cell death results if glutathione depletion is extensive. Acetaminophen is an example of a substance that exhibits such liver toxicity at very high doses. Cytochrome P-450, a redox enzyme system in the liver, oxidizes acetaminophen to an imine derivative of a benzoquinone, which in turn consumes glutathione. Vitamin C is capable of reversing the oxidation.

Synthetic analogs of vitamin E are preservatives

Synthetic phenol derivatives are widely used as antioxidants and preservatives in the food industry. Perhaps two of the most familiar are 2-(1,1-dimethylethyl)-4-methoxyphenol (butylated hydroxyanisole, or BHA) and 2,6-bis(1,1-dimethylethyl)-4-methylphenol (butylated hydroxytoluene, or BHT; see Exercise 16-14). For example, addition of BHA to butter increases its storage life from months to years. Both BHA and BHT function like vitamin E, reducing oxygen radicals and interrupting the propagation of oxidation processes.

In Summary Oxygen-derived radicals are capable of initiating radical chain reactions in lipids, thereby leading to toxic decomposition products. Vitamin E is a naturally occurring phenol derivative that functions as an antioxidant to inhibit these processes within membrane lipids. Vitamin C and glutathione are biological reducing agents located in the intracellular and extracellular aqueous environments. High concentrations of benzoquinones can bring
about cell death by consumption of glutathione; vitamin C can protect the cell by reduction of the benzoquinone. Synthetic food preservatives are structurally designed to mimic the antioxidant behavior of vitamin E.

### 22-10 Arenediazonium Salts

As mentioned in Section 22-4, \( N \)-nitrosation of primary benzenamines (anilines) furnishes arenediazonium salts, which can be used in the synthesis of phenols. Arenediazonium salts are stabilized by resonance of the \( \pi \) electrons in the diazo function with those of the aromatic ring. They are converted into haloarenes, arenecarbonitriles, and other aromatic derivatives through replacement of nitrogen by the appropriate nucleophile.

**Arenediazonium salts are stabilized by resonance**

The reason for the stability of arenediazonium salts, relative to their alkane counterparts, is resonance and the high energy of the aryl cations formed by loss of nitrogen. One of the electron pairs making up the aromatic \( \pi \) system can be delocalized into the functional group, which results in charge-separated resonance structures containing a double bond between the benzene ring and the attached nitrogen.

At elevated temperatures (>50°C), nitrogen extrusion does take place, however, to form the very reactive phenyl cation. When this is done in aqueous solution, phenols are produced (Section 22-4).

Why is the phenyl cation so reactive? After all, it is a carbocation that is part of a benzene ring. Should it not be resonance stabilized, like the phenylmethyl (benzyl) cation? The answer is no, as may be seen in the molecular-orbital picture of the phenyl cation (Figure 22-5). The empty orbital associated with the positive charge is one of the \( sp^2 \) hybrids aligned in perpendicular fashion to the \( \pi \) framework that normally produces aromatic resonance stabilization. Hence, this orbital cannot overlap with the \( \pi \) bonds, and the positive charge is not stabilized by resonance.

**Figure 22-5** (A) Line structure of the phenyl cation. (B) Orbital picture of the phenyl cation. The alignment of its empty \( sp^2 \) orbital is perpendicular to the six-\( \pi \)-electron framework of the aromatic ring. As a result, the positive charge is not stabilized by resonance. (C) The electrostatic potential map of the phenyl cation, shown at an attenuated scale for better contrast, pinpoints much of the positive charge (blue edge on the right) as located in the plane of the six-membered ring.
charge cannot be delocalized. Moreover, the cationic carbon would prefer \( sp \) hybridization, an arrangement precluded by the rigid frame of the benzene ring. We used a similar argument to explain the difficulty in deprotonating benzene to the corresponding phenyl anion (Section 22-4).

**Arenediazonium salts can be converted into other substituted benzenes**

When arenediazonium salts are decomposed in the presence of nucleophiles other than water, the corresponding substituted benzenes are formed. For example, diazotization of arenamines (anilines) in the presence of hydrogen iodide results in the corresponding iodoarenes.

Attempts to obtain other haloarenes in this way are frequently complicated by side reactions. One solution to this problem is the **Sandmeyer** reaction, which makes use of the fact that the exchange of the nitrogen substituent for halogen is considerably facilitated by the presence of cuprous [Cu(I)] salts. The detailed mechanism of this process is complex, and radicals are participants. Addition of cuprous cyanide, CuCN, to the diazonium salt in the presence of excess potassium cyanide gives aromatic nitriles.

**Sandmeyer Reactions**

1. \( \text{HCl}, \text{NaNO}_2, 0^\circ \text{C} \) to \( \text{CH}_3\text{N}_2^+\text{Cl}^- \\
2. \( \text{CuCl}, 60^\circ \text{C} \) to \( \text{CH}_3\text{Cl} \\
3. \( \text{Br} \) to \( \text{CH}_3\text{Br} \)

\*Dr. Traugott Sandmeyer (1854–1922), Geigy Company, Basel, Switzerland.
The diazonium group can be removed by reducing agents. The sequence diazotization–reduction is a way to replace the amino group in arenamines (anilines) with hydrogen. The reducing agent employed is aqueous hypophosphorous acid, $\text{H}_3\text{PO}_2$. This method is especially useful in syntheses in which an amino group is used as a removable directing substituent in electrophilic aromatic substitution (Section 16-5).

$$

1-Bromo-3-methylbenzene

(3-Methoxy-1-Bromobenzene)

85%

Another application of diazotization in synthetic strategy is illustrated in the synthesis of 1,3-dibromobenzene ($m$-dibromobenzene). Direct electrophilic bromination of benzene is not feasible for this purpose; after the first bromine has been introduced, the second will attack ortho or para. What is required is a meta-directing substituent that can be transformed eventually into bromine. The nitro group is such a substituent. Double nitration of benzene furnishes 1,3-dinitrobenzene ($m$-dinitrobenzene). Reduction (Section 16-5) leads to the benzenediamine, which is then converted into the dihalo derivative.

### Synthesis of 1,3-Dibromobenzene by Using a Diazotization Strategy

$$
\text{HNO}_3, \text{H}_2\text{SO}_4, \Delta
\xrightarrow{\text{Br}}
\text{H}_2, \text{Pd}
\xrightarrow{1. \text{NaNO}_2, \text{H}^+, \text{H}_2\text{O}, 2. \text{CuBr}, 100^\circ\text{C}}
$$

### Exercise 22-31

Propose a synthesis of 1,3,5-tribromobenzene from benzene.

### In Summary

Arenediazonium salts, which are more stable than alkanediazonium salts because of resonance, are starting materials not only for phenols, but also for haloarenes,
arenecarbonitriles, and reduced aromatics by displacement of nitrogen gas. The intermediates in some of these reactions may be aryl cations, highly reactive because of the absence of any electronically stabilizing features, but other, more complicated mechanisms may be followed. The ability to transform arenediazonium salts in this way gives considerable scope to the regioselective construction of substituted benzenes.

**22-11 Electrophilic Substitution with Arenediazonium Salts:**

**Diazocoupling**

Being positively charged, arenediazonium ions are electrophilic. Although they are not very reactive in this capacity, they can accomplish electrophilic aromatic substitution when the substrate is an activated arene, such as phenol or benzenamine (aniline). This reaction, called **diazocoupling**, leads to highly colored compounds called **azo dyes**. For example, reaction of \(N,N\)-dimethylbenzenamine (\(N,N\)-dimethylaniline) with benzenediazonium chloride gives the brilliant orange dye Butter Yellow. This compound was once used as a food coloring agent but has been declared a suspect carcinogen by the Food and Drug Administration.

\[
\begin{align*}
\text{Diazo Coupling} & \\
\text{N(CH}_3\text{)}_2\text{Cl} & \xrightarrow{\text{H}^+, \text{H}_2\text{O}, \text{pH} = 3-5} \text{N(CH}_3\text{)}_2\text{H}^+ \text{NCl}^- \\
& \text{HCl}
\end{align*}
\]

Dyes used in the clothing industry usually contain sulfonic acid groups that impart water solubility and allow the dye molecule to attach itself ionically to charged sites on the polymer framework of the textile.

**Industrial Dyes**

- **Methyl Orange**
  - pH = 3.1, red
  - pH = 4.4, yellow

- **Congo Red**
  - pH = 3.0, blue-violet
  - pH = 5.0, red

Dyes are important additives in the textile industry. Azo dyes, while still in widespread use, are becoming less attractive for this purpose because some have been found to degrade to carcinogenic benzenamines.
William Perkin and the Origins of Industrial and Medicinal Chemistry

In 1851, William Perkin* was a 13-year-old pupil at City of London School. His teacher, Thomas Hall, recognized Perkin’s interest and aptitude in science but also realized his own limitations. Hall therefore encouraged Perkin to attend lectures at the Royal Institution, including a series presented by the legendary scientist Michael Faraday.† A few years earlier, Faraday and others had sponsored the founding of the Royal College of Chemistry in response to Justus Liebig’s‡ scathing criticism of the sorry state of chemical research in England. Liebig’s brilliant young student, August von Hofmann,§ was hired as its first director.

London in the 1850s was perhaps the filthiest, most polluted city in the world. It was lit by gas lamps, with the gas extracted from coal. The residue of the extraction was massive quantities of coal tar, most of which was simply dumped into London’s streams and rivers. However, coal tar was rich in aromatic amines, and Hofmann, who found these compounds fascinating, could obtain coal tar in London by the barrelful, just by asking.

By 1856, Perkin had begun studying in Hofmann’s laboratory. Malaria was rampant in England (indeed, in most of the world) at the time, and the only remedy was quinine, the single source of which was the bark of the South American cinchona tree. Perkin knew that the molecular formula of quinine was C20H24N2O2 and that Hofmann had isolated several 10-carbon amines, including naphthalenamine, C10H9N. Lacking any knowledge of molecular structure, Perkin decided to try to synthesize quinine by oxidative dimerization of such coal tar–derived 10-carbon aromatic amines. What could be more useful than to convert a major environmental pollutant into a desperately needed medicine? Perkin’s experiments gave black crude products, out of which could be extracted brightly colored powders. Pursuing these experiments with more amines and, eventually, amine mixtures, Perkin stumbled onto a procedure that gave a brilliant purple substance to which was given the name “mauve.”

Within a short time, dyes based on Perkin’s mauve had transformed the world of fashion—not exactly what he had in mind originally, but the discovery did make him very rich. Previously, the only source of purple dye (so-called Royal Purple, because only royalty could afford it) was from the shell lining of a species of mollusk found in only two locations on the Mediterranean coast. Thus was born the synthetic dye industry, the first of the large-scale industries based on chemical science.

Remarkably, the correct basic chemical structure of Perkin’s mauve was not determined and published until 1994, by Professor Otto Meth-Cohn and undergraduate Mandy Smith, at the University of Sunderland, England. The reaction that forms the major constituent of the dye is shown below.

---

†This the same Faraday as the discoverer of benzene (Chapter 15 Opening).
‡Baron Justus von Liebig (1803–1873), University of Munich, Germany.
§This is the same Hofmann as that of the Hofmann rule (Section 11-6) and the Hofmann rearrangement (Section 20-7).

### Exercise 22-32

Write the products of diazo coupling of benzenediazonium chloride with each of the following molecules. (a) Methoxybenzene; (b) 1-chloro-3-methoxybenzene; (c) 1-(dimethylamino)-4-(1,1-dimethylethyl)benzene. (Hint: Diazocouplings are quite sensitive to steric effects.)

### In Summary

Arenediazonium cations attack activated benzene rings by diazo coupling, a process that furnishes azobenzenes, which are often highly colored.
The process involves oxidation of some of the amine starting material to nitrosobenzenes, such as C₆H₅NO, followed by acid-catalyzed electrophilic aromatic substitution reactions between the nitroso compounds and other molecules of amine.

Perkin’s discovery did not help cure malaria, but it nevertheless had an enormous impact on medical science. In the 1860s, Robert Koch†, one of the founders of the field of bacteriology, began to follow up on reports that anthrax was caused by microscopic rod-shaped bodies found in the blood of infected sheep. He developed practical techniques for culturing and growing colonies of bacteria, a concept introduced by Pasteur a generation earlier but never demonstrated. Koch went on to discover the microorganisms that caused tuberculosis, conjunctivitis, amebic dysentery, and cholera, publishing superb micrographs to support his findings. By the last decades of the nineteenth century, Paul Ehrlich** became aware of reports that Perkin’s dyes could be used to stain cells, and he applied these ideas to help better visualize Koch’s tuberculosis bacilli. He realized that the staining phenomena were in fact chemical reactions and that the dyes stained different microbiological entities differently. Ehrlich found that some dyes could be used as therapeutic agents to combat the effects of bacterial toxins, thus pioneering the field of chemotherapy and making great strides in the development of immunology. In 1910, Ehrlich developed the first effective drug to combat syphilis, a disease that had become a worldwide scourge. His work helped give birth to the fields of biochemistry, cell biology, and medicinal chemistry. Thus, Perkin’s discoveries of a half-century earlier had changed more than the world of fashion: They changed the world.

†Professor H. H. Robert Koch (1843–1910), University of Göttingen, Germany, Nobel Prize 1905 (physiology or medicine).

**Professor Paul Ehrlich, (1854–1915), Royal Institute for Experimental Therapy, Frankfurt, Germany, Nobel Prize 1908 (physiology or medicine).

THE BIG PICTURE
This chapter completes our understanding of the interplay between the benzene ring and its alkyl, hydroxy, and amino or modified amino substituents. Just as much as the electronic character of such substituents may activate or deactivate the ring with respect to substitution (Chapter 16; Sections 22-4 and 22-6) and the way in which substituents are positioned controls the location of attack by electrophiles and nucleophiles, the ring imparts special reactivity on attached nuclei because of its resonating capacity. In other words, and to repeat the underlying theme of the text, the structure of the substituted aromatic compound...
determines its function. In many respects, this behavior is a simple extension of the chemistry of delocalized systems (Chapter 14) with the added feature of aromaticity (Chapter 15).

In the next chapter, we shall continue to examine the effect that two functional groups in the same molecule have on each other, now turning to carbonyl groups. In Chapter 24, we shall study molecules containing the carbonyl and several hydroxy groups and their biological relevance. Then, in Chapters 25 and 26, we conclude with biologically important compounds containing an array of functionality.

CHAPTER INTEGRATION PROBLEMS

22-33. 5-Amino-2,4-dihydroxybenzoic acid A is a potential intermediate in the preparation of natural products of medicinal value (Section 22-3). Propose syntheses, starting from methylbenzene (toluene).

\[
\begin{array}{c}
\text{CH}_3 \\
\text{HO} \\
\text{COOH} \\
\text{NH}_2 \\
\text{OH} \\
\end{array}
\rightarrow
\begin{array}{c}
\text{HO} \\
\text{COOH} \\
\end{array}
\]

SOLUTION

This problem builds on the expertise that you gained (Chapter 16) in controlling the substitution patterns of target benzenes, but now with a greatly expanded range of reactions. The key is, again, recognition of the directing power of substituents—ortho, para or meta (Section 16-2)—and their interconversion (Section 16-5).

Retrosynthetic analysis of compound A reveals one carbon-based substituent, the carboxy group, which can be readily envisaged to be derivable from the methyl group in the starting material (by oxidation, Section 22-2). In the starting material, the carbon-based substituent is ortho, para directing, suggesting its use (retrosynthesis 1) in the introduction of the two hydroxy functions (as in compound B, through nitration–reduction–diazoctization–hydrolysis; Sections 22-4 and 22-10). In compound A, it is meta directing and potentially utilizable (retrosynthesis 2) for the amination at C3 (as in compound C, through nitration–reduction).

The question is, Are compounds B and C effective precursors of compound A? The answer is yes. Nitration of compound B should take place at the desired position (C3 in the product), ortho and para, respectively, to the two hydroxy substituents, thus placing the nitrogen at its position in compound A. Electrophilic attack between the OH groups would be expected to be sterically hindered (Section 16-5).
Conversely, the amino group in compound C, especially when protected as an amide, should direct electrophilic substitution to the less hindered ortho carbon and the para carbon, again yielding the desired pattern. The actual proposed synthetic schemes would be then as follows.

**Synthesis 1**

![Synthesis 1 diagram](image1)

**Synthesis 2**

![Synthesis 2 diagram](image2)

22-34. A key reaction in the early development of the “pill” (Section 4-7; Chemical Highlight 4-3) was the “dienone-phenol” rearrangement shown below. Write a mechanism.

![22-34 reaction](image3)

**SOLUTION**

This is a mechanistic problem involving an acid-catalyzed rearrangement featuring a migrating alkyl (methyl) group. Sound familiar? Review Section 9-3 on carbocation rearrangements! How do we obtain a suitable carbocation from our starting material? **Answer:** Protonation of the carbonyl group, which furnishes a resonance-stabilized hydroxypentadienyl cation (Section 14-6, 14-7, and Exercise 18-22).

**Protonation of Dienone Function**

![Protonation of Dienone Function](image4)
Two of the resonance structures (write all of them) place a positive charge next to the methyl group. Only form A is "productive," inasmuch as it leads to product by aromatization, which is the major driving force for the whole process.

**Methyl Shift and Phenol Formation**

![Chemical structure](image)

**New Reactions**

**Benzylic Resonance**

1. **Radical Halogenation (Section 22-1)**

   \[
   \text{RCH}_2 + \text{HX} \rightarrow \text{RCHX} + \text{H}^+ \text{ through } \text{RCH} + \text{H}^+ \rightarrow \text{etc.}
   \]

   Requires heat, light, or a radical initiator

2. **Solvolysis (Section 22-1)**

   \[
   \text{RCHOSO}_2\text{R} + \text{R'}\text{OH} \xrightarrow{\text{S}_\text{n}^1} \text{RCHOR'} + \text{RSO}_3\text{H} \text{ through } \text{etc.}
   \]

   Benzylic cation

3. **S\text{N}_2 Reactions of (Halomethyl)benzenes (Section 22-1)**

   \[
   \text{CH}_2\text{X} + \text{Nu}^- \rightarrow \text{CH}_2\text{Nu} + \text{X}^-
   \]

   Through delocalized transition state

4. **Benzylic Deprotonation (Section 22-1)**

   \[
   \text{CH}_3 + \text{RLi} \rightarrow \text{CH}_3\text{Li} + \text{RH}
   \]

   Phenylmethylolithium (Benzylithium)

**Oxidation and Reduction Reactions on Aromatic Side Chains**

5. **Oxidation (Section 22-2)**

   \[
   \text{RCO} \rightarrow \text{RCH}_2 \xrightarrow{1. \text{KMnO}_4, \text{H}^+ , \Delta} \text{RCH} \xrightarrow{2. \text{H}^+ , \text{H}_2\text{O}} \text{COOH}
   \]
Benzylic alcohols

\[
\begin{align*}
RCHOH & \quad \xrightarrow{\text{MnO}_2, \text{acetone}} \quad RCOOH \\
\end{align*}
\]

6. Reduction by Hydrogenolysis (Section 22-2)

\[
\begin{align*}
\text{CH}_2\text{OR} & \quad \xrightarrow{\text{H}_2, \text{Pd–C, ethanol}} \quad \text{CH}_3 + \text{ROH} \\
\end{align*}
\]

\(\text{C}_6\text{H}_5\text{CH}_2\) is a protecting group for ROH.

**Phenols and Ipso Substitution**

7. Acidity (Section 22-3)

\[
\begin{align*}
\text{OH} & \quad \xrightarrow{\text{H}^+} \quad \text{H}^+ + \text{Ph}^+ \\
\text{Ph}^+ & \quad \xrightarrow{\text{etc.}} \quad \text{Phenoxide ion} \\
\end{align*}
\]

\(p\text{K}_a \approx 10\)

Much stronger acid than simple alkanols

8. Nucleophilic Aromatic Substitution (Section 22-4)

\[
\begin{align*}
\text{Cl} & \quad \text{NO}_2 & \quad \text{Nu} \quad \xrightarrow{\text{Na}^+} \quad \text{Cl} & \quad \text{NO}_2 \\
\text{Nu} & \quad \text{Cl} & \quad \text{NO}_2 & \quad \text{Cl} \\
\end{align*}
\]

Nucleophile attacks at ipso position.

9. Aromatic Substitution Through Benzyne Intermediates (Section 22-4)

\[
\begin{align*}
\text{Cl} & \quad \xrightarrow{\text{NaNH}_2, \text{NH}_3\text{H}_2\text{O}, \Delta} \quad \text{NH}_2 \\
\end{align*}
\]

Nucleophile attacks at both ipso and ortho positions.

10. Arenediazonium Salt Hydrolysis (Section 22-4)

\[
\begin{align*}
\text{NH}_2 & \quad \xrightarrow{\text{NaNO}_2, \text{H}^+, 0^\circ\text{C}} \quad \text{N}_2^+ \\
\text{N}_2^+ & \quad \xrightarrow{\text{H}_2\text{O}, \Delta} \quad \text{OH} + \text{N}_2 \\
\end{align*}
\]
11. Substitution with Pd Catalysis

\[ \text{KOH, Pd catalyst, PR, 100°C} \]

Reactions of Phenols and Alkoxybenzenes

12. Ether Cleavage (Section 22-5)

\[ \text{HBr, } \Delta \]

Aryl C–O bond is not cleaved.

13. Ether Formation (Section 22-5)

\[ \text{NaOH, H}_2\text{O} \]

Williamson method (Section 9-6)

14. Esterification (Section 22-5)

\[ \text{Base} \]

Phenyl alkanoate

15. Electrophilic Aromatic Substitution (Section 22-6)

\[ \text{NaOH} \]

16. Phenolic Resins (Section 22-6)
17. Kolbe Reaction (Section 22-6)

\[
\text{+ CO}_2 \quad \overset{\text{1. NaOH, pressure}}{\rightarrow} \quad \text{COOH}
\]

18. Claisen Rearrangement (Section 22-7)

Aromatic Claisen rearrangement

Aliphatic Claisen rearrangement

19. Cope Rearrangement (Section 22-7)

20. Oxidation (Section 22-8)

2,5-Cyclohexadiene-1,4-dione

\[
\text{Na}_2\text{Cr}_2\text{O}_7, \text{H}^+ \quad \rightarrow \quad \text{2,5-Cyclohexadiene-1,4-dione (p-Benzooquinone)}
\]

21. Conjugate Additions to 2,5-Cyclohexadiene-1,4-diones (p-Benzooquinones) (Section 22-8)

\[
\text{+ HCl} \quad \rightarrow \quad \text{Cl}
\]
22. Diels-Alder Cycloadditions to 2,5-Cyclohexadiene-1,4-diones (p-Benzquinones) (Section 22-8)

\[
\begin{align*}
\text{Diels-Alder Cycloaddition} & \quad \text{Product} \\
\text{2,5-Cyclohexadiene-1,4-dione} & \quad \text{Addition Partner} \\
\end{align*}
\]

23. Lipid Peroxidation (Section 22-9)

\[
\begin{align*}
\text{O}_2, \text{radical chain reaction} & \quad \rightarrow \quad \text{Oxygen} \\
\text{Fragmentation to alkxy radicals,} & \quad \rightarrow \quad \text{Alkxy radicals} \\
\text{followed by } \beta\text{-scission} \quad & \quad \rightarrow \quad \text{4-hydroxy-2-alkenals} \\
\end{align*}
\]

24. Inhibition by Antioxidants (Section 22-9)

\[
\begin{align*}
\text{Vitamin E} & \quad \text{or BHA or BHT} \\
\text{Vitamin E} & \quad \text{or BHA or BHT} \\
\end{align*}
\]

25. Vitamin C as an Antioxidant (Section 22-9)

\[
\begin{align*}
\text{Semidehydroascorbic} & \quad \text{acid} \\
\text{Semidehydroascorbic} & \quad \text{acid} \\
\end{align*}
\]

**Arene Diazonium Salts**

26. Sandmeyer Reactions (Section 22-10)

\[
\begin{align*}
\text{Sandmeyer Reaction} & \quad \text{Product} \\
\text{CuX} \quad & \quad \text{Heterocycle} \\
\text{X} & \quad \text{Halogen} \\
\end{align*}
\]

27. Reduction (Section 22-10)

\[
\begin{align*}
\text{Reduction} & \quad \text{Product} \\
\text{H}_2\text{PO}_4^- & \quad \text{Heterocycle} \\
\end{align*}
\]
28. Diazo Coupling (Section 22-11)

Azo compound

Occurs only with strongly activated rings

Important Concepts

1. Phenylmethyl and other benzylic radicals, cations, and anions are reactive intermediates stabilized by resonance of the resulting centers with a benzene π system.

2. Nucleophilic aromatic ipso substitution accelerates with the nucleophilicity of the attacking species and with the number of electron-withdrawing groups on the ring, particularly if they are located ortho or para to the point of attack.

3. Benzyne is destabilized by the strain of the two distorted carbons forming the triple bond.

4. Phenols are aromatic enols, undergoing reactions typical of the hydroxy group and the aromatic ring.

5. Benzoquinones and benzenediols function as redox couples in the laboratory and in nature.

6. Vitamin E and the highly substituted phenol derivatives BHA and BHT function as inhibitors of the radical-chain oxidation of lipids. Vitamin C also is an antioxidant, capable of regenerating vitamin E at the surface of cell membranes.

7. Arenediazonium ions furnish reactive aryl cations whose positive charge cannot be delocalized into the aromatic ring.

8. The amino group can be used to direct electrophilic aromatic substitution, after which it is replaceable by diazotization and substitution, including reduction.

Problems

35. Give the expected major product(s) of each of the following reactions.

(a)  
(b)  

36. Formulate a mechanism for the reaction described in Problem 35(b).

37. Propose syntheses of each of the following compounds, beginning in each case with ethylbenzene. (a) 1-Chloroethyl)benzene; (b) 2-phenylpropanoic acid; (c) 2-phenylethanol; (d) 2-phenyloxacyclopropane.

38. Predict the order of relative stability of the three benzylic cations derived from chloromethylbenzene (benzyl chloride), 1-(chloromethyl)-4-methoxybenzene (4-methoxybenzyl chloride), and 1-(chloromethyl)-4-nitrobenzene (4-nitrobenzyl chloride). Rationalize your answer with the help of resonance structures.

39. By drawing appropriate resonance structures, illustrate why halogen atom attachment at the para position of phenylmethyl (benzyl) radical is unfavored compared with attachment at the benzylic position.

40. Triphenylmethyl radical, \((\text{C}_6\text{H}_5)_3\text{C}^\cdot\), is stable at room temperature in dilute solution in an inert solvent, and salts of triphenylmethyl cation, \((\text{C}_6\text{H}_5)_3\text{C}^+\), can be isolated as stable crystalline solids. Propose explanations for the unusual stabilities of these species.
41. Give the expected products of the following reactions or reaction sequences.

(a) \( \text{BrCH}_2\text{CH}_2\text{CH}_2\longrightarrow \text{CH}_2\text{Br} \xrightarrow{\text{H}_2\text{O}, \Delta} \text{b} \)

(b) \( \text{CH}_2\text{Cl} \xrightarrow{1. \text{KCN, DMSO}, 2. \text{H}^+, \text{H}_2\text{O}, \Delta} \)

(c) \( \text{1. CH}_3\text{CH}_2\text{CH}_2\text{Li}, (\text{CH}_3)_2\text{NCH}_2\text{CH}_2\text{N(CH}_3)_2, \text{THF} \)

\( \text{2. C}_6\text{H}_5\text{CHO} \)

\( \text{3. H}^+, \text{H}_2\text{O}, \Delta \) \( \rightarrow \text{C}_{10}\text{H}_{14} \)

42. The hydrocarbon with the common name fluorene is acidic enough (\( pK_a < 23 \)) to be a useful indicator in deprotonation reactions of compounds of greater acidity. Indicate the most acidic hydrogen(s) in fluorene. Draw resonance structures to explain the relative stability of its conjugate base.

43. Outline a straightforward, practical, and efficient synthesis of each of the following compounds. Start with benzene or methylbenzene. Assume that the para isomer (but not the ortho isomer) may be separated efficiently from any mixtures of ortho and para substitution products.

44. Rank the following compounds in descending order of reactivity toward hydroxide ion.

45. Predict the main product(s) of the following reactions. In each case, describe the mechanism(s) in operation.

46. Starting with benzenamine, propose a synthesis of aklomide, an agent used to treat certain exotic fungal and protozoal infections in veterinary medicine. Several intermediates are shown to give you the general route. Fill in the blanks that remain; each requires as many as three sequential reactions. (Hint: Review the oxidation of amino- to nitroarenes in Section 16-5.)
47. Explain the mechanism of the following synthetic transformation. (**Hint**: Two equivalents of butyllithium are used.)

\[
\begin{align*}
\text{F} &\quad \text{CH}_2\text{CH}_2\text{CH}_2\text{Li} \\
\text{OCH}_3 &\quad \text{H}_2\text{C} &\quad \text{OCH}_3 \\
\text{CH}_2\text{OH} &\quad \text{CH}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

48. In nucleophilic aromatic substitution reactions that proceed by the addition–elimination mechanism, fluorine is the most easily replaced halogen in spite of the fact that \( \text{F}^- \) is by far the worst leaving group among halide ions. For example, 1-fluoro-2,4-dinitrobenzene reacts much more rapidly with amines than does the corresponding chloro compound. Suggest an explanation. (**Hint**: Consider the effect of the identity of the halogen on the rate-determining step.)

49. Based on the mechanism presented for the Pd-catalyzed reaction of a halobenzene with hydroxide ion, write out a reasonable mechanism for the Pd-catalyzed reaction of 1-bromo-3-methoxybenzene with 2-methyl-1-propanamine shown in Section 22-4.

50. Give the likely products of each of the following reactions. Each one is carried out in the presence of a Pd catalyst, a phosphine, and heat.

(a) \( \text{F}_3\text{C}-\text{Cl} \quad + \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{NH} \)

(b) \( \text{Br} \quad + \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{SH} \)

(c) \( \text{CH}_3\text{O}-\text{I} \quad + \quad \text{Na}^+ \cdot \text{CN} \)

(d) \( \text{Br} \quad + \quad \text{O} \)

51. A very efficient short synthesis of resveratrol (Chemical Highlight 22-1) was reported in 2006. Fill in reasonable reagents for steps (a) through (d). Refer to the referenced text sections as needed.

52. The reaction sequence shown below illustrates the synthesis of 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), a powerful herbicide. A 1:1 mixture of the butyl esters of 2,4,5-T and its dichlorinated analog 2,4-D was used between 1965 and 1970 as a defoliant during the Vietnam War.
under the code name Agent Orange. Propose mechanisms for the reactions in the synthesis of this substance, whose effects on the health of those exposed to it remain topics of considerable controversy.

\[
\begin{array}{ccc}
\text{Cl} & \text{Cl} & \text{Cl} \\
\text{Cl} & \text{Cl} & \text{Cl} \\
\text{Cl} & \text{Cl} & \text{Cl}
\end{array}
\xrightarrow{1. \text{NaOH, } 150^\circ \text{C}}
\begin{array}{c}
\text{Cl} \\
\text{OH}
\end{array}
\xrightarrow{2. \text{H}_2\text{O}}
\begin{array}{c}
\text{Cl} \\
\text{OCH}_2\text{COOH}
\end{array}
\]

53. Give the expected major product(s) of each of the following reactions and reaction sequences.

(a) \[
\begin{array}{c}
\text{CH}_3
\end{array}
\xrightarrow{1. \text{KMnO}_4, \text{H}_2\text{O}}
\begin{array}{c}
\text{OH}
\end{array}
\xrightarrow{2. \text{H}_2\text{O}}
\begin{array}{c}
\text{CH}_3
\end{array}
\]

(b) \[
\begin{array}{c}
\text{CH}_2\text{OH}
\end{array}
\xrightarrow{1. \text{MnO}_2, \text{acetone}}
\begin{array}{c}
\text{O}
\end{array}
\xrightarrow{2. \text{KOH, H}_2\text{O}}
\begin{array}{c}
\text{CH}_3
\end{array}
\]

(c) \[
\begin{array}{c}
\text{ClCH}_2\text{COOH}, \text{NaOH, H}_2\text{O}
\end{array}
\xrightarrow{4. \text{H}_2\text{O}}
\begin{array}{c}
\text{Cl}
\end{array}
\]

54. Rank the following compounds in order of descending acidity.

(a) CH\textsubscript{3}OH (b) CH\textsubscript{3}COOH (c) OH (d) OH (e) OH (f) OH

55. Design a synthesis of each of the following phenols, starting with either benzene or any mono-substituted benzene derivative.

(a) \[
\begin{array}{c}
\text{OH}
\end{array}
\]
(b) \[
\begin{array}{c}
\text{Br}
\end{array}
\]
(c) The three benzenediols
(d) \[
\begin{array}{c}
\text{Cl}
\end{array}
\]

56. Starting with benzene, propose syntheses of each of the following phenol derivatives.

(a) \[
\begin{array}{c}
\text{Cl}
\end{array}
\]
(b) \[
\begin{array}{c}
\text{NHCOCH}_3
\end{array}
\]
(c) \[
\begin{array}{c}
\text{OCCH}_3
\end{array}
\]

The herbicide 2,4-D
Phenacetin (The active ingredient in Midol)
Dibromoaspirin (An experimental drug for the treatment of sickle-cell anemia)
57. Name each of the following compounds.

(a) ![Structure A]
(b) ![Structure B]
(c) ![Structure C]
(d) ![Structure D]
(e) ![Structure E]

58. Give the expected product(s) of each of the following reaction sequences.

(a) ![Reaction A]
(b) ![Reaction B]
(c) ![Reaction C]
(d) ![Reaction D]
(e) ![Reaction E]

59. As a children’s medicine, acetaminophen (Tylenol) has a major marketing advantage over aspirin: Liquid Tylenol preparations (essentially, acetaminophen dissolved in flavored water) are stable, whereas comparable aspirin solutions are not. Explain.

60. Chili peppers contain significant quantities of vitamins A, C, and E, as well as folic acid and potassium. They also contain small quantities of capsaicin, the fiery essence responsible for the “hot” in hot peppers. The pure substance is in fact quite dangerous: Chemists working with capsaicin must work in special filtered-air enclosures and wear full body protection. One milligram placed on the skin will cause a severe burn. Although capsaicin has no odor or flavor of its own, its pungency—in the form of detectable stimulation of the nerves in the mucous membranes of the mouth—can be detected even when the substance is diluted to one part in 17 million of water. The hottest peppers exhibit about 1/20th of this level of pungency.

The structure of capsaicin is shown on p. 1028. Some of the data that were used in its elucidation are presented below. Interpret as much of this information as you can.

- **MS:** $m/z = 122, 137$ (base peak), 195 (tricky!), 305.
- **IR:** $\tilde{\nu} = 972, 1660, 3016, 3445, 3541$ cm$^{-1}$.
- **$^1$H NMR:** $\delta = 0.93$ (6H, d, $J = 8$ Hz), 1.35 (2H, quin, $J = 7$ Hz), 1.62 (2H, quin, $J = 7$ Hz), 1.97 (2H, q, $J = 7$ Hz), 2.18 (2H, t, $J = 7$ Hz), 2.20 (1H, m), 3.85 (3H, s), 4.33 (2H, d, $J = 6$ Hz), 5.33 (2H, m), 5.82 (2H, broad s), 6.73 (1H, d, $J = 9$ Hz), 6.78 (1H, s), 6.85 (1H, d, $J = 9$ Hz) ppm.

61. Biochemical oxidation of aromatic rings is catalyzed by a group of liver enzymes called aryl hydroxylases. Part of this chemical process is the conversion of toxic aromatic
hydrocarbons such as benzene into water-soluble phenols, which can be easily excreted. However, the primary purpose of the enzyme is to enable the synthesis of biologically useful compounds, such as the amino acid tyrosine.

![Chemistry of Benzene Substituents]

(a) Extrapolating from your knowledge of benzene chemistry, which of the following three possibilities seems most reasonable: The oxygen is introduced by electrophilic attack on the ring; the oxygen is introduced by free-radical attack on the ring; or the oxygen is introduced by nucleophilic attack on the ring? (b) It is widely suspected that oxacycloprenes play a role in arene hydroxylation. Part of the evidence is the following observation: When the site to be hydroxylated is initially labeled with deuterium, a substantial proportion of the product still contains deuterium atoms, which have apparently migrated to the position ortho to the site of hydroxylation.

Suggest a plausible mechanism for the formation of the oxacyclopropane intermediate and its conversion into the observed product. (Hint: Hydroxylase converts O₂ into hydrogen peroxide, HO–OH.) Assume the availability of catalytic amounts of acids and bases, as necessary.

Note: In victims of the genetically transmitted disorder called phenylketonuria (PKU), the hydroxylase enzyme system described here does not function properly. Instead, phenylalanine in the brain is converted into 2-phenyl-2-oxopropionic (phenylpyruvic) acid, the reverse of the process shown in Problem 57 of Chapter 21. The buildup of this compound in the brain can lead to severe retardation; thus people with PKU (which can be diagnosed at birth) must be restricted to diets low in phenylalanine.

62. A common application of the Cope rearrangement is in ring-enlargement sequences. Fill in the reagents and products missing from the following scheme, which illustrates the construction of a 10-membered ring.

![Scheme for Cope Rearrangement]
63. As mentioned in Section 22-10, the Sandmeyer reactions, in which copper(I) ion catalyzes substitution of the nitrogen in arenediazonium salts by Cl, Br, or CN, take place by complex mechanisms involving radicals. Explain why these substitutions do not follow either the S_N1 or S_N2 pathway.

64. Formulate a detailed mechanism for the diazotization of benzenamine (aniline) in the presence of HCl and NaNO_2. Then suggest a plausible mechanism for its subsequent conversion into iodobenzene by treatment with aqueous iodide ion (e.g., from K^I^). Bear in mind your answer to Problem 63.

65. Show how you would convert 3-methylbenzenamine into each of the following compounds: (a) methylbenzene; (b) 1-bromo-3-methylbenzene; (c) 3-methylphenol; (d) 3-methylbenzonitrile; (e) N-ethyl-3-methylbenzenamine.

66. Devise a synthesis of each of the following substituted benzene derivatives, starting from benzene.

![Chemical structures](image)

67. Write the most reasonable structure of the product of each of the following reaction sequences.

![Chemical structures with reaction conditions](image)

For the following reaction, assume that electrophilic substitution occurs preferentially on the most activated ring.

![Chemical structures with reaction conditions](image)
68. Show the reagents that would be necessary for the synthesis by diazo coupling of each of the following three compounds. For structures, see Section 22-11.

(a) Methyl Orange

(b) Congo Red

(c) Prontosil, $\text{H}_2\text{N}\begin{array}{c} \text{N} \\ \text{SO}_2\text{NH}_2 \end{array}$, which is converted microbially into sulfanilamide, $\text{H}_2\text{N}\begin{array}{c} \text{N} \\ \text{SO}_2\text{NH}_2 \end{array}$

(The accidental discovery of the antibacterial properties of prontosil in the 1930s led indirectly to the development of sulfa drugs as antibiotics in the 1940s.)

69. **Challenge** (a) Give the key reaction that illustrates the inhibition of fat oxidation by the preservative BHT. (b) The extent to which fat is oxidized in the body can be determined by measuring the amount of pentane exhaled in the breath. Increasing the amount of vitamin E in the diet decreases the amount of pentane exhaled. Examine the processes described in Section 22-9 and identify one that could produce pentane. You will have to do some extrapolating from the specific reactions shown in the section.

70. **Challenge** The urushiols are the irritants in poison ivy and poison oak that give you rashes and make you itch upon exposure. Use the following information to determine the structures of urushiols I ($\text{C}_{21}\text{H}_{36}\text{O}_2$) and II ($\text{C}_{21}\text{H}_{34}\text{O}_2$), the two major members of this family of unpleasant compounds.

\[
\begin{align*}
\text{Urushiol II} & \xrightarrow{\text{H}_2, \text{Pd–C}, \text{CH}_3\text{CH}_2\text{OH}} \text{urushiol I} \\
\text{Urushiol II} & \xrightarrow{\text{Excess CH}_3\text{I}, \text{NaOH}} \text{C}_{23}\text{H}_{38}\text{O}_2 \\
\text{Dimethylurushiol II} & \xrightarrow{1. \text{O}_x, \text{CH}_2\text{Cl}_2, 2. \text{Zn, H}_2\text{O}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CHO} + \text{C}_{16}\text{H}_{24}\text{O}_3 \\
& \text{Aldehyde A}
\end{align*}
\]

**Synthesis of Aldehyde A**

\[
\begin{align*}
\text{C}_3\text{H}_7\text{NSO}_6 & \xrightarrow{1. \text{SO}_3, \text{H}_2\text{SO}_4, 2. \text{HNO}_3, \text{H}_2\text{SO}_4} \text{C}_3\text{H}_2\text{NSO}_6 \\
& \xrightarrow{\text{H}^+, \text{H}_2\text{O}, \Delta} \text{C}_3\text{H}_7\text{NO}_3 \\
& \xrightarrow{1. \text{H}_2, \text{Pd, CH}_3\text{CH}_2\text{OH}, 2. \text{NaNO}_2, \text{H}_2\text{O}, 3. \text{H}_2\text{O}, \Delta} \text{aldehyde A}
\end{align*}
\]

71. Is the site of reaction in the biosynthesis of norepinephrine from dopamine (see Chapter 5, Problem 65) consistent with the principles outlined in this chapter? Would it be easier or more difficult to duplicate this transformation nonenzymatically? Explain.
Team Problem

72. As a team, consider the following schemes that outline steps toward the total synthesis of taxodone D, a potential anticancer agent. For the first scheme, divide your team into two groups, one to discuss the best option for A to effect the initial reduction step, the second to assign a structure to B, using the partial spectral data provided.

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{CHCO} & \quad \text{OCCH}_3 \\
\text{H}_2\text{C} & \quad \text{H}_2\text{C} \\
\text{H} & \quad \text{H} \\
\text{O} & \quad \text{O} \\
\end{align*}
\]

\[
A \xrightarrow{\text{H}^+, \text{toluene}, \Delta} B
\]

\[\text{H}^+ \text{NMR: } \delta = 5.99 \text{ (dd, 1 H)}, 6.50 \text{ (d, 1 H) ppm.} \]
\[\text{IR: } \tilde{\nu} = 1720 \text{ cm}^{-1}. \]
\[\text{MS: } m/z = 384 (M^+). \]

Reconvene to discuss both parts of the first scheme. Then, as a group, analyze the remainder of the synthesis shown in the second scheme below. Use the spectroscopic data to help you determine the structures of C and taxodone, D.

\[
\begin{align*}
& \quad \text{O} \\
& \quad \text{COOH} \\

Propose a mechanism for the formation of D from C. \textbf{(Hint: After ester hydrolysis, one of the phenoxide oxygens can donate its electron pair through the benzene ring to effect a reaction at the para position. The product contains a carbonyl group in its enol form. For the interpretation of some of the spectral data, see Section 17-3.)}

Preprofessional Problems

73. After chlorobenzene has been boiled in water for 2 h, which of the following organic compounds will be present in greatest concentration?

\[
\begin{align*}
& (\text{a}) \text{ C}_6\text{H}_5\text{OH} \quad (\text{b}) \text{ C}_6\text{H}_5\text{Cl} \\
& (\text{c}) \text{ C}_6\text{H}_5\text{Cl} \quad (\text{d}) \text{ C}_6\text{H}_5\text{I} \\
& (\text{e}) \text{ Cl}\text{CH}_3 \\
\end{align*}
\]

74. What are the products of the following reaction? \text{C}_6\text{H}_5\text{OCH}_3 \xrightarrow{\text{HI, D}} ?

\[
\begin{align*}
& (\text{a}) \text{ C}_6\text{H}_5\text{I} + \text{CH}_3\text{OH} \quad (\text{b}) \text{ C}_6\text{H}_5\text{OH} + \text{CH}_3\text{I} \\
& (\text{c}) \text{ C}_6\text{H}_5\text{I} + \text{CH}_3\text{I} \quad (\text{d}) \text{ C}_6\text{H}_5\text{I} + \text{H}_2
\end{align*}
\]
75. The transformation of 4-methylbenzenediazonium bromide to toluene is best carried out by using:
   (a) $\text{H}^+, \text{H}_2\text{O}$  (b) $\text{H}_3\text{PO}_2, \text{H}_2\text{O}$  (c) $\text{H}_2\text{O}, \text{OH}^-$ (d) $\text{Zn}, \text{NaOH}$

76. What is the principal product after the slurry obtained on treating benzenamine (aniline) with potassium nitrite and HCl at 0°C has been added to 4-ethylphenol?

77. Examination of the $^1\text{H}$ NMR spectra of the following three isomeric nitrophenols reveals that one of them displays a hydroxy (phenolic) proton at substantially lower field than do the other two. Which one?
In Chapter 18, during our survey of carboxyl chemistry, we learned that many techniques developed by the synthetic organic chemist are in fact based on natural processes for the construction of carbon–carbon bonds in biological systems. The aldol condensation (Sections 18-5 through 18-7) is one such process, a powerful method for converting aldehydes and ketones into $\beta$-hydroxycarbonyl compounds. In this chapter we shall examine first the related Claisen condensation, in which attack of an ester enolate on a carbonyl group generates a new carbon–carbon bond. We have already seen its use in the biosynthesis of long-chain carboxylic acids (Section 19-13). The products of Claisen condensations are 1,3-dicarbonyl compounds, more commonly known as $\beta$-dicarbonyl compounds, which are important for their versatility in synthesis.

Another natural carbon–carbon bond-forming process that has been adapted for use by synthetic chemists involves thiamine, or vitamin B$_1$, shown on page 1100. Thiamine plays an essential role in several biochemical processes, including the biosynthesis of sugars, as we shall see in Chapter 24. Chemical Highlight 23-2 describes how thiamine also mediates sugar metabolism by converting pyruvic acid, a product of sugar metabolism, into acetyl CoA (Section 19-13). The relevant carbon–carbon bond-forming process makes use of a new kind of nucleophile derived from aldehydes and ketones, an acyl anion equivalent.
These species illustrate how a normally electrophilic carbonyl carbon atom can be temporarily made nucleophilic and used to form a new carbon–carbon bond with the carbonyl carbon of another aldehyde or ketone molecule, giving \( \alpha \)-hydroxyketones as the ultimate products.

**23-1 \( \beta \)-Dicarbonyl Compounds: Claisen Condensations**

Ester enolates undergo addition–elimination reactions with ester functions, furnishing \( \beta \)-ketoesters. These transformations, known as Claisen* condensations, are the ester analogs of the aldol reaction (Section 18-5).

**Claisen condensations form \( \beta \)-dicarbonyl compounds**

Ethyl acetate reacts with a stoichiometric amount of sodium ethoxide to give ethyl 3-oxobutanoate (ethyl acetoacetate).

![Claisen Condensation of Ethyl Acetate](image)

Unlike imine formation (Section 17-9) or the aldol condensation (Section 18-5), in which two molecules are joined with elimination of water, the Claisen condensation proceeds by elimination of a molecule of alcohol.

The Claisen condensation begins with formation of the ester enolate ion (step 1). Addition–elimination of this species to the carbonyl group of another ester molecule furnishes a 3-ketoester (steps 2 and 3). These steps are reversible; the overall process is endothermic through this stage. Indeed, the initial deprotonation of the ester (\( \text{pK}_a = 25 \)) by ethoxide is particularly unfavorable (\( \text{pK}_a \) of ethanol = 15.9).

**Mechanism of the Claisen Condensation**

**Step 1. Ester enolate formation**

**Step 2. Nucleophilic addition**

*This is the Claisen of the Claisen rearrangement (Section 22-7).*
Step 3. Elimination

\[
\begin{align*}
\text{CH}_3\text{C} & \text{O} \text{CH}_2\text{CH}_3 \\
\text{CH}_2\text{COCH}_2\text{CH}_3 & \quad \xrightarrow{\text{H}^+} \\
\text{O} & \quad \text{CH}_3\text{C} \text{O} \text{CH}_2\text{CH}_3 \\
\text{O} & \quad \text{CH}_3\text{C} \text{O} \text{CH}_2\text{CH}_3
\end{align*}
\]

3-Ketoester

The product of step 3, a 3-ketoester (or β-ketoester), possesses hydrogens on its central carbon atom that are unusually acidic (pK\text{a} < 11) due to the presence of carbonyl groups on both sides. As a result, this ketoester immediately loses a proton to ethoxide, converting the base into ethanol (step 4). This is the reason that a stoichiometric rather than a catalytic amount of ethoxide is necessary for a Claisen condensation to succeed: Each molecule of 3-ketoester formed protonates a molecule of ethoxide, thereby removing the base needed to catalyze steps 1 to 3. The use of a stoichiometric amount of ethoxide assures that the base will not be completely depleted until all of the starting ester has been converted to product. Furthermore, the highly favorable deprotonation in step 4 also serves to drive the unfavorable equilibria of steps 1 to 3 in the forward direction. Work-up with aqueous acid (step 5) restores the proton to the central carbon atom of the ketoester, furnishing the final product and completing the process.

Step 4. Deprotonation of ketoester drives equilibrium

\[
\begin{align*}
\text{CH}_3\text{C} & \text{COCH}_2\text{CH}_3 \\
\quad & \quad \xrightarrow{\text{H}^+} \\
\text{O} & \quad \text{CH}_3\text{C} \text{COCH}_2\text{CH}_3 \\
\text{O} & \quad \text{CH}_3\text{C} \text{COCH}_2\text{CH}_3
\end{align*}
\]

Acidic, pK\text{a} ≈ 11

Step 5. Protonation upon aqueous work-up

\[
\begin{align*}
\text{CH}_3\text{C} & \text{HCOCH}_2\text{CH}_3 \\
\quad & \quad \xrightarrow{\text{H}^+ + \text{H}_2\text{O}} \\
\text{O} & \quad \text{CH}_3\text{C} \text{HCOCH}_2\text{CH}_3 \\
\text{O} & \quad \text{CH}_3\text{C} \text{HCOCH}_2\text{CH}_3
\end{align*}
\]

To prevent transesterification, both the alkoxide and the ester are usually derived from the same alcohol.

Exercise 23-1

Give the products of Claisen condensation of (a) ethyl propanoate; (b) ethyl 3-methylbutanoate; (c) ethyl pentanoate. For each, the base is sodium ethoxide, the solvent ethanol.

Protons flanked by two carbonyl groups are acidic

How does the structure of the 3-ketoester make its deprotonation so favorable? The acidity of the hydrogens flanked by the two carbonyl groups is much enhanced by resonance stabilization of the corresponding anion. Table 23-1 lists the pK\text{a} values of several β-dicarbonyl compounds and related systems, such as methyl cyanoacetate and propanedinitrile (malonodinitrile).

The importance of the final deprotonation step in the Claisen condensation is made clear when condensation is attempted with an ester bearing only one α-hydrogen. The product of a
reaction with such an ester would be a 2,2-disubstituted 3-ketoester lacking the acidic protons necessary to drive the equilibrium. Hence, no Claisen condensation product is observed.

That this result is due to an unfavorable equilibrium can be demonstrated by treating a 2,2-disubstituted 3-ketoester with base: Complete reversal of the Claisen condensation process (called retro-Claisen condensation) ensues, giving two molecules of simple ester through a mechanism that is the exact reverse of the forward reaction.

**Exercise 23-2**

Explain the following observation.

Claisen condensations can have two different esters as reactants

Mixed Claisen condensations start with two different esters. Like crossed aldol condensations (Section 18-6), they are typically unselective and furnish product mixtures. However,
Intramolecular Claisen condensations result in cyclic compounds. The intramolecular version of the Claisen reaction, called the Dieckmann* condensation, produces cyclic 3-ketoesters. As expected (Section 9-6), it works best for the formation of five- and six-membered rings.

A Selective Mixed Claisen Condensation

Exercise 23-3

Give all the Claisen condensation products that would result from treatment of a mixture of ethyl acetate and ethyl propanoate with sodium ethoxide in ethanol.

Exercise 23-4

Is the mixed Claisen condensation between ethyl formate and ethyl acetate likely to afford one major product? Explain and give the structure(s) of the product(s) you expect.

Intramolecular Claisen condensations result in cyclic compounds

The intramolecular version of the Claisen reaction, called the Dieckmann* condensation, produces cyclic 3-ketoesters. As expected (Section 9-6), it works best for the formation of five- and six-membered rings.

Exercise 23-5

Working with the Concepts: Predicting a Successful Claisen Condensation

Two cyclic products are possible from the Dieckmann (intramolecular Claisen) condensation shown below, but only one of them actually forms. Describe and explain briefly the outcome of this reaction.

---

*Professor Walter Dieckmann (1869–1925), University of Munich, Germany.
Strategy
To draw the possible products, use the mechanistic pattern described throughout this section.

Solution
• Form a new carbon–carbon bond between the carbon atom $\alpha$ to one of the ester carbonyl groups and the carbonyl carbon atom of the other. The products of the two possible options are shown below:

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OCCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CHCOCH}_2\text{CH}_3 & \xrightarrow{1. \text{CH}_3\text{CH}_2\text{O}^+\text{Na}^+, \text{CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{CO}_2\text{CH}_2\text{CH}_3 \\
\text{CH}_3\text{CH}_2\text{OCCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CHCOCH}_2\text{CH}_3 & \xrightarrow{1. \text{CH}_3\text{CH}_2\text{O}^+\text{Na}^+, \text{CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{CH}_2\text{OCCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CHCOCH}_2\text{CH}_3 \\
\end{align*}
\]

• Notice that the product of the first condensation lacks an acidic $\alpha$-hydrogen between its two carbonyl groups. This molecule is not isolated under Claisen condensation conditions, because the equilibrium associated with its formation cannot be driven to completion by deprotonation (step 4 of the mechanism presented earlier in this section; see also “Failure of a Claisen Condensation”). Only the product of the second condensation process is obtained.

Chemical Highlight 23-1
Claisen Condensations in Biochemistry

The coupling processes that build fatty acid chains from thioesters of coenzyme A (Section 19-13) are forms of Claisen condensations. The carboxylation of acetyl CoA into malonyl CoA (shown above) is a variant in which the carbon of CO$_2$ rather than that of an ester carbonyl group is the site of nucleophilic attack.

The methylene group in the carboxylated species is much more reactive than the methyl group in acetyl thioesters and participates in a wide variety of Claisenlike condensations. Although these processes require enzyme catalysis, they may be written in simplified form, shown below.

The product of the reaction above, the acetoacetyl derivative of the acyl carrier protein, is the starting point for the biosynthesis of other compounds besides fatty acids. Steroids derive from a sequence of enzyme-catalyzed Claisen-like condensations that produce the branched five-carbon skeleton of 2-methyl-1,3-butadiene (isoprene), the building block of the terpenes (Section 4-7). In this variation, the enolate of acetyl CoA adds to the ketocarbonyl of acetoacetyl CoA,
Ketones undergo mixed Claisen reactions

Ketones can participate in the Claisen condensation. Because they are more acidic than esters, they are deprotonated before the ester has a chance to undergo self-condensation. The products (after acidic work-up) may be β-diketones, β-ketoaldehydes, or other β-dicarbonyl compounds. The reaction can be carried out with a variety of ketones and esters both inter- and intramolecularly.

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{CH}_3\text{COCH}_2\text{CH}_3 & \quad + \quad \text{O} \\
\text{CH}_3\text{C} & \quad \text{OH} \\

\text{Mevalonic acid} & \quad \text{HMG synthase, thiolase} \\
\text{H}_3\text{C} & \quad \text{C} \quad \text{H}_3\text{C} \quad \text{O} \\
\text{H}_2\text{O} & \quad \text{HMG CoA reductase} \\
\text{β-Hydroxy-β-methylglutaryl CoA (HMG CoA)} & \quad \text{Adenosine triphosphate (ATP, Chemical Highlight 23-2)} \\
\text{Isoprenyl pyrophosphate} & \quad \text{− CO}_2\text{, − H}_2\text{O} \\
\end{align*}
\]

In animals, six molecules of isoprenyl pyrophosphate are used to construct the hydrocarbon squalene, which contains a 24-carbon chain and six methyl substituents. Squalene, in turn, undergoes a complex sequence of cyclization, rearrangement, and bond cleavage to give steroids, such as cholesterol (Sections 4–7 and 14–10).
Retrosynthetic analysis clarifies the synthetic utility of the Claisen condensation

Having seen a variety of types of Claisen condensations, we can now ask how this process may be logically analyzed for synthetic use. Three facts are available to help us: (1) Claisen condensations always form 1,3-dicarbonyl compounds; (2) one of the reaction partners in a Claisen condensation must be an ester, whose alkoxide group is lost in the course of the condensation; and (3) the other reaction partner (the source of the nucleophilic enolate) must contain at least two acidic hydrogens on an α-carbon. In addition, if a mixed condensation is being considered, one reaction partner should be incapable of self-condensation (e.g., it should lack α-hydrogens). If we are given the structure of a target molecule and wish to determine whether (and, if so, how) it can be made by a Claisen condensation, we must analyze it retro-synthetically with the preceding points in mind. For example, let us consider whether 2-benzoylcyclohexanone can be made by a Claisen condensation.

It is a 1,3-dicarbonyl compound, meeting the first requirement. What bond forms in a Claisen condensation? By examining all the examples in this section, we find that the new carbon–carbon bond always connects one of the carbonyl groups of the 1,3-dicarbonyl moiety to the carbon atom between them. Our target molecule contains two such bonds, which we label a and b. As we continue our analysis by disconnecting each of these strategic bonds in turn, we must employ the second point: The carbonyl group at which the new carbon–carbon bond forms starts out as part of an ester function. Thus, working backward, we must imagine reattaching an alkoxy group to this carbonyl carbon. Thus:

Disconnection of bond a reveals a ketoester, which undergoes intramolecular Claisen condensation in the forward direction, whereas disconnection of bond b gives cyclohexanone and a benzoic ester. Both condensations are quite feasible; however, the second is preferable because it constructs the target from two smaller pieces:

**Exercise 23-7**

1,3-Cyclohexanedi-one (margin) can be prepared by an intramolecular mixed Claisen condensation between the ketone carbonyl and ester functions of a single molecule. What is the structure of this substrate molecule?

**Exercise 23-8**

**Working with the Concepts: Claisen Retrosynthetic Analysis**

Show a synthesis of using a Claisen or a Dieckmann condensation.
**Strategy**

Begin by identifying the strategic bonds—the ones that may be made in a Claisen-type condensation. Once you have found them (there will be two), disconnect each one in turn and attach an alkoxy group to the separated carbonyl carbon. This procedure will give you the two possible starting points for the Claisen-based synthesis.

**Solution**

- The strategic bonds are those connecting the two carbonyl groups to the shared atom between them (arrows). Label them \( a \) and \( b \).
- (1) Break each of these bonds, and (2) attach an ethoxy group to the carbonyl fragment (use an ethoxy group because the target molecule is an ethoxy ester). You should come up with something like this, which constitutes your retrosynthetic analysis:

![Retrosynthetic Analysis Diagram]

- At this stage you have identified the two possible starting points. To complete the exercise, write the condensation reactions in the forward direction:

**Synthesis \( a \):**

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{OC} & \quad \text{O} \\
\text{C}_3\text{H}_7\text{O} & \quad \text{O} \\
\text{C}_3\text{H}_7\text{O} & \quad \text{C}_2\text{H}_4\text{O} \\
\text{O} & \quad \text{O} \\
\text{O} & \quad \text{O}
\end{align*}
\]

1. \( \text{CH}_3\text{CH}_2\text{ONa, CH}_3\text{CH}_2\text{OH} \)
2. \( \text{H}^+, \text{H}_2\text{O} \)

**Synthesis \( b \):**

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{O} & \quad \text{C}_3\text{H}_7\text{OC} \\
\text{CH}_3\text{CH}_2\text{O} & \quad \text{C}_2\text{H}_4\text{O} \\
\text{CH}_3\text{CH}_2\text{OC} & \quad \text{C}_2\text{H}_4\text{O} \\
\text{O} & \quad \text{O} \\
\text{O} & \quad \text{O}
\end{align*}
\]

1. \( \text{CH}_3\text{CH}_2\text{ONa, CH}_3\text{CH}_2\text{OH} \)
2. \( \text{H}^+, \text{H}_2\text{O} \)

**Synthesis \( a \) is a Dieckmann condensation featuring attack of the \( \alpha \)-carbon of the ketone enolate on the ester carbonyl at the other end of the molecule. Synthesis \( b \) is a mixed Claisen condensation in which cyclohexanone enolate attacks one of the two ester groups of diethyl ethanedioate (diethyl oxalate).**
In Summary  Claisen condensations are endothermic and therefore would not take place without a stoichiometric amount of base strong enough to deprotonate the resulting 3-ketoester. Mixed Claisen condensations between two esters are nonselective, unless they are intramolecular (Dieckmann condensation) or one of the components is devoid of α-hydrogens. Ketones also participate in selective mixed Claisen reactions because they are more acidic than esters.

23-2  β-Dicarbonyl Compounds as Synthetic Intermediates

Having seen how to prepare β-dicarbonyl compounds, let us explore their synthetic utility. This section will show that the corresponding anions are readily alkylated and that 3-ketoesters are hydrolyzed to the corresponding acids, which can be decarboxylated to give ketones or new carboxylic acids. These transformations open up versatile synthetic routes to other functionalized molecules.

β-Dicarbonyl anions are nucleophilic

The unusually high acidity of the methylene hydrogens of β-ketocarbonyl compounds can be used to synthetic advantage. Their unusually low pKₐ values (ca. 9–13, see Table 23-1) allow alkoxide bases to remove a proton from this methylene group essentially quantitatively, giving an enolate ion that may be alkylated to produce substituted derivatives. For example, treatment of ethyl 3-oxobutanoate (ethyl acetoacetate) with NaOCH₂CH₃ effects complete deprotonation to the enolate, which reacts via the S_N2 mechanism with iodomethane to afford the methylated derivative shown. The remaining acidic hydrogen at this position can be abstracted with the somewhat stronger base KOCH₃. The resulting anion may undergo another S_N2 alkylation, shown here with benzyl bromide, to yield the doubly substituted product.

β-Ketoester Alkylations

Exercise 23-9

Try It Yourself

Suggest syntheses of the following molecules by Claisen or Dieckmann condensations.

(a) CH₃CCH₂CH₂
(b) CO₂CH₂CH₃
(c) H₃C

In Summary  Claisen condensations are endothermic and therefore would not take place without a stoichiometric amount of base strong enough to deprotonate the resulting 3-ketoester. Mixed Claisen condensations between two esters are nonselective, unless they are intramolecular (Dieckmann condensation) or one of the components is devoid of α-hydrogens. Ketones also participate in selective mixed Claisen reactions because they are more acidic than esters.

23-2  β-Dicarbonyl Compounds as Synthetic Intermediates

Having seen how to prepare β-dicarbonyl compounds, let us explore their synthetic utility. This section will show that the corresponding anions are readily alkylated and that 3-ketoesters are hydrolyzed to the corresponding acids, which can be decarboxylated to give ketones or new carboxylic acids. These transformations open up versatile synthetic routes to other functionalized molecules.

β-Dicarbonyl anions are nucleophilic

The unusually high acidity of the methylene hydrogens of β-ketocarbonyl compounds can be used to synthetic advantage. Give a synthesis of 2,2-dimethyl-1,3-cyclohexanedione from methyl 5-oxohexanoate.

### 3-Ketoacids readily undergo decarboxylation

Hydrolysis of 3-ketoesters furnishes 3-ketoacids, which in turn readily undergo decarboxylation under mild conditions. The products—ketones and carboxylic acids—contain the alkyl groups introduced in prior alkylation steps.

#### Formation and Decarboxylation of 3-Ketoacids

  - 3-Methylpentanoic acid
Decarboxylation, or loss of CO₂, is not a typical reaction of carboxylic acids under ordinary conditions. However, β-ketoacids are unusually prone to decarboxylation for two reasons. First, the Lewis basic oxygen of the 3-keto function is ideally positioned to bond with the carboxy hydrogen by means of a cyclic six-atom transition state. Second, this transition state has aromatic character (Section 15-3), because three electron pairs shift around the cyclic six-atom array. The species formed in decarboxylation are CO₂ and an enol, which tautomerizes rapidly to the final ketone product.

Mechanism of Decarboxylation of 3-Ketoacids

![Mechanism of Decarboxylation of 3-Ketoacids](image)

Note that only carboxylic acids with a second carbonyl group in the 3- or β-position are structurally capable of reacting in this way. Carboxylic acids lacking a β-carbonyl function do not decarboxylate, regardless of the presence of C=O groups elsewhere in the molecule.

Loss of CO₂ occurs readily only from the neutral carboxylic acid. If the ester is hydrolyzed with base, acid must be added to protonate the resulting carboxylate salt in order for decarboxylation to occur. Decarboxylation of substituted propanedioic (malonic) acids follows the same mechanism.

**Exercise 23-11**

Formulate a detailed mechanism for the decarboxylation of CH₃CH(COOH)₂ (methylmalonic acid).

**The acetoacetic ester synthesis leads to methyl ketones**

The combination of alkylation followed by ester hydrolysis and finally decarboxylation allows ethyl 3-oxobutanoate (ethyl acetoacetate) to be converted ultimately into 3-substituted or 3,3-disubstituted methyl ketones. This strategy is called the **acetoacetic ester synthesis**.

![Acetoacetic Ester Synthesis](image)

Methyl ketones with either one or two substituent groups on C3 can be synthesized by using the acetoacetic sequence.
Like the acetoacetic ester route to ketones, the malonic ester synthesis can lead to carboxylic acids with either one or two substituents at C2.

\[

\]

**Exercise 23-12**

Propose syntheses of the following ketones, beginning with ethyl 3-oxobutanoate (ethyl acetoacetate).

(a) 2-Hexanone; (b) 2-octanone; (c) 3-ethyl-2-pentanone; (d) 4-phenyl-2-butane.

**The malonic ester synthesis furnishes carboxylic acids**

Diethyl propanedioate (malonic ester) is the starting material for preparing 2-alkylated and 2,2-dialkylated acetic acids, a method called the **malonic ester synthesis**.

**Malonic Ester Synthesis**

\[
\text{CH}_3\text{CH}_2\text{OCCH}_2\text{COCH}_2\text{CH}_3 \quad \rightarrow \quad \text{CH}_3\text{CH}_2\text{OC}(\text{R})\text{COCH}_2\text{CH}_3 \quad \rightarrow \quad \text{H}(\text{R})\text{C}={\text{COOH}}
\]

2,2-Dialkylated Acetic Acid

Like the acetoacetic ester route to ketones, the malonic ester synthesis can lead to carboxylic acids with either one or two substituents at C2.

**Synthesis of a 2,2-Dialkylated Acetic Acid**

\[
\text{CH}_3\text{CH}_2\text{OCCH}_2\text{COCH}_2\text{CH}_3 \quad \xrightarrow{1. \text{NaOCH}_2\text{CH}_3, \text{CH}_3\text{CH}_2\text{OH}, 2. \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br, 80}\degree\text{C}} \quad \text{CH}_3\text{CH}_2\text{OCCH}_2\text{COCH}_2\text{CH}_3 \quad \xrightarrow{1. \text{NaOH}, \text{H}_2\text{O}, 2. \text{H}_2\text{SO}_4, \text{H}_2\text{O, 180}\degree\text{C}} \quad \text{CH}_3(\text{CH}_2)_9\text{CHCOOH} \quad 74\%
\]

Diethyl 2-methylpropanedioate (Diethyl methylmalonate) 2-Methyldecanoic acid
Chapter 23  
Ester Enolates and the Claisen Condensation

Exercise 23-13

(a) Give the structure of the product formed after each of the first three steps in the preceding synthesis of 2-methyldecanoic acid. (b) How would you make the starting material, diethyl 2-methylpropanedioate?

The rules and limitations governing S_N2 reactions apply to the alkylation steps. Thus, tertiary haloalkanes exposed to β-dicarbonyl anions give mainly elimination products. However, the anions can successfully attack acyl halides, α-bromoesters, α-bromoketones, and oxacyclopropanes.

Exercise 23-14

The first-mentioned compound in each of the following parts is treated with the subsequent series of reagents. Give the final products. (Note: The choice of the conditions for the last step(s), either direct acid-catalyzed hydrolysis–decarboxylation or stoichiometric base hydrolysis–acidification–
decarboxylation, are arbitrary. The conditions given below are those that gave the best yields experimentally.)

(a) CH_3CH_2O_2C(CH_2)_5CO_2CH_3: NaOCH_2CH_3; CH_3(CH_2)_3I; NaOH; and H^+, H_2O, Δ
(b) CH_3CH_2O_2CCH_2CO_2CH_3: NaOCH_2CH_3; CH_3I; KOH; and H^+, H_2O, Δ
(c) CH_3.CH_2CHCO_2CH_3: NaH, C_6H_5Cl; and H^+, H_2O, Δ
(d) CH_3CH_2CH_2CO_2CH_3: NaOCH_2CH_3; BrCH_2CO_2CH_2CH_3; NaOH; and H^+, H_2O, Δ
(e) CH_3.CH_2CH(CO_2CH_2CH_3)_2: NaOCH_2CH_3; BrCH_2CO_2CH_2CH_3; and H^+, H_2O, Δ
(f) CH_3CH_2CHC(CO_2CH_2CH_3)CH_3: NaOCH_2CH_3; BrCH_2CCH_3; and H^+, H_2O, Δ

Exercise 23-15

Working with the Concepts: Syntheses Using β-Dicarbonyl Compounds

Propose a synthesis of cyclohexanecarboxylic acid from diethyl propanedioate (malonate), CH_3(CO_2CH_2CH_3)_, and 1-bromo-5-chloropentane, Br(CH_2)_5Cl.

Strategy

Begin by comparing the structures of the two starting materials with that of the target molecule. Identify the strategic bonds in the product—the ones that may be made in a β-dicarbonyl-based carboxylic acid synthesis. Once you have done so, find the carbon atoms in the starting materials that give rise to these bonds.

Solution

• The strategic bonds are those at the α-carbon of the target carboxylic acid (arrows). Line up the product structure with those of the starting molecules in a way that clarifies how they are to be linked. You should come up with something like this, which constitutes your retrosynthetic analysis:
In Summary  

**β-Dicarbonyl compounds** such as ethyl 3-oxobutanoate (acetoacetate) and diethyl propanedioate (malonate) are versatile synthetic building blocks for elaborating more complex molecules. Their unusual acidity makes it easy to form the corresponding anions, which can be used in nucleophilic displacement reactions with a wide variety of substrates. Their hydrolysis produces 3-ketoacids that are unstable and undergo decarboxylation on heating.

**23-3 β-Dicarbonyl Anion Chemistry: Michael Additions**

Reaction of the stabilized anions derived from β-dicarbonyl compounds and related analogs (Table 23-1) with α,β-unsaturated carbonyl compounds leads to 1,4-additions. This transformation, an example of **Michael addition** (Section 18-11), is base-catalyzed and works with α,β-unsaturated ketones, aldehydes, nitriles, and carboxylic acid derivatives, all of which are termed **Michael acceptors**.

---

Exercise 23-16

**Try It Yourself**

How would you modify the synthesis in Exercise 23-15 in order to use it to prepare heptanediioic acid, HOOC(CH₂)₅COOH? (Hint: The same starting materials may be used.)

---

In Summary  

β-Dicarbonyl compounds such as ethyl 3-oxobutanoate (acetoacetate) and diethyl propanedioate (malonate) are versatile synthetic building blocks for elaborating more complex molecules. Their unusual acidity makes it easy to form the corresponding anions, which can be used in nucleophilic displacement reactions with a wide variety of substrates. Their hydrolysis produces 3-ketoacids that are unstable and undergo decarboxylation on heating.

**23-3 β-Dicarbonyl Anion Chemistry: Michael Additions**

Reaction of the stabilized anions derived from β-dicarbonyl compounds and related analogs (Table 23-1) with α,β-unsaturated carbonyl compounds leads to 1,4-additions. This transformation, an example of **Michael addition** (Section 18-11), is base-catalyzed and works with α,β-unsaturated ketones, aldehydes, nitriles, and carboxylic acid derivatives, all of which are termed **Michael acceptors**.
Why do stabilized anions undergo 1,4- rather than 1,2-addition to Michael acceptors? 1,2-Addition occurs, but is reversible with relatively stable anionic nucleophiles, because it leads to a relatively high-energy alkoxide. Conjugate addition is favored thermodynamically because it produces a resonance-stabilized enolate ion.

**Exercise 23-17**

Formulate a detailed mechanism for the Michael addition process just depicted. Why is the base required in only catalytic amounts?

**Exercise 23-18**

Give the products of the following Michael additions [base in square brackets].

(a) $\text{CH}_3\text{CH}_2\text{CH}($CO$_2\text{CH}_2\text{CH}_3)_2 + \text{CH}_2=\text{CHCH} \quad [\text{Na}^+\text{OCH}_2\text{CH}_3]$

(b) $\text{CH}_2=\text{CHCN} \quad [\text{Na}^+\text{OCH}_3]$

(c) $\text{H}_3\text{C} \quad \text{CO}_2\text{CH}_2\text{CH}_3 + \text{CH}_2\text{CH}=\text{CHCO}_2\text{CH}_2\text{CH}_3 \quad [\text{K}^+\text{OCH}_2\text{CH}_3]$

**Exercise 23-19**

Explain the following observation. (Hint: Consider proton transfer in the first Michael adduct.)

The following reaction is a useful application of Michael addition of anions of $\beta$-ketoesters to $\alpha,\beta$-unsaturated ketones. The addition gives initially the diketone shown in the margin. Deprotonation of the $\alpha$-methyl group in the side chain gives an enolate that is perfectly positioned to react with the carbonyl carbon of the cyclohexanone ring. This intramolecular aldol condensation forms a second six-membered ring. Recall (Section 18-11) that the synthesis of six-membered rings by Michael addition followed by aldol condensation is called Robinson annulation.
Exercise 23-20

Working with the Concepts: Mechanism of Robinson Annulation

Formulate a detailed mechanism for the preceding transformation.

**Strategy**

You need to show every step of the process in sequence, starting with the Michael addition and following with the intramolecular aldol condensation. Review the details of these reactions in Section 18-11.

**Solution**

- Following the cues in the text, we begin with a step-by-step description of the Michael addition: deprotonation of the α-carbon between the ketone and ester carbonyl groups in the cyclic β-ketoester, addition to the β-carbon of the α,β-unsaturated ketone, and protonation of the resulting enolate by a molecule of alcohol.

- The intramolecular aldol reaction follows: Ethoxide deprotonates the α-methyl group, giving the corresponding enolate, which adds to the ring carbonyl carbon. The resulting alkoxide is protonated by alcohol. Ethoxide then initiates loss of a molecule of water by removal of an α-hydrogen and expulsion of hydroxide from the β-carbon, completing the aldol condensation and giving the final product.

Exercise 23-21

Try It Yourself

Illustrate a Robinson annulation that ensues upon treatment of a mixture of \( \text{\textbf{\text{\text{\text{O}}}}} \) and 3-buten-2-one with sodium ethoxide in ethanol. Draw the intermediate of the initial Michael addition.
In Summary  β-Dicarbonyl anions, like ordinary enolate anions, undergo Michael additions to α,β-unsaturated carbonyl compounds. Addition of a β-ketoester to an enone gives a diketone, which can generate six-membered rings by intramolecular aldol condensation (Robinson annulation).

23-4 Acyl Anion Equivalents: Preparation of α-Hydroxyketones

Throughout our study of carbonyl compounds, we have been used to thinking of the carbonyl carbon atom as being electrophilic and its α-carbon, in the form of an enol or an enolate, as being nucleophilic. These tendencies govern the rich chemistry of the functional groups built around the C=O unit. However, although the array of transformations available to carbonyl compounds is large, it is not without limits. For example, we have no way of making a direct connection between two carbonyl carbon atoms, because both are electrophilic: Neither can serve as a nucleophilic electron source to attack the other. One may imagine a hypothetical carbonyl-derived nucleophilic species, such as an acyl anion (margin), which might add to an aldehyde or ketone to give an α-hydroxyketone, as follows.

![Acyl anion](image)

A Plausible (but Unfeasible) Synthesis of α-Hydroxyketones

The ability to generate such an anion would expand the versatility of carbonyl chemistry immensely, making a wide variety of 1,2-difunctionalized systems available, in analogy to the 1,3-difunctional products that we can prepare by using aldol and Claisen condensations. Unfortunately, acyl anions are high-energy species and cannot be generated readily for synthetic applications. Consequently, chemists have explored the construction of other chemical species containing negatively charged carbon atoms that can undergo addition reactions and later be transformed into carbonyl groups. These special nucleophiles, called masked acyl anions or acyl anion equivalents, are the subject of this section.

Exercise 23-22

Why are acyl anions not formed by reaction of a base with an aldehyde? (Hint: See Sections 17-5 and 18-1.)

Cyclic thioacetals are masked acyl anion precursors

Cyclic thioacetals are formed by the reaction of dithiols with aldehydes and ketones (Section 17-8). The hydrogens on the carbon positioned between the two sulfur atoms in thioacetals are acidic enough (pK_a = 31) to be removed by suitably strong bases, such as alkyllithiums. The negative charge in the conjugate base is stabilized inductively by the highly polarizable sulfur atoms.

Deprotonation of 1,3-Dithiacyclohexane, a Cyclic Thioacetal, by Butyllithium

![Deprotonation](image)
The anion of 1,3-dithiacyclohexane, as well as the anions of its substituted derivatives, are nucleophilic and add to aldehydes and ketones, furnishing alcohols with an adjacent thioacetal group. The example below shows a sequence that begins with the formation of a substituted 1,3-dithiacyclohexane (also known as a 1,3-dithiane) from an aldehyde. Deprotonation gives the masked acyl anion, which adds to the carbonyl group of 2-cyclohexenone to give an alcohol. Finally, hydrolysis of the thioacetal function in this substance returns the original carbonyl group, now as part of an \( \alpha \)-hydroxyketone product.

In this synthesis, the electrophilic carbonyl carbon of the starting aldehyde is transformed into a nucleophilic atom, the negatively charged C2 of a 1,3-dithiacyclohexane anion. After this anion is added to the ketone, hydrolysis of the thioacetal function regenerates the original electrophilic carbonyl group. The sequence therefore employs the reversal of the polarization of this carbon atom to form the carbon–carbon bond. Reagents exhibiting reverse polarization greatly increase the strategies available to chemists in planning syntheses. We have in fact seen this strategy before: Conversion of a haloalkane into an organometallic (e.g., Grignard) reagent (Section 8-7) reverses the polarity of the functionalized carbon from electrophilic (\( \delta^+ \mathrm{C}–\mathrm{X}^\delta^- \)) to nucleophilic (\( \delta^- \mathrm{C}–\mathrm{M}^{\delta^+} \)).

While this section describes the application of dithiacyclohexane anions as masked acyl anions to the preparation of \( \alpha \)-hydroxyketones only, it is readily apparent that their alkylation with other electrophilic reagents allows for a general ketone synthesis (see Chapter Integration Problem 23-26).

**Exercise 23-23**

Formulate a synthesis of 2-hydroxy-2,4-dimethyl-3-pentanone, beginning with simple aldehydes and ketones and using a 1,3-dithiacyclohexane anion.

**Thiazolium salts catalyze aldehyde coupling**

Masked acyl anions can be generated catalytically in the reaction of aldehydes with thiazolium salts. These salts are derived from thiazoles by alkylation at nitrogen. Thiazole (margin) is a heteroaromatic compound (Section 25-4) containing sulfur and nitrogen. Thiazolium salts have an unusual feature—a relatively acidic proton located between the two heteroatoms (at C2).
The catalytic activity of thiazolium salts in aldehyde dimerization has an analogy in nature: the action of thiamine, or vitamin B1. Thiamine, in the form of its pyrophosphate, is a coenzyme* for several biochemical transformations, including the breakdown of the sugar glucose (Chapter 24).

In living systems, the tricarboxylic acid (TCA) cycle, also known as the citric acid or Krebs† cycle, generates two-thirds of the energy derived from food in higher organisms. The TCA cycle combines acetyl CoA (Section 19-13) with 2-oxobutanedioic (oxaloacetic) acid to form citric acid. In each turn of the cycle, two carbons of citric acid are oxidized to CO₂, regenerating oxaloacetic acid and giving rise in a coupled process to a molecule of adenosine triphosphate (ATP), the main energy source in cells. (For the structure of adenosine, see Section 26-9.) Acetyl CoA is the only molecule capable of entering the TCA cycle; therefore, for any food-derived compound to serve as an energy source, it must first be converted into acetyl CoA.

The metabolism of glucose leads to pyruvic (2-oxopropanoic) acid. The role of thiamine is to catalyze the conversion of pyruvic acid into acetyl CoA by first facilitating loss of a molecule of CO₂ and then activating the remaining acetyl fragment as an acyl anion equivalent.

The first transformation begins with addition of the thiamine conjugate base to the α-keto carbon of pyruvate. The adduct thus formed decarboxylates readily, generating CO₂ and a resonance-stabilized zwitterion. This product is an acetyl anion equivalent, which participates in nucleophilic attack on a sulfur atom of a substance called lipoamide. The result is a tetrahedral intermediate from which the thiamine catalyst, having done its job, is eliminated. Finally, in a transesterification-like process (Section 20-4), the thiol group of coenzyme A replaces the dihydrolipoamide (DHLPA) function at the acetyl carbonyl carbon, furnishing acetyl CoA.

Under nonoxidative (anaerobic, or “oxygen debt”) conditions, such as those found in muscle tissue undergoing extreme exertion, an alternative process drives the formation of energy-rich ATP: Pyruvic acid is reduced enzymatically...
to (S)-(+) -2-hydroxypropanoic (lactic) acid. Excessive buildup of lactic acid in muscle tissue causes fatigue and cramps. Removal of the lactic acid from the muscle occurs both by slow diffusion into the bloodstream and by enzyme-catalyzed conversion back into pyruvic acid, once the condition of oxygen debt has been relieved. This need to alleviate oxygen debt is the reason why you breathe hard during and after physical exercise.

The final event in the women’s heptathlon at the 2004 Olympic games in Athens, the 800-m run, took place in 40°C (100°F) heat. Here, the gold medalist (left) and another competitor show the combined effects of oxygen debt and lactic acid buildup in their muscles.
Thiazolium Salts Are Acidic

\[
\begin{align*}
\text{Thiazolium salt} & \quad \xrightarrow{\text{H}^+} \quad \text{Resonance-stabilized thiazolium salt conjugate base} \\
\text{pK}_a & \approx 17-19
\end{align*}
\]

In the presence of thiazolium salts, aldehydes undergo conversion into \(\alpha\)-hydroxy-ketones. An example of this process is the conversion of two molecules of butanal into 5-hydroxy-4-octanone. The catalyst is \(N\)-dodecylthiazolium bromide, which contains a long-chain alkyl substituent to improve its solubility in organic solvents.

**Aldehyde Coupling**

\[
\begin{align*}
2 \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 & \xrightarrow{N\text{-Dodecylthiazolium bromide, NaOH, H}_2\text{O}} \text{CH}_3\text{CH}_2\text{CH}_2\text{C(OH)}\text{CHCH}_2\text{CH}_2\text{CH}_3 \\
& \quad 76\%
\end{align*}
\]

The mechanism of this reaction begins with reversible addition of C2 in the deprotonated thiazolium salt to the carbonyl function of an aldehyde.

**Mechanism of Thiazolium Salt Catalysis in Aldehyde Coupling**

**Step 1.** Deprotonation of thiazolium salt

**Step 2.** Nucleophilic attack by catalyst

**Step 3.** Masked acyl anion formation

**Step 4.** Nucleophilic attack on second aldehyde
Step 5. Liberation of α-hydroxyketone

\[
\begin{align*}
\text{N} & \quad \text{C} \quad \text{C} \quad \text{R} \\
\text{HO} & \quad \text{OH} & \quad \text{HO} & \quad \text{OH} & \quad \text{HO} & \quad \text{OH} & \quad \text{HO} & \quad \text{OH} & \quad \text{HO} & \quad \text{OH} & \quad \text{HO} & \quad \text{OH} \\
\text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} & \quad \text{R} \\
\text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} & \quad \text{H} \\
\end{align*}
\]

The product alcohol of step 2 contains a thiazolium unit as a substituent. This group is electron withdrawing and increases the acidity of the adjacent proton. Deprotonation leads to an unusually stable masked acyl anion. Nucleophilic attack by this anion on another molecule of aldehyde, followed by loss of the thiazolium substituent, liberates the α-hydroxyketone.

Comparison of the thiazolium method for synthesis of α-hydroxyketones with the use of dithiacycloclohexane anions is instructive. Thiazolium salts have the advantage in that they are needed in only catalytic amounts. However, their use is limited to the synthesis of molecules \( \text{R–C–CH–R} \) in which the two R groups are identical. The dithiacycloclohexane method is more versatile and can be used to prepare a much wider variety of substituted α-hydroxyketones.

Exercise 23-24

Which of the following compounds can be prepared by using thiazolium ion catalysts, and which are accessible only from 1,3-dithiacycloclohexane anions? Formulate syntheses of at least two of these substances, one by each route.

(a) \[
\begin{align*}
\text{O} & \quad \text{OH} \\
\text{O} & \quad \text{OH} \\
\end{align*}
\]

(b) \[
\begin{align*}
\text{O} & \quad \text{C} \quad \text{CH}_2 \quad \text{OH} \\
\text{O} & \quad \text{C} \quad \text{CH}_2 \quad \text{OH} \\
\end{align*}
\]

(c) \[
\begin{align*}
\text{O} & \quad \text{OH} \\
\text{O} & \quad \text{OH} \\
\end{align*}
\]

(d) \[
\begin{align*}
\text{C} \quad \text{CH} \quad \text{OH} \\
\text{C} \quad \text{CH} \quad \text{OH} \\
\end{align*}
\]

(e) \[
\begin{align*}
\text{O} & \quad \text{OH} \\
\text{O} & \quad \text{OH} \\
\end{align*}
\]

In Summary α-Hydroxyketones are available from addition of masked acyl anions to aldehydes and ketones. The conversion of aldehydes into the anions of the corresponding 1,3-dithiacycloclohexanes (1,3-dithianes) illustrates the method of reverse polarization. The electrophilic carbon changes into a nucleophilic center, thereby allowing addition to an aldehyde or ketone carbonyl group. Thiazolium ions catalyze the dimerization of aldehydes, again through the transformation of the carbonyl carbon into a nucleophilic atom.

THE BIG PICTURE

Returning to the chemistry of the C═O functional group, we have seen further evidence of the central role that carbonyl compounds play in synthesis, both in the laboratory and in nature. While there are a variety of reactions introduced in this chapter that appear to be new, they have close analogs in processes we have seen before. The most prominent of these is the Claisen condensation, which is the ester counterpart to the aldol condensation of aldehydes and ketones and similarly gives a product with multiple functional groups. Notice how this topic again brings us back to the concepts of acid-base chemistry, especially with regard to the deprotonation of α-carbons whose hydrogens are rendered acidic by either
one or (in the case of $\beta$-dicarbonyl compounds) two neighboring C$\equiv$O functions. Decarboxylation is an elimination reminiscent of other reactions with aromatic transition states, including several described in Chapter 15, as well as the rearrangements just discussed in Section 22-7. Finally, the two types of acyl anion equivalents illustrate very different ways to modify a carbonyl carbon such that it can support a negative charge and thus behave as a nucleophile. This is a more sophisticated form of functional group modification, but conceptually it relies on nothing more complicated than an application of the principles discussed at the beginning of Chapter 2: To make a hydrogen acidic, stabilize the negative charge associated with its conjugate base. The innovation in this chemistry is the use of reversible modification of the C$\equiv$O group to accomplish this task, such that the carbonyl function can be restored after its modified, nucleophilic “alter ego” has done its job.

Chapter 24 begins the final phase of our introductory course in organic chemistry, wherein we have a closer look at some of the organic compounds of nature. Fittingly, we start with the carbohydrates, compounds combining the familiar features of alcohols and carbonyl compounds.

**CHAPTER INTEGRATION PROBLEMS**

23-25. a. Consider the process shown below. Although it is a mixed Claisen condensation, it forms a single product with the molecular formula $C_{11}H_{14}O_6$ in 80% yield. Propose a structure for the product and rationalize the pathway by which it forms. The first component, diethyl ethanedioate (diethyl oxalate), is used in excess.

**SOLUTION**

We begin by noticing that diethyl oxalate lacks $\alpha$-hydrogens and therefore cannot undergo Claisen condensation on its own. Next we see that the formula of the product equals the sum of the formulas of the two starting materials ($C_{15}H_{26}O_8$) minus two molecules of ethanol ($C_4H_{12}O_2$)—a change that would be expected for the product of a process involving two Claisen condensations. Because the oxalate is present in excess, it is logical to assume that the first reaction is a Claisen condensation between one of its ester carbonyl groups and an enolate ion derived from the pentanedioate ester:

![Reaction Diagram]

The formula of this intermediate product is $C_{13}H_{20}O_7$—one molecule of ethanol has been eliminated so far. A second condensation must still take place, but it cannot involve addition to another molecule, because the product we are aiming for does not contain enough atoms in its formula. The only option is a second intramolecular Claisen condensation, between the remaining ester group of the oxalate-derived portion of this intermediate and the other $\alpha$-carbon of the pentanedioate-derived moiety:

![Reaction Diagram]
b. Propose a synthesis of the following compound:

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{O} \\
\text{CO}_2\text{CH}_2\text{CH}_3 & \quad \text{O} \\
\text{H}_3\text{C} & \quad \text{CO}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

**SOLUTION**

Using the approach illustrated in (a), we can analyze this target retrosynthetically in the context of ring-formation by double Claisen condensation:

\[
\begin{align*}
\text{H}_3\text{C} & \quad \text{O} \\
\text{CO}_2\text{CH}_2\text{CH}_3 & \quad \text{O} \\
\text{H}_3\text{C} & \quad \text{CO}_2\text{CH}_2\text{CH}_3
\end{align*} \implies
\begin{align*}
\text{H}_3\text{C} & \quad \text{O} \\
\text{CO}_2\text{CH}_2\text{CH}_3 & \quad \text{O} \\
\text{H}_3\text{C} & \quad \text{CO}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

What makes this mixed Claisen condensation feasible? Although both diesters possess \(\alpha\)-hydrogens and can therefore give rise to enolate ions upon treatment with base, the first (dimethyl substituted) ester will not undergo successful condensation with a second identical molecule, because the product will lack the necessary additional \(\alpha\)-hydrogen that needs to be removed to drive the equilibrium forward. Thus, this diester may be used in excess and will participate only as the carbonyl partner in reaction with enolate ions derived from the pentanedioate. Reaction of the ester mixture with excess ethoxide in ethanol, followed by treatment with aqueous acid, gives rise to the desired product.

**23-26.** Propose syntheses of the two ketones in (a) and (b), using the methodology introduced in this chapter. Ground rules for these problems: You may use any organic compounds provided that they contain no more than six carbons each. Any inorganic reagents are allowable.

a. \[
\begin{align*}
\text{O}
\end{align*}
\]

(an intermediate in the synthesis of the widely used perfume essence linalool—see Problem 52 of Chapter 13)

**SOLUTION**

Where do we start? We note that the target molecule is a 2-alkanone—a \textit{methyl} ketone. As a result, we may be able to utilize the acetoacetic ester chemistry introduced in Section 23-2, which is specific in the preparation of methyl ketones. Recall that the acetoacetic ester synthesis affords ketones of the general formulas \(\text{RCH}_2\text{COCH}_3\) and \(\text{RR'}\text{CHOCOH}_2\), depending on whether we alkylate the starting ester once or twice. The desired product fits the first of these general formulas, so let us examine a retrosynthetic analysis along these lines. The strategic bond (Section 8-9) is the one between the \(\text{R}\) group and the \(\text{C}_3\) \(\alpha\)-carbon of the ketone:

\[
\begin{align*}
\text{O} \\
\text{Cl} \\
\text{CO}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

With a general strategy in hand, let us look at its details: A \(\beta\)-ketoester alkylation is necessary and we know (Section 18-4) that alkylations of enolates in general follow the \(S_n2\) mechanism. Is the proposed substrate suitable for this process? We note that the leaving group, \(\text{Cl}\), is located on a carbon atom that is both primary and allylic; hence this substance should be an excellent \(S_n2\) substrate (Sections 6-9, 7-9, and 14-3). The final synthesis can therefore be laid out in a manner virtually identical with that of 2-heptanone on page 1091, replacing 1-bromobutane with the allylic chloride:

\[
\begin{align*}
\text{O} \\
\text{NaOCH}_2\text{CH}_3, \text{CH}_3\text{CH}_2\text{OH} \\
\text{CO}_2\text{CH}_2\text{CH}_3
\end{align*}
\]

b. \[
\begin{align*}
\text{O}
\end{align*}
\]

(an intermediate in the synthesis of the sex attractant of the bark beetle \textit{Ips confusus})
SOLUTION
We note immediately that this target molecule is not a methyl ketone; thus the acetoacetic ester synthesis is not conveniently applicable. We have made simple ketones before by adding organometallic reagents to aldehydes to give secondary alcohols, followed by oxidation (Section 8-9). By this route, the strategic bonds are those to the corresponding alcohol carbon, giving us two potential retrosynthetic disconnections, as shown here.

While the preceding provides perfectly good solutions, the problem requires us to employ methodology from the current chapter. Having ruled out acetoacetic ester chemistry, we have an alternative in the use of acyl anion equivalents, for which we saw examples applied to the synthesis of \( \alpha \)-hydroxyketones (Section 23-4). Can simple aldehydes and ketones be prepared with these equivalents as well? The answer is yes, by simple alkylation with RX, followed by hydrolysis. Thus,

Turning to the problem at hand, we analyze retrosynthetically, identifying the two possible strategic bonds in the disubstituted 1,3-dithiacyclohexane corresponding to our target. The resulting monosubstituted dithianes are readily derived from the corresponding aldehydes by thioacetalization (Section 17-8):
two even-sized (five-carbon-unit) pieces with separated functional groups. Our synthetic scheme for the solution is therefore as shown.

**New Reactions**

**Synthesis of $\beta$-Dicarbonyl Compounds**

1. **Claisen Condensation (Section 23-1)**

   
   \[
   \begin{align*}
   &\text{2. } \text{CH}_3\text{CH}_2\text{CH}_2\text{Li} \\
   &\text{1. } \text{CH}_3\text{CH}_2\text{CH}_2\text{Li} \\
   &\text{2. Br}
   \end{align*}
   \]

2. **Dieckmann Condensation (Section 23-1)**

   \[
   \begin{align*}
   &\text{1. Na}^+\text{-OR, ROH} \\
   &\text{2. H}^+\text{-H}_2\text{O}
   \end{align*}
   \]

3. **$\beta$-Diketone Synthesis (Section 23-1)**

   \[
   \begin{align*}
   &\text{1. Na}^+\text{-OR, ROH} \\
   &\text{2. H}^+\text{-H}_2\text{O}
   \end{align*}
   \]

& \quad \text{RC} - \quad \text{CR} \\
& \quad \text{H}
\end{align*}
\]
Important Concepts

1. The Claisen condensation is driven by the stoichiometric generation of a stable \( \beta \)-dicarbonyl anion in the presence of excess base.

2. \( \beta \)-Dicarbonyl compounds contain acidic hydrogens at the carbon between the two carbonyl groups because of the inductive electron-withdrawing effect of the two neighboring carbonyl functions and because the anions resulting from deprotonation are resonance stabilized.

3. Although mixed Claisen condensations between esters are usually not selective, they can be so with certain substrates (nonenolizable esters, intramolecular versions, ketones).

4. 3-Ketoacids are unstable; they decarboxylate in a concerted process through an aromatic transition state. This property, in conjunction with the nucleophilic reactivity of 3-ketoester anions, allows the synthesis of substituted ketones and acids.

5. Because acyl anions are not directly available by deprotonation of aldehydes, they have to be made as masked reactive intermediates or stoichiometric reagents by transformations of functional groups.

Problems

27. Arrange the following compounds in order of increasing acidity. Estimate \( pK_a \) values for each.

(a) \( \text{O} \)
(b) \( \text{CH}_3\text{CO}_2\text{H} \)
(c) \( \text{CH}_3\text{OH} \)
(d) \( \text{O} \)
(e) \( \text{CH}_3\text{CHO} \)
(f) \( \text{O} \)
(g) \( \text{CH}_3\text{O}_2\text{CCH}_2\text{CO}_2\text{CH}_3 \)
(h) \( \text{CH}_3\text{O}_2\text{CCO}_2\text{CH}_3 \)

28. Give the expected results of the reaction of each of the following molecules (or combinations of molecules) with excess \( \text{NaOCH}_2\text{CH}_3 \) in \( \text{CH}_3\text{CH}_2\text{OH} \), followed by aqueous acidic work-up.

(a) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{COOCH}_2\text{CH}_3 \)
(b) \( \text{C}_6\text{H}_5\text{CHCH}_2\text{COOCH}_2\text{CH}_3 \)
(c) \( \text{C}_6\text{H}_5\text{CHCH}_2\text{COOCH}_2\text{CH}_3 \)
(d) \( \text{CH}_3\text{CH}_2\text{OC(CH}_2)_3\text{COCH}_2\text{CH}_3 \)
(e) \( \text{CH}_3\text{CH}_2\text{OC(CH}_2)_3\text{COCH}_2\text{CH}_3 \)
(f) \( \text{C}_6\text{H}_5\text{CH}_2\text{CO}_2\text{CH}_3 + \text{HCO}_2\text{CH}_3 \)
(g) \( \text{C}_6\text{H}_5\text{CO}_2\text{CH}_3 + \text{CH}_3\text{CH}_2\text{CH}_2\text{CO}_2\text{CH}_3 \)
(h) \( \text{CO}_2\text{CH}_2\text{CH}_3 \)

(i) \( \text{CH}_2\text{CO}_2\text{CH}_2\text{CH}_3 \) + \( \text{CH}_3\text{CH}_2\text{OC} - \text{COCH}_2\text{CH}_3 \)
29. The following mixed Claisen condensation works best when one of the starting materials is present in large excess. Which of the two starting materials should be present in excess? Why? What side reaction will compete if the reagents are present in comparable amounts?

\[
\text{CH}_3\text{CH}_2\text{COCH}_3 + (\text{CH}_3)_2\text{CHCOCH}_3 \xrightarrow{\text{NaOCH}_3, \text{CH}_3\text{OH}} (\text{CH}_3)_2\text{CHCHCOCH}_3
\]

30. Suggest a synthesis of each of the following \(\beta\)-dicarbonyl compounds by Claisen or Dieckmann condensations.

\[\text{(a) } \text{CH}_2\text{CCHCOCH}_2\text{CH}_3 \quad \text{(b) } \text{C}_6\text{H}_5\text{CCHCOCH}_2\text{CH}_3 \]

\[\text{(c) } \text{CH}_3\text{C} = \text{CO}_2\text{CH}_3 \quad \text{(d) } \text{HCCCH}_2\text{COCH}_2\text{CH}_3 \quad \text{(e) } \text{C}_6\text{H}_5\text{CCH}_2\text{CC}_6\text{H}_5 \]

\[\text{(f) } \text{CH}_3\text{CH}_2\text{OCCH}_2\text{COCH}_2\text{CH}_3 \quad \text{(g) } \text{CCH}_2\text{CCH}_3 \]

31. Do you think that propanedial, shown in the margin, can be easily prepared by a simple Claisen condensation? Why or why not?

32. Devise a preparation of each of the following ketones by using the acetoacetic ester synthesis.

\[\text{(a) } \text{O} \quad \text{(b) } \quad \text{(c) } \quad \text{(d) } \text{CH}_3\text{CH}_2\text{OCCH}_2\text{COCH}_2\text{CH}_3 \]

33. Devise a synthesis for each of the following four compounds by using the malonic ester synthesis.

\[\text{(a) } \text{H}_2\text{CCOOH} \quad \text{(b) } \text{H}_2\text{CCOOH} \quad \text{(c) } \text{H}_2\text{CCOOH} \quad \text{(d) } \text{COOH} \]

34. Use the methods described in Section 23-3, with other reactions if necessary, to synthesize each of the following compounds. In each case, your starting materials should include one aldehyde or ketone and one \(\beta\)-dicarbonyl compound.
35. **CHALLENGE** Carbonic acid, $\text{H}_2\text{CO}_3$, is commonly assumed to be an unstable compound that easily decomposes into a molecule of water and a molecule of carbon dioxide: $\text{H}_2\text{CO}_3 \rightarrow \text{H}_2\text{O} + \text{CO}_2$. Indeed, the evidence of our own experience in opening a container of any carbonated beverage supports this apparently obvious notion. However, in 2000 it was discovered that this assumption is not quite correct: Carbonic acid is actually a perfectly stable, isolatable compound in the complete absence of water. Its decomposition, which is a decarboxylation reaction, is strongly catalyzed by water. It is exceedingly difficult to completely exclude water without the use of special techniques, which explains why carbonic acid has been such an elusive species to obtain in pure form.

Based on the discussion of the mechanism of decarboxylations of 3-ketocarboxylic acids in Section 23-2, suggest a role for a molecule of water to play in catalyzing the decarboxylation of carbonic acid. (Hint: Try to arrange one water and one carbonic acid molecule to give a six-membered ring stabilized by hydrogen bonds, and then see if a cyclic aromatic transition state for decarboxylation exists.)

36. Based on your answer to Problem 35, predict whether or not water should catalyze the decarboxylation of each of the following compounds. For each case in which your answer is yes, draw the transition state and the final products.

(a) \( \text{H}_2\text{CO}_3 \) (a monoester of carbonic acid)  
(b) \( \text{H}_2\text{CO}_3 \) (a diester of carbonic acid)

(c) \( \text{H}_2\text{CO}_3 \) (carbamic acid)  
(d) \( \text{H}_2\text{CO}_3 \) (a carbamate ester)

37. Write out, in full detail, the mechanism of the Michael addition of malonic ester to 3-buten-2-one in the presence of ethoxide ion. Be sure to indicate all steps that are reversible. Does the overall reaction appear to be exo- or endothermic? Explain why only a catalytic amount of base is necessary.

38. Give the likely products of each of the following reactions. All are carried out in the presence of a Pd catalyst, a ligand for the metal such as a phosphine, and heat. (Hint: Refer to Section 22-4 for related Pd-catalyzed reactions of halobenzenes with a nucleophile.)

(a) \( \text{Br} \)  
(b) \( \text{Cl} \)  
(c) \( \text{H}_2\text{N} \)  
(d) \( \text{H}_2\text{N} \)

39. Based on the mechanism presented for the Pd-catalyzed reaction of a halobenzene with hydroxide ion (Section 22-4), write out a reasonable mechanism for the Pd-catalyzed reaction of Problem 38(a).
40. Using the methods described in this chapter, design a multistep synthesis of each of the following molecules, making use of the indicated building blocks as the sources of all the carbon atoms in your final product.

(a) \[
\begin{align*}
\text{CH}_3 \quad \text{O} \\
\text{O} \\
\text{CH}_3
\end{align*}
\]
, from \(\text{CH}_3\text{CO}_2\text{CH}_2\text{CH}_3\) and \(\text{CH}_3\text{CCH}==\text{CH}_2\)

(b) \[
\begin{align*}
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O}
\end{align*}
\]
, from \(\text{CH}_3\text{I}, \text{CH}_2(\text{CO}_2\text{CH}_2\text{CH}_3)_2\) and \(\text{CH}_3\text{CCH}==\text{CH}_2\) (Hint: First make \(\text{O} \quad \text{O} \quad \text{O} \quad \text{O} \quad \text{O}\)).

(c) \[
\begin{align*}
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O}
\end{align*}
\]
, from \(\text{CH}_3\text{I}, \text{CH}_2(\text{CO}_2\text{CH}_2\text{CH}_3)_2\) and \(\text{BrCH}_2\text{CCH}_3\) (Hint: First make \(\text{O} \quad \text{O} \quad \text{O} \quad \text{O} \quad \text{O}\)).

41. Give the products of reaction of the following aldehydes with catalytic \(N\)-dodecylthiazolium bromide. (a) \((\text{CH}_3)_2\text{CHCHO}\); (b) \(\text{C}_6\text{H}_5\text{CHO}\); (c) cyclohexanecarbaldehyde; (d) \(\text{C}_6\text{H}_5\text{CH}_2\text{CHO}\).

42. Give the products of the following reactions.

(a) \(\text{C}_6\text{H}_5\text{CHO} + \text{HS(}\text{CH}_2)_2\text{SH} \xrightarrow{\text{BF}_3} \) (b) Product of (a) + \(\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Li} \xrightarrow{\text{THF}} \)

What are the results of reaction of the substance formed in (b) with each aldehyde in Problem 41, followed by hydrolysis in the presence of \(\text{HgCl}_2\)?

43. (a) On the basis of the following data, identify unknowns \(A\), found in fresh cream prior to churning, and \(B\), possessor of the characteristic yellow color and buttery odor of butter.

\(A\): MS: \(m/z\) (relative abundance) = 88(\(M^+\), weak), 45(100), and 43(80).

\(^1\text{H NMR}: \delta = 1.36 \text{ (d, } J = 7 \text{ Hz, } 3 \text{ H}), 2.18 \text{ (s, } 3 \text{ H}), 3.73 \text{ (broad } s, \) 1 H), 4.22 \text{ (q, } J = 7 \text{ Hz, } 1 \text{ H) ppm.}

IR: \(\tilde{v} = 1718\) and 3430 cm\(^{-1}\).

\(B\): MS: \(m/z\) (relative abundance) = 86(17) and 43(100).

\(^1\text{H NMR}: \delta = 2.29 \text{ (s) ppm.}

IR: \(\tilde{v} = 1708\) cm\(^{-1}\).

(b) What kind of reaction is the conversion of compound \(A\) into compound \(B\)? Does it make sense that this should take place in the churning of cream to make butter? Explain. (c) Outline laboratory syntheses of compounds \(A\) and \(B\), starting only with compounds containing two carbons. (d) The UV spectrum of compound \(A\) has a \(\lambda_{\text{max}}\) at 271 nm, whereas that of compound \(B\) has a \(\lambda_{\text{max}}\) at 290 nm. (Extension of the latter absorption into the violet region of the visible spectrum is responsible for the yellow color of compound \(B\).) Explain the difference in \(\lambda_{\text{max}}\).

44. Write chemical equations to illustrate all primary reaction steps that can occur between a base such as ethoxide ion and a carbonyl compound such as acetaldehyde. Explain why the carbonyl carbon is not deprotonated to any appreciable extent in this system.

45. The nootkatones are bicyclic ketones responsible for the flavor and aroma of grapefruits. Nootkatones also repel termites and are used commercially to protect wood structures from termite infestation. Fill in the missing reagents in the partial synthetic sequence for the preparation of isonootkatone shown on the next page. More than one synthetic step may be needed for each transformation.
46. β-Dicarbonyl compounds condense with aldehydes and ketones that do not undergo self-aldol reaction. The products are α,β-unsaturated dicarbonyl compounds, and the process goes by the colorful name of Knoevenagel condensation. (a) An example of a Knoevenagel condensation is given below. Propose a mechanism.

\[
\text{CHO} + \text{CH}_3\text{CCH}_2\text{CO}_2\text{CH}_2\text{CH}_3 \xrightarrow{\text{NaOCH}_2\text{CH}_3, \text{CH}_3\text{CH}_2\text{OH}} \text{CCH}_3
\]

(b) Give the product of the Knoevenagel condensation shown below.

47. The following ketones cannot be synthesized by the acetoacetic ester method (why?), but they can be prepared by a modified version of it. The modification includes the preparation (by Claisen condensation) and use of an appropriate 3-ketoester, RC\text{CH}_2\text{COCH}_2\text{CH}_3, containing an R group that appears in the final product. Synthesize each of the following ketones. For each, show the structure and synthesis of the necessary 3-ketoester as well.

(a) \( \text{O} \)

(b) \( \text{O} \)

(c) \( \text{O} \) (Hint: Use a Dieckmann condensation.)

(d) \( \text{O} \) \( \text{O} \) \( \text{O} \) \( \text{O} \) \( \text{O} \) (Hint: Use a double Claisen condensation.)
48. Some of the most important building blocks for synthesis are very simple molecules. Although cyclopentanone and cyclohexanone are readily available commercially, an understanding of how they can be made from simpler molecules is instructive. The following are possible retrosynthetic analyses (Section 8-9) for both of these ketones. Using them as a guide, write out a synthesis of each ketone from the indicated starting materials.

\[
\begin{align*}
\text{Cyclopentanone} & \quad \O \quad \O \\
& \quad \rightarrow \quad \O \quad \rightarrow \quad \O \quad \rightarrow \quad \text{BrCH}_2\text{CCH}_3 \quad \Rightarrow \quad \O \\
& \quad \text{O} \\
& \quad \text{HCCH}_2\text{CCH}_3 & \quad \Rightarrow \quad \O \\
& \quad \text{O} & \quad \text{CH}_3\text{CCH}_3 \quad + & \quad \text{O} \\
& \quad \text{O} & \quad \text{HCCH}_2\text{COCH}_2\text{CH}_3 & \quad \Rightarrow \quad \O \\
& \quad \text{O} & \quad \text{CH}_3\text{COCH}_2\text{CH}_3 \quad + & \quad \text{O} \\
& \quad \text{O} & \quad \text{HCCH}_2\text{COCH}_2\text{CH}_3 & \quad \Rightarrow \quad \O \\
& \quad \text{O} & \quad \text{CH}_3\text{COCH}_2\text{CH}_3 \quad + & \quad \text{O}
\end{align*}
\]

49. A short construction of the steroid skeleton (part of a total synthesis of the hormone estrone) is shown here. Formulate mechanisms for each of the steps. (**Hint:** A process similar to that taking place in the second step is presented in Problem 48 of Chapter 18.)

\[
\begin{align*}
\text{CH}_3\text{O} \\
& \quad \rightarrow \quad \text{KOH, CH}_3\text{OH, }\Delta \\
& \quad \text{O} \quad \text{CH}_3 \quad \text{O} \\
& \quad \text{KOH, CH}_3\text{OH, }\Delta \\
& \quad \text{CH}_3\text{O} \\
& \quad \text{O} \quad \text{O} \quad \text{CH}_3 \quad \text{O} \\
& \quad \text{H}_3\text{C} \quad \text{C}_6\text{H}_6, \Delta \\
& \quad \text{HO} \quad \text{O} \\
& \quad \text{CH}_3 \quad \text{O} \\
& \quad \text{O} \quad \text{O} \quad \text{CH}_3 \quad \text{O} \\
& \quad \text{H}_3\text{C} \quad \text{C}_6\text{H}_6, \Delta \\
\end{align*}
\]

50. **[CHALLENGE]** Using methods described in Section 23-4 (i.e., reverse polarization), propose a simple synthesis of each of the following molecules.

(a) \( \text{CH}_2=\text{CHCHCHCCH}_2\text{C}_6\text{H}_5 \)  
(b) \( \text{CH}_3\text{CHCHCHCHO} \)  
(c) \( \text{CH}_3\text{CHCHCHCHO} \)

51. **[CHALLENGE]** Propose a synthesis of ketone C, which was central in attempts to synthesize several antitumor agents. Start with aldehyde A, lactone B, and anything else you need.

\[
\begin{align*}
\text{A} & \quad \text{B} & \quad \text{C}
\end{align*}
\]
Team Problem

52. Split your team in two, each group to analyze one of the following reaction sequences by a mechanism (\(^{13}\text{C} = \text{carbon-13 isotope})

(a)\[ \begin{align*}
\text{O} & \quad \text{O} \\
\text{1. } & \text{NaH} \\
\text{2. } & \text{CH_3CHCHCH_3Li} \\
\text{3. } & \text{CH}_3 \\
\text{4. } & \text{OH, H_2O} \\
\text{5. } & \text{H^+, H_2O, } \Delta
\end{align*}\]

(b)\[ \begin{align*}
\text{O} & \quad \text{O} \\
\text{1. } & \text{CH_3CH_2O} \\
\text{2. } & \text{(CH_3)_3CCl} \\
\text{3. } & \text{OH, H_2O} \\
\text{4. } & \text{H^+, H_2O, } \Delta
\end{align*}\]

Reconvene and discuss your results. Specifically, address the position of the \(^{13}\text{C} \) label in the product of (a) and the failure to obtain alkylation in (b).

As a complete team, also discuss the mechanism of the following transformation. (Hint: For the first step, a minimum of three equivalents of KNH\(_2\) is required.)

Preprofessional Problems

53. Two of the following four compounds are more acidic than CH\(_3\)OH (i.e., two of these have \(K_a\) greater than methanol). Which ones?

(a) A and B; (b) B and C; (c) C and D; (d) D and A; (e) D and B.

54. The reaction of ethyl butanoate with sodium ethoxide in CH\(_3\)CH\(_2\)OH gives

(a) \[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CO}_2\text{CH}_3 \]

(b) \[ \text{CH}_3\text{CH}_2\text{CH}_2\text{CCHCO}_2\text{CH}_3 \]

(c) \[ \text{CH}_3\text{CH}_2\text{CCH}_2\text{CO}_2\text{CH}_3 \]

(d) \[ \text{CH}_3\text{CH}_2\text{CHCH}_2\text{CO}_2\text{CH}_3 \]
55. When acid A (margin) is heated to 230°C, CO₂ and H₂O are evolved and a new compound is formed. Which one?

(a) HO₂CCH₂CH═C
(b) HO₂CCH₂CH₂CH₃

(c) CH₃CH₂CH(CO₂H)₂
(d) HO₂C(CH₂)₂CH

56. A compound with m.p. = −22°C has a parent peak in its mass spectrum at m/z = 113. The ^1H NMR spectrum shows absorptions at δ = 1.2 (t, 3 H), 3.5 (s, 2 H), and 4.2 (q, 2 H). The IR spectrum exhibits significant bands at ν = 3000, 2250, and 1750 cm⁻¹. What is its structure?

(a) H N
OCH₂CH₂CH₃
(b) CH₂
(c) OCH(CH₃)₂
(d) OCH₂CH₃
(e) NCCH₂CO₂CH₂CH₃
Take a piece of bread and place it in your mouth. After a few minutes it will begin to taste distinctly sweet, as if you had added sugar to it. Indeed, in a way, this is what happened. The acid and enzymes in your saliva have cleaved the starch in the bread into its component units: glucose molecules. You all know glucose as dextrose or grape sugar. The polymer, starch, and its monomer, glucose, are two examples of carbohydrates.

Carbohydrates are most familiar to us as major contributors to our daily diets, in the form of sugars, fibers, and starches, such as bread, rice, and potatoes. In this capacity, they function as chemical energy-storage systems, being metabolized to water, carbon dioxide, and heat or other energy. Members of this class of compounds give structure to plants, flowers, vegetables, and trees. They also serve as building units of fats (Sections 19-13 and 20-5) and nucleic acids (Section 26-9). Carbohydrates are considered to be polyfunctional, because they possess multiple functional groups. Glucose, $C_6(H_2O)_6$, and many related simple members of this compound class form the building blocks of the complex carbohydrates and have the empirical formulas $C_n(H_2O)_n$, essentially hydrated carbon.

We shall first consider the structure and naming of the simplest carbohydrates—the sugars. We shall then turn our attention to their chemistry, which is governed by the presence of carbonyl and hydroxy functions along carbon chains of various lengths. Sections 24-1 through 24-3 will address aspects of their properties and chemical behavior. Beginning with Section 24-4, we shall discuss reactions of carbohydrates that are useful preparatively, both for elucidating their structure as well as converting them into other substances. We have already seen an example of the biosynthesis of carbohydrates (Chemical Highlight 18-1). Finally, we shall describe a sampling of more complex types of carbohydrates found in nature.

24-1 Names and Structures of Carbohydrates

The simplest carbohydrates are the sugars, or saccharides. As chain length increases, the increasing number of stereocenters gives rise to a multitude of diastereomers. Fortunately for chemists, nature deals mainly with only one of the possible series of enantiomers. Sugars are polyhydroxy carbonyl compounds and many form stable cyclic hemiacetals, which affords additional structural and chemical variety.
Sugars are classified as aldoses and ketoses

Carbohydrate is the general name for the monomeric (monosaccharides), dimeric (disaccharides), trimeric (trisaccharides), oligomeric (oligosaccharides), and polymeric (polysaccharides) forms of sugar (saccharum, Latin, sugar). A monosaccharide, or simple sugar, is an aldehyde or ketone containing at least two additional hydroxy groups. Thus, the two simplest members of this class of compounds are 2,3-dihydroxypropanal (glyceraldehyde) and 1,3-dihydroxyacetone (margin). Complex sugars (Section 24-11) are those formed by the linkage of simple sugars through ether bridges.

Aldehydic sugars are classified as aldoses; those with a ketone function are called ketoses.

On the basis of their chain length, we call sugars trioses (three carbons), tetroses (four carbons), pentoses (five carbons), hexoses (six carbons), and so on. Therefore, 2,3-dihydroxypropanal (glyceraldehyde) is an aldotriose, whereas 1,3-dihydroxyacetone is a ketotriose.

Glucose, also known as dextrose, blood sugar, or grape sugar (glykys, Greek, sweet), is a pentahydroxyhexanal and hence belongs to the class of aldohexoses. It occurs naturally in many fruits and plants and in concentrations ranging from 0.08 to 0.1% in human blood. A corresponding isomeric ketohexose is fructose, the sweetest natural sugar (some synthetic sugars are sweeter), which also is present in many fruits (fructus, Latin, fruit) and in honey. Another important natural sugar is the aldopentose ribose, a building block of the ribonucleic acids (Section 26-9).

A disaccharide is derived from two monosaccharides by the formation of an ether (usually, acetal) bridge (Sections 17-7 and 24-11). Hydrolysis regenerates the monosaccharides. Ether formation between a mono- and a disaccharide results in a trisaccharide, and repetition of this process eventually produces a natural polymer (polysaccharide). Polysaccharides constitute the framework of cellulose and starch (Section 24-12).

Exercise 24-1

To which classes of sugars do the following monosaccharides belong?

<table>

</tbody>
</table>

(a) Erythrose
(b) Lyxose
(c) Xylulose

Diabetics need to carefully monitor the glucose levels in their blood, as with the simple device shown.
Most sugars are chiral and optically active

With the exception of 1,3-dihydroxyacetone, all the sugars mentioned so far contain at least one stereocenter. The simplest chiral sugar is 2,3-dihydroxypropanal (glyceraldehyde), with one asymmetric carbon. Its dextrorotatory form is found to be \( R \) and the levorotatory enantiomer \( S \), as shown in the Fischer projections of the molecule. Recall that, by convention, the horizontal lines in Fischer projections represent bonds to atoms above the plane of the page (Section 5-4).

\[
\begin{align*}
\text{CHO} & \quad \text{CH}_2\text{OH} \\
\text{HO} & \quad \text{CH}_2\text{OH}
\end{align*}
\]

Even though \( R \) and \( S \) nomenclature is perfectly satisfactory for naming sugars, an older system is still in general use. It was developed before the absolute configuration of sugars was established, and it relates all sugars to 2,3-dihydroxypropanal (glyceraldehyde). Instead of \( R \) and \( S \), it uses the prefixes \( d \) for the \((+1)\) enantiomer of glyceraldehyde and \( l \) for the \((-1)\) enantiomer (Chemical Highlight 5-2). Those monosaccharides whose highest-numbered stereocenter (i.e., the one farthest from the aldehyde or keto group) has the same absolute configuration as that of \( d-(+1)-2,3\)-dihydroxypropanal \([d-(+1)-\text{glyceraldehyde}]\) are then labeled \( d \); those with the opposite configuration at that stereocenter are named \( l \). Two diastereomers that differ only at one stereocenter are also called epimers.

Designation of a \( d \) and an \( l \) Sugar

The \( d,l \) nomenclature divides the sugars into two groups. As the number of stereocenters increases, so does the number of stereoisomers. For example, the aldohexose 2,3,4,5,6-pentahydroxyhexanal has five stereocenters and hence may exist as 2^5 = 32 stereoisomers: two diastereomers, each as a pair of enantiomers. The next higher homolog, 2,3,4,5,6-pentahydroxyhexanal, has six stereocenters, and therefore eight stereoisomers are possible: four diastereomeric pairs of enantiomers. Similarly, 16 stereoisomers (as eight enantiomeric pairs) may be formulated for the corresponding hexahydroxyheptanal.

Like many natural products, these diastereomers have common names that are often used, mainly because the complexity of these molecules leads to long systematic names. This chapter will therefore deviate from our usual procedure of labeling molecules systematically. The isomer of 2,3,4-trihydroxybutanal with \( 2R,3R \) configuration is called erythrose; its diastereomer, threose. Note that each of these isomers has two enantiomers, one belonging to the family of the \( d \) sugars, its mirror image to the \( l \) sugars. The sign of the optical rotation is not correlated with the \( d \) and \( l \) label (just as in the \( R,S \) notation: \((-)\) Does not necessarily correspond to \( S \), and \((+)\) does not necessarily correspond to \( R \); see Section 5-3). For example, \( d \)-glyceraldehyde is dextrorotatory, but \( d \)-erythrose is levorotatory.
As mentioned previously, an aldopentose has three stereocenters and hence $2^3 = 8$ stereoisomers. There are $2^4 = 16$ such isomers in the group of aldohexoses. Why then use the d,l nomenclature even though it designates the absolute configuration of only one stereocenter? Probably because almost all naturally occurring sugars have the d configuration. Evidently, somewhere in the structural evolution of the sugar molecules, nature “chose” only one configuration for one end of the chain. The amino acids are another example of such selectivity (Chapter 26).

Figure 24-1 shows Fischer projections of the series of d-aldoses up to the aldohexoses. To prevent confusion, chemists have adopted a standard way to draw these projections: The carbon chain extends vertically and the aldehyde terminus is placed at the top. In this convention, the hydroxy group at the highest-numbered stereocenter (at the bottom) points to the right in all d sugars. Figure 24-2 shows the analogous series of ketones.

**Exercise 24-2**

Give a systematic name for (a) d-(−)-ribose and (b) d-(+)-glucose. Remember to assign the R and S configuration at each stereocenter.

**Exercise 24-3**

Redraw the hashed-wedged line structure of sugar A (shown in the margin) as a Fischer projection and find its common name in Figure 24-1.

**In Summary** The simplest carbohydrates are sugars, which are polyhydroxy aldehydes (aldoses) and ketones (ketoses). They are classified as d when the highest-numbered stereocenter is R, l when it is S. Sugars related to each other by inversion at one stereocenter are called epimers. Most of the naturally occurring sugars belong to the d family.
Figure 24-1  D-Aldoses (up to the aldohexoses), their signs of rotation, and their common names.

Figure 24-2  D-Ketoses (up to the ketohexoses), their signs of rotation, and their common names.

Carbohydrates

24-2 Conformations and Cyclic Forms of Sugars

Sugars are molecules with multiple functional groups and multiple stereocenters. This structural complexity gives rise to a variety of chemical properties. To enable chemists to focus on the portion of a sugar molecule involved in any given chemical process, several ways of depicting sugars have been developed. We have seen the Fischer representation in Section 24-1; this section shows how to interconvert Fischer and hashed-wedged representations. In addition, it introduces the cyclic isomers that exist in solutions of simple sugars.

Fischer projections depict all-eclipsed conformations

Recall (Section 5-4) that the Fischer projection represents the molecule in an all-eclipsed arrangement. It can be translated into an all-eclipsed hashed-wedged line picture.

Fischer Projection and Hashed-Wedged Line Structures for D-(+)-Glucose

A molecular model can help you see that the all-eclipsed form actually possesses a roughly circular shape, as illustrated by the “scrolled” rendition above (center picture). In the subsequent all-eclipsed hashed-wedged line structure, notice that the groups on the right of the carbon chain in the original Fischer projection now project upward (wedged bonds). From this conformer, we can reach the all-staggered form by 180° rotations of C3 and C5.

Sugars form intramolecular hemiacetals

Sugars are hydroxycarbonyl compounds that should be capable of intramolecular hemiacetal formation (see Section 17-7). Indeed, glucose and the other hexoses, as well as the pentoses, exist as an equilibrium mixture with their cyclic hemiacetal isomers, in which the hemiacetals strongly predominate. In principle, any one of the five hydroxy groups could add to the carbonyl group of the aldehyde. However, three- and four-membered rings are too strained, and five- and six-membered rings are the products, the latter usually dominating. The six-membered ring structure of a monosaccharide is called a pyranose, a name derived from pyran, a six-membered cyclic ether (see Sections 9-6 and 25-1). Sugars in the five-membered ring form are called furanoses, from furan (Section 25-3).
Five- and Six-Membered Cyclic Hemiacetal Formation

![Cyclic hemiacetal formation by glucose diagram]

To depict a d-series sugar correctly in its cyclic form, draw the hashed-wedged line representation of the all-eclipsed structure on the previous page and flip it upside down, as shown below. Rotation of C5 places its hydroxy group in position to form a six-membered cyclic hemiacetal by addition to the C1 aldehyde carbon. Similarly, a five-membered ring can be made by rotation of C4 to place its OH group in position to bond to C1. The resulting drawings depict the ring in a somewhat artificial way: It is shown as if it were planar and from a perspective in which the bottom-most ring bonds (between C2 and C3 in the structures below) are interpreted as being in front of the plane of the page. As we shall see shortly, a slightly modified version of this type of drawing is quite commonly used to depict the cyclic forms of sugars.
In contrast with glucose, which exists primarily as the pyranose, fructose forms both fructopyranose and fructofuranose in a rapidly equilibrating 68:32 mixture.

**Cyclic Hemiacetal Formation by Fructose**

Note that, upon cyclization, the carbonyl carbon turns into a new stereocenter. As a consequence, hemiacetal formation leads to two new compounds, two diastereomers differing in the configuration of the hemiacetal group. If that configuration is $S$ in a d-series sugar, that diastereomer is labeled $\alpha$; when it is $R$ in a d sugar, the isomer is called $\beta$. Hence, for example, d-glucose may form $\alpha$- or $\beta$-d-glucopyranose or -furanose. Because this type of diastereomer formation is unique to sugars, such isomers have been given a separate name: anomers. The new stereocenter is called the anomeric carbon.

**Exercise 24-4**

Draw the Fischer projection of l-(-)-glucose and illustrate its transformation into the corresponding six-membered cyclic hemiacetal.

**Exercise 24-5**

**Working with the Concepts: Relationships Between Sugar Stereoisomers**

The anomers $\alpha$- and $\beta$-glucopyranose should form in equal amounts because they are enantiomers. True or false? Explain your answer.

**Strategy**

Be sure that you understand the meanings of enantiomer and diastereomer, and how physical properties of molecules relate to those stereoisomeric relationships, before you answer this question about anomers.

**Solution**

False! Anomers differ in configuration at only the anomeric carbon (C1). The configurations at the remaining stereocenters (C2 through C5) are the same in $\alpha$-glucopyranose as they are $\beta$-glucopyranose. Anomers are therefore diastereomers—not enantiomers—and should not form in equal amounts. Enantiomers differ from each other in configuration at every stereocenter.
Fischer, Haworth, and chair cyclohexane projections help depict cyclic sugars

How can we represent the stereochemistry of the cyclic forms of sugars? One approach uses Fischer projections. We simply draw elongated lines to indicate the bonds formed upon cyclization, preserving the basic “grid” of the original formula.

Adapted Fischer Projections of Glucopyranoses

In the Fischer projection of the α form of a D sugar, the anomeric OH points toward the right. In the Fischer projection of the β form, the anomeric OH is on the left.

Haworth* projections more accurately represent the real three-dimensional structure of the sugar molecule. The cyclic ether is written in line notation as a pentagon or a hexagon, the anomeric carbon (in a D sugar) placed on the right, and the ether oxygen put on top. The substituents located above or below the ring are attached to vertical lines. In relating the Haworth projection to a three-dimensional structure, we interpret the ring bond at the bottom (between C2 and C3) to be in front of the plane of the paper, and the ring bonds containing the oxygen are understood to be in back.

Haworth Projections

In a Haworth projection, the α anomer has the OH group at the anomeric carbon pointing down, whereas the β anomer has it pointing up.

---

Haworth projections are used extensively in the literature, but here, to make use of our knowledge of conformation (Sections 4-3 and 4-4), the cyclic forms of sugars will be presented mostly as envelope (for furanoses) or chair (for pyranoses) conformations (Figures 4-4 and 4-6). As in Haworth notation, the ether oxygen will be placed usually top right and the anomeric carbon at the right vertex of the envelope or chair.

Exercise 24-7

Draw Haworth projections of (a) α-d-fructofuranose; (b) β-d-glucofuranose; and (c) β-d-arabinopyranose.

Although there are exceptions, most aldohexoses adopt the chair conformation that places the bulky hydroxymethyl group at the C5 terminus in the equatorial position. For glucose, this preference means that, in the α form, four of the five substituents can be equatorial, and one is forced to lie axial; in the β form, all substituents can be equatorial. This situation is unique for glucose; the other seven d aldohexoses (see Figure 24-1) contain one or more axial substituents.

Exercise 24-8

Using the values in Table 4-3, estimate the difference in free energy between the all-equatorial conformer of β-d-glucopyranose and that obtained by ring flip (assume that $\Delta G_{\text{CH}_2\text{OH}} = \Delta G_{\text{CH}_2} = 1.7 \text{ kcal mol}^{-1}$ and that the ring oxygen mimics a CH$_2$ group).

In Summary  Hexoses and pentoses can take the form of five- or six-membered cyclic hemiacetals. These structures rapidly interconvert through the open-chain polyhydroxy-aldehyde or ketone, with the equilibrium usually favoring the six-membered (pyranose) ring.
Anomers of Simple Sugars: Mutarotation of Glucose

Glucose precipitates from concentrated solutions at room temperature to give crystals that melt at 146°C. Structural analysis by X-ray diffraction reveals that these crystals contain only the α-D- (+)-glucopyranose anomer (Figure 24-3). When crystalline α-D- (+)-glucopyranose is dissolved in water and its optical rotation measured immediately, a value \( [\alpha]_{25}^{D} = +112 \) is obtained. Curiously, this value decreases with time until it reaches a constant +52.7. The process that gives rise to this effect is the interconversion of the α and β anomers.

In solution, the α-pyranose rapidly establishes an equilibrium (in a reaction that is catalyzed by acid and base; see Section 17-7) with a small amount of the open-chain aldehyde, which in turn undergoes reversible ring closure to the β anomer.

**Interconversion of Open-Chain and Pyranose Forms of D-Glucose**

The β form has a considerably lower specific rotation (+18.7) than its anomer; therefore, the observed α value in solution decreases. Similarly, a solution of the pure β anomer (m.p. 150°C, obtainable by crystallizing glucose from acetic acid) gradually increases its specific rotation from +18.7 to +52.7. At this point, a final equilibrium has been reached, with 36.4% of the α anomer and 63.6% of the β anomer. The change in optical rotation observed when a sugar equilibrates with its anomer is called mutarotation (mutare, Latin, to change). Interconversion of α and β anomers is a general property of sugars. This includes all monosaccharides capable of existing as cyclic hemiacetals.

**Exercise 24-9**

An alternative mechanism for mutarotation bypasses the aldehyde intermediate and proceeds through oxonium ions. Formulate it.
Carbohydrates

In Summary

The hemiacetal carbon (anomeric carbon) can have two configurations: α or β. In solution, the α and β forms of the sugars are in equilibrium with each other. The equilibration can be followed by starting with a pure anomer and observing the changes in specific rotation, a phenomenon also called mutarotation.

24-4 Polyfunctional Chemistry of Sugars: Oxidation to Carboxylic Acids

Simple sugars exist as isomers: the open-chain structure and the α and β anomers of various cyclic forms. Because all of these isomers equilibrate rapidly, the relative rates of their individual reactions with various reagents determine the product distribution of a particular transformation. We can therefore divide the reactions of sugars into two groups, those of the linear form and those of the cyclic forms, because the two structures contain different functional groups. Although the two forms may sometimes react competitively, we see in this section that reactions of aldoses with oxidizing agents take place at the aldehyde moiety of the open-chain form, not the hemiacetal function of the cyclic isomers.

Fehling’s and Tollens’s tests detect reducing sugars

Because they are polyfunctional compounds, the open-chain monosaccharides undergo the reactions typical of each of their functional groups. For example, aldoses contain the oxidizable

Exercise 24-10

Working with the Concepts: Calculating Specific Rotations of Diastereomeric Sugar Mixtures

Calculate the equilibrium ratio of α- and β-glucopyranose (which has been given in the text) from the specific rotations of the pure anomers and the observed specific rotation at mutarotational equilibrium.

Strategy

The specific rotation of an equilibrium mixture is the average of the rotations of the contributing isomers—however, weighted by the respective mole fractions in the mixture. All the raw data you need are given in the problem statement.

Solution

• Let’s designate the mole fraction of the α form as \( x_a \) and the mole fraction of its β isomer as \( x_b \). Their respective specific rotations are given as \(+112^\circ\) (α) and \(+18.7^\circ\) (β), whereas the equilibrium mixture exhibits a value of \(+52.7^\circ\). Thus, we have

\[
+52.7 = (+112)(x_a) + (+18.7)(x_b)
\]

• By the definition of mole fraction, \( x_a + x_b = 1 \), so we can substitute one for the other in the above equation. Solving gives \( x_a = 0.364 \) and \( x_b = 0.636 \). Therefore the equilibrium ratio is \( x_a / x_b = (0.364) / (0.636) = 1.75 \).

Exercise 24-11

Try It Yourself

The pure α and β forms of α-galactose exhibit [α] \( \text{D} \) values of +150.7 and +52.8, respectively. The equilibrium mixture after mutarotation in water shows a specific rotation of +80.2. Calculate the composition of the equilibrium mixture.

Exercise 24-12

By using Table 4-3, estimate the difference in energy between α- and β-glucopyranose at room temperature (25°C). Then calculate it by using the equilibrium percentage.

In Summary

The hemiacetal carbon (anomeric carbon) can have two configurations: α or β.
formyl group and therefore respond to the standard oxidation tests such as exposure to Fehling’s or Tollens’s solutions (Section 17-14). The \( \alpha \)-hydroxy substituent in ketoses is similarly oxidized.

**Results of Fehling’s and Tollens’s Tests on Aldoses and Ketoses**

\[
\begin{align*}
\text{CHO} & \quad \text{COOH} \\
\text{H} & \quad \text{H} \\
\text{HO} & \quad \text{HO} \\
\text{H} & \quad \text{H} \\
\text{H} & \quad \text{H} \\

\text{CHO} & \quad \text{COOH} \\
\text{H} & \quad \text{H} \\
\text{HO} & \quad \text{HO} \\
\text{H} & \quad \text{H} \\
\text{H} & \quad \text{H} \\
\text{CH}_2\text{OH} & \quad \text{CH}_2\text{OH}
\end{align*}
\]

**d-Gluconic acid**

In these reactions, the aldoses are transformed into **aldonic acids**, ketoses into \( \alpha \)-dicarbonyl compounds. Sugars that respond positively to these tests are called **reducing sugars**. All ordinary monosaccharides are reducing sugars.

**Oxidation of aldoses can give mono- or dicarboxylic acids**

Aldonic acids are made on a preparative scale by oxidation of aldoses with bromine in buffered aqueous solution (pH 5–6). For example, d-mannose yields d-mannonic acid in this way. Upon subsequent evaporation of solvent from the aqueous solution of the aldonic acid, the \( \gamma \)-lactone (Section 20-4) forms spontaneously.

**Aldonic Acid Preparation and Subsequent Dehydration to Give an Aldonolactone**

\[
\begin{align*}
\text{CHO} & \quad \text{COH} \\
\text{H} & \quad \text{H} \\
\text{HO} & \quad \text{HO} \\
\text{H} & \quad \text{H} \\
\text{H} & \quad \text{H} \\
\text{CH}_2\text{OH} & \quad \text{CH}_2\text{OH}
\end{align*}
\]

**d-Mannose**

\[
\begin{align*}
\text{CHO} & \quad \text{COH} \\
\text{H} & \quad \text{H} \\
\text{HO} & \quad \text{HO} \\
\text{H} & \quad \text{H} \\
\text{H} & \quad \text{H} \\

\text{H} & \quad \text{H} \\
\text{H} & \quad \text{H} \\
\text{CH}_2\text{OH} & \quad \text{CH}_2\text{OH}
\end{align*}
\]

**d-Mannono-\( \gamma \)-lactone**

**Exercise 24-13**

What would the product be if the oxidation of d-mannose took place at the hemiacetal hydroxy group of the cyclic pyranose form, rather than at the carbonyl group of the open-chain isomer, as shown above?

More vigorous oxidation of an aldose leads to attack at the primary hydroxy function as well as at the formyl group. The resulting dicarboxylic acid is called an **aldaric**, or
saccharic, acid. This oxidation can be achieved with warm dilute aqueous nitric acid (see Section 19-6). For example, d-mannose is converted into d-mannaric acid under these conditions.

![Preparation of an Aldaric Acid](image)

**Exercise 24-14**

The two sugars d-allose and d-glucose (Figure 24-1) differ in configuration only at C3. If you did not know which was which and you had samples of both, a polarimeter, and nitric acid at your disposal, how could you distinguish the two? (**Hint:** Write the products of oxidation.)

**In Summary** The chemistry of the sugars is largely that expected for carbonyl compounds containing several hydroxy substituents. Oxidation (by Br₂) of the formyl group of aldoses gives aldonic acids; more vigorous oxidation (by HNO₃) converts sugars into aldaric acids.

### 24-5 Oxidative Cleavage of Sugars

The methods for oxidation of sugars discussed so far leave the basic skeleton intact. A reagent that leads to C–C bond rupture is periodic acid, HIO₄. This compound oxidatively degrades vicinal diols to give carbonyl compounds.

**Oxidative Cleavage of Vicinal Diols with Periodic Acid**

![Reaction](image)

**Mechanism of Periodic Acid Cleavage of Vicinal Diols**

![Mechanism](image)

The mechanism of this transformation proceeds through a cyclic **periodate ester**, which decomposes to give two carbonyl groups.
Because most sugars contain several pairs of vicinal diols, oxidation with HIO₄ can give complex mixtures. Sufficient oxidizing agent causes complete degradation of the chain to one-carbon compounds, a technique that has been applied in the structural elucidation of sugars. For example, treatment of glucose with five equivalents of HIO₄ results in the formation of five equivalents of formic acid and one of formaldehyde. Similar degradation of the isomeric fructose consumes an equal amount of oxidizing agent, but the products are three equivalents of the acid, two of the aldehyde, and one of carbon dioxide.

**Periodic Acid Degradation of Sugars**

It is found that (1) the breaking of each C–C bond in the sugar consumes one molecule of HIO₄, (2) each aldehyde and secondary alcohol unit furnishes an equivalent of formic acid, and (3) the primary hydroxy function gives formaldehyde. The carbonyl group in ketoses gives CO₂. The number of equivalents of HIO₄ consumed reveals the size of the sugar molecule, and the ratios of products are important clues to the number and arrangement of hydroxy and carbonyl functions. Notice in particular that, after degradation, each carbon fragment retains the same number of attached hydrogen atoms as were present in the original sugar.

**Exercise 24-15**

Write the expected products (and their ratios), if any, of the treatment of the following compounds with HIO₄: (a) 1,2-Ethanediol (ethylene glycol); (b) 1,2-propanediol; (c) 1,2,3-propanetriol; (d) 1,3-propanediol; (e) 2,4-dihydroxy-3,3-dimethylcyclobutanone; (f) d-threose.

**Exercise 24-16**

Would degradation with HIO₄ permit the following sugars to be distinguished? Explain. (For structures, see Figures 24-1 and 24-2.) (a) d-Arabinose and d-glucose; (b) d-erythrose and d-erythrulose; (c) d-glucose and d-mannose.

**In Summary**

Oxidative cleavage with periodic acid degrades the sugar backbone to formic acid, formaldehyde, and CO₂. The ratio of these products depends on the structure of the sugar.

**24-6 Reduction of Monosaccharides to Alditols**

Aldoses and ketoses are reduced by the same types of reducing agents that convert aldehydes and ketones into alcohols. The resulting polyhydroxy compounds are called **alditols**. For example, d-glucose gives d-glucitol (older name, d-sorbitol) when treated with sodium borohydride. The hydride reducing agent traps the small amount of the open-chain form of the sugar, in this way shifting the equilibrium from the unreactive cyclic hemiacetal to the product.
Red seaweed contains relatively large amounts of d-glucitol.

Many alditols are found in nature. d-Glucitol is present in red seaweed in concentrations as high as 14%, as well as in many berries (but not in grapes), in cherries, in plums, in pears, and in apples. It is prepared commercially from d-glucose by high-pressure hydrogenation or by electrochemical reduction. Glucitol is widely used as a sweetener in products such as mints, cough drops, mouthwashes, and chewing gum, where it is often identified by its alternative name, sorbitol. Glucitol is similar in caloric content to glucose. However, the types of bacteria present in the mouth that cause dental caries are less capable of metabolizing glucitol than glucose.

**Exercise 24-17**

(a) Reduction of d-ribose with NaBH₄ gives a product without optical activity. Explain. (b) Similar reduction of d-fructose gives two optically active products. Explain.

**In Summary** Reduction of the carbonyl function in aldoses and ketoses (by NaBH₄) furnishes alditols.

**24-7 Carbonyl Condensations with Amine Derivatives**

As might be expected, the carbonyl function in aldoses and ketoses undergoes condensation reactions with amine derivatives (Section 17-9). For example, treatment of d-mannose with phenylhydrazine gives the corresponding hydrazone, d-mannose phenylhydrazone. Surprisingly, the reaction does not stop at this stage but can be induced to continue with additional phenylhydrazine (two extra equivalents). The final product is a double phenylhydrazone, also called an osazone (here, phenylosazone). In addition, one equivalent each of benzeneamine (aniline), ammonia, and water is generated.

**Phenyldrazone and Phenyllosazone Formation**

The mechanism of osazone synthesis involves tautomerism to a 2-ketoamine, followed by a complex sequence of eliminations and condensations. Once formed, the osazones do
not continue to react with excess phenylhydrazine but are stable under the conditions of the reaction.

Historically, the discovery of osazone formation marked a significant advance in the practical aspects of sugar chemistry. Sugars are well known for their reluctance to crystallize from syrups. Their osazones, however, readily form yellow crystals with sharp melting points, thus simplifying the isolation and characterization of many sugars, particularly if they have been formed as mixtures or are impure.

**Exercise 24-18**

Compare the structures of the phenylosazones of d-glucose, d-mannose, and d-fructose. In what way are they related?

**In Summary** One equivalent of phenylhydrazine converts a sugar into the corresponding phenylhydrazone. Additional hydrazine reagent causes oxidation of the center adjacent to the hydrazone function to furnish the osazone.

**24-8 Ester and Ether Formation: Glycosides**

Because of their multiple hydroxy groups, sugars can be converted into alcohol derivatives. This section explores the formation of simple esters and ethers of monosaccharides and also addresses selective reactions at the anomeric hydroxy group in their cyclic isomers.

**Sugars can be esterified and methylated**

Esters can be prepared from monosaccharides by standard techniques (Sections 19-9, 20-2, and 20-3). Excess reagent will completely convert all hydroxy groups, including the hemiacetal function. For example, acetic anhydride transforms \( \beta \)-d-glucopyranose into the pentaacetate.

**Complete Esterification of Glucose**

\[
\begin{align*}
\text{\( \beta \)-d-Glucopyranose} & \quad \xrightarrow{5 \text{ CH}_3\text{COCH}_3, \text{ pyridine, } 0^\circ \text{C, 24 h}} \quad \text{\( \beta \)-d-Glucopyranose pentaacetate} \\
& \quad \text{(91%)}
\end{align*}
\]

Williamson ether synthesis (Section 9-6) allows complete methylation.

**Complete Methylation of a Pyranose**

\[
\begin{align*}
\text{\( \beta \)-d-Ribopyranose} & \quad \xrightarrow{4 \text{ CH}_3\text{OSCH}_3, \text{ NaOH}} \quad \text{\( \beta \)-d-Ribopyranose tetramethyl ether} \\
& \quad \text{(70%)}
\end{align*}
\]

Notice that the hemiacetal function at C1 is converted into an acetal group. The acetal function can be selectively hydrolyzed back to the hemiacetal (see Section 17-7).
Selective Hydrolysis of a Sugar Acetal

It is also possible to convert the hemiacetal unit of a sugar selectively into the acetal. For example, treatment of d-glucose with acidic methanol leads to the formation of the two methyl acetals. Sugar acetals are called glycosides. Thus, glucose forms glucosides.

Selective Preparation of a Glycoside (Sugar Acetal)

Because glycosides contain a blocked anemic carbon atom, they do not show mutarotation in the absence of acid, they test negatively to Fehling’s and Tollens’s reagents (they are nonreducing sugars), and they are unreactive toward reagents that attack carbonyl groups. Such protection can be useful in synthesis and in structural analysis (see Exercise 24-19).

Exercise 24-19

The same mixture of glucosides is formed in the methylation of d-glucose with acidic methanol, regardless of whether you start with the α or β form. Why?

Exercise 24-20

Draw the structure of methyl α-β-d-arabinofuranoside.

Exercise 24-21

Methyl α-β-d-glucopyranoside consumes two equivalents of HIO₄ to give one equivalent each of formic acid and dialdehyde A (shown in the margin). An unknown aldopentose methyl furanoside reacted with one equivalent of HIO₄ to give dialdehyde A, but no formic acid. Suggest a structure for the unknown. Is there more than one solution to this problem?

Neighboring hydroxy groups in sugars can be linked as cyclic ethers

The presence of neighboring pairs of hydroxy groups in the sugars allows for the formation of cyclic ether derivatives. For example, it is possible to synthesize five- or six-membered cyclic sugar acetals from the vicinal (and also from some β-diol) units by treating them with carbonyl compounds (Section 17-8).
Cyclic Acetal Formation from Vicinal Diols

\[
\text{OH} + \text{CH}_3\text{CCH}_3 \xrightarrow{\text{W}} \text{Acetone acetal}
\]

Such processes work best when the two OH groups are positioned cis to allow a relatively unstrained five- or six-membered ring to form. Cyclic acetal and ether formation is often employed to protect selected alcohol functions. The remaining hydroxy moieties can then be converted into leaving groups, transformed by elimination, or oxidized to carbonyl compounds, as is done in the commercial synthesis of Vitamin C (Chemical Highlight 24-1).

Exercise 24-22

Suggest a synthesis of the compound shown in the margin from D-galactose. (Caution: You will need protecting groups. Hint: Consider a strategy that uses cyclic acetals for protection.)
**In Summary** The various hydroxy groups of sugars can be esterified or converted into ethers. The hemiacetal unit can be selectively protected as the acetal, also called a glycoside. Finally, the various diol units in the sugar backbone can be linked as cyclic acetals, depending on steric requirements.

**24-9 Step-by-Step Buildup and Degradation of Sugars**

Larger sugars can be made from smaller ones and vice versa, by chain lengthening and chain shortening. These transformations can also be used to structurally correlate various sugars, a procedure applied by Fischer to prove the relative configuration of all the stereocenters in the aldoses shown in Figure 24-1.

**Cyanohydrin formation and reduction lengthens the chain**

To lengthen the chain of a sugar, an aldose is first treated with HCN to give the corresponding cyanohydrin (Section 17-11). Because this transformation forms a new stereocenter, two diastereomers appear. Separation of the diastereomers and partial reduction of the nitrile group by catalytic hydrogenation in aqueous acid then gives the aldehyde groups of the chain-extended sugars.

![Sugar Chain Extension Through Cyanohydrins](image)

**Step 1. Cyanohydrin formation**

\[
\begin{align*}
\text{HC} &= \text{O} \\
\text{HC} &= \text{N} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\text{H} &= \text{O} \\
\end{align*}
\]

**Step 2. Reduction and hydrolysis (only one diastereomer is shown)**

In this hydrogenation, a modified palladium catalyst (similar to the Lindlar catalyst, Section 13-6) allows selective reduction of the nitrile to the imine, which hydrolyzes under the reaction conditions. The special catalyst is necessary to prevent the hydrogenation from proceeding all the way to the amine (Section 20-8). The preceding chain-lengthening sequence is an improved and shortened version of what is known as the Kiliani-Fischer* synthesis of chain-extended sugars. In the late 1800s, Kiliani demonstrated that addition of cyanide to an aldose gives the cyanohydrin, which, upon hydrolysis (Sections 19-6 and 20-8), is converted into the chain-extended aldonic acid. Fischer subsequently succeeded in converting this aldonic acid into an aldose by lactone formation (Sections 19-9 and 24-4) followed by reduction (Section 20-4; for Fischer’s reduction method, see Problem 62 at the end of this chapter).

*Professor Heinrich Kiliani (1855–1945), University of Freiburg, Germany; Professor Emil Fischer (see Section 5-4).
Chapter 24

Ruff degradation shortens the chain

Whereas the preceding approach synthesizes higher sugars, complementary strategies degrade higher sugars to lower sugars one carbon at a time. One of these strategies is the Ruff degradation. This procedure removes the carbonyl group of an aldose and converts the neighboring carbon into the aldehyde function of the new sugar.

The Ruff degradation is an oxidative decarboxylation. The sugar is first oxidized to the aldonic acid by aqueous bromine. Exposure to hydrogen peroxide in the presence of ferric ion then leads to the loss of the carboxy group and oxidation of the new terminus to the aldehyde function of the lower aldose.

\[
\begin{align*}
\text{HC} &= \text{O} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\text{H} &\quad \text{OH} \\
\end{align*}
\]

Ruff Degradation of Sugars

The oxidative decarboxylation takes place by means of two one-electron oxidations. The first gives a carboxy radical, which is unstable and rapidly loses CO\(_2\). The resulting hydroxy-substituted radical is oxidized again to give the aldehyde.

Mechanism of Oxidative Decarboxylation

Exercise 24-23

Working with the Concepts: Sugar Synthesis

What are the products of chain extension of d-erythrose?

**Strategy**

As the text above indicates, Kiliani-Fischer chain extension adds a new formyl group to C1 of an aldose, converting the original formyl function into that of a secondary alcohol. Find d-erythrose in Figure 24-2 and identify the sugar(s) that should result from operation of this process.

**Solution**

- d-Erythrose is a four-carbon aldose. Addition of a formyl substituent to C1 leaves C2, C3, and C4 unchanged, while changing the original carbonyl group to that of a secondary alcohol. The emerging new stereocenter may form with either the R or S configuration.
- Figure 24-2 shows that both d-ribose and d-arabinose have five carbons, and in both of them the “bottom” three carbons (C3, C4, and C5) are identical in structure and stereochemistry to the corresponding three carbon atoms (C2, C3, and C4) in d-erythrose. d-Ribose and d-arabinose differ only at C2, the new stereocenter. They are the products of d-erythrose chain extension.

Exercise 24-24

Try It Yourself

What are the chain-extension products of d-arabinose?

*Professor Otto Ruff (1871–1939), University of Danzig, Germany.
Chapter 24

Carbohydrates

Ruff degradation gives low yields because of the sensitivity of the products to the reaction conditions. Nevertheless, the procedure is useful in structural elucidations (Exercise 24-25). Fischer originally carried out such studies to establish the relative configurations of the monosaccharides (the Fischer proof). The next section will describe some of the logic behind his approach to the problem.

Exercise 24-25

Ruff degradation of two D pentoses, A and B, gave two new sugars, C and D. Oxidation of C with HNO₃ gave meso-2,3-dihydroxybutanedioic (tartaric) acid, that of D resulted in an optically active acid. Oxidation of either A or B with HNO₃ furnished an optically active aldaric acid. What are compounds A, B, C, and D?

CHEMICAL HIGHLIGHT 24-2

Sugar Biochemistry

In nature, carbohydrates are produced primarily by a reaction sequence called photosynthesis (see also Section 9-11). In this process, sunlight impinging on the chlorophyll of green plants is absorbed. The photochemical energy thus obtained is used to convert carbon dioxide and water into oxygen and the polyfunctional structure of carbohydrates.

The detailed mechanism of this transformation is complicated and takes many steps, the first of which is the absorption of one quantum of light by the extended π system (Section 14-11) of chlorophyll (chloros, Greek, green, and phyllon, Greek, leaf).

Photosynthesis of Glucose in Green Plants

\[ 6 \text{CO}_2 + 6 \text{H}_2\text{O} \xrightarrow{\text{Sunlight, chlorophyll}} \text{C}_6(\text{H}_2\text{O})_6 + 6 \text{O}_2 \]

Chemical Highlight 18-1 described an aldol-based biosynthesis of carbohydrates, and Chemical Highlight 23-2 introduced thiamine pyrophosphate (TPP) in its role in the metabolism of glucose to produce biochemical energy. Here we illustrate another biochemical sequence that uses thiamine catalysis to interconvert ketoses.

In ketose interconversion, the enzyme transketolase employs a molecule of thiamine to catalyze the transfer of a (hydroxymethyl)carbonyl unit from xylulose to erythrose, producing fructose in the process.

Mechanistically, the deprotonated thiazolium ion first attacks the carbonyl group of the donor sugar (xylulose) to form an addition product, in a way completely analogous to addition to aldehydes (Section 23-4). Because the donor sugar contains a hydroxy group next to the reaction site, this initial product can decompose by the reverse of the addition process to an aldehyde (glyceraldehyde) and a new thiamine intermediate. This new intermediate attacks another aldehyde (erythrose) to produce a new addition product. The catalyst then dissociates as TPP, releasing the new sugar molecule (fructose).

The cycle of photosynthesis, carbohydrate interconversion, and carbohydrate metabolism is a beautiful example of how nature reuses its resources. First, CO₂ and H₂O are consumed to convert solar energy into chemical energy and O₂. When an organism needs some of the stored energy, it is generated by conversion of carbohydrate into CO₂ and H₂O, using up roughly the same amount of O₂ originally liberated.
In Summary Sugars can be made from other sugars by step-by-step one-carbon chain lengthening (cyanohydrin formation and reduction) or shortening (Ruff degradation).

24-10 Relative Configurations of the Aldoses: An Exercise in Structure Determination

Imagine that we have been presented with 14 jars, each filled with one of the aldoses in Figure 24-1, each labeled with a name, but no structural formula. How would we establish the structure of each substance without using spectroscopy?

This was the challenge faced by Fischer over a century ago. In an extraordinary display of scientific logic, Fischer solved this problem by interpreting the results of a combination of carefully thought out synthetic manipulations, designed to convert the aldoses he had
available to him into one another and into related substances. Fischer made one assumption: That the dextrorotatory enantiomer of 2,3-dihydroxypropanal (glyceraldehyde) had the D (and not the L) configuration. This assumption was proved correct only after a special kind of X-ray analysis was developed in 1950, long after Fischer’s time. Fischer’s was a lucky guess; otherwise, all the structures of the d sugars in Figure 24-1 would have had to be changed into their mirror images. Fischer’s goal was to establish the relative configurations of all the stereoisomers—that is, to associate each unique sugar with a unique relative sequence of stereocenters.

The structures of the aldotetroses and aldopentoses can be determined from the optical activity of the corresponding aldaric acids

Beginning with the structure of D-glyceraldehyde, we shall now set out to prove unambiguously the structures of the higher D aldoses. We shall use Fischer’s logic, although not his procedures, because most of these aldoses were unavailable in his time. (Consult Figure 24-1 as required while following these arguments.) We begin with chain extension of D-glyceraldehyde, obtaining a mixture of D-erythrose and D-threose. Oxidation of D-erythrose with nitric acid gives optically inactive meso-tartaric acid, which tells us that D-erythrose must have structure 1, with both \(-\text{OH}\) groups on the same side in the Fischer representation. In contrast, oxidation of D-threose forms an optically active acid. Thus, D-threose must have the opposite stereochemistry at C2 (structure 2). Both must have the same (\(R\)) configuration at C3, the carbon derived from the C2 stereocenter of our starting material, D-glyceraldehyde. The difference is at C2: D-erythrose is 2\(R\); D-threose, 2\(S\).

Now that we know the structures of D-erythrose and D-threose, we continue as follows. Chain extension of D-erythrose (Exercise 24-23) gives a mixture of two pentoses: D-ribose and D-arabinose. Their configurations at C3 and C4 must be the same as those of C2 and C3 in D-erythrose; they differ at C2, the new stereocenter created in the lengthening procedure. Nitric acid oxidation of D-ribose gives an optically inactive (meso) acid; thus D-ribose has structure 3. D-Arabinose oxidizes to an optically active acid; it must have structure 4.

Proceeding in the same way from D-threose, chain extension gives a mixture of D-xylose and D-lyxose. The oxidation product of D-xylose is meso; therefore D-xylose has structure 5. The optically active oxidation product of D-lyxose confirms its structure as 6.
Symmetry properties also define the structures of the aldohexoses

We now know the structures of the four aldopentoses and can extend the chain of each of them. This process gives us four pairs of aldohexoses, each pair distinguished from the others by the unique sequence of stereocenters at C3, C4, and C5. The members of each pair differ only in their configuration at C2.

The structural assignment for the four sugars obtained from d-ribose and d-lyxose, respectively, is again accomplished by oxidation to the corresponding aldaric acids. Both d-allose and d-galactose give optically inactive oxidation products, in contrast with d-altrose and d-talose, which give optically active dicarboxylic acids.

The structural assignments of the four remaining hexoses (with structures 7–10) cannot be based on the approach taken so far, because all give optically active diacids upon oxidation. We join the actual strategy devised by Fischer to solve a problem that had become substantially more complicated. He found that chain extension of d-arabinose gave a mixture of d-glucose and d-mannose, one of which must have structure 7 and the other structure 8. Displaying synthetic creativity decades ahead of his time, he developed a procedure to exchange the functionalities at C1 and C6 of a hexose—converting C1 to a primary alcohol and C6 to an aldehyde. Carrying out this procedure starting with both d-glucose and d-mannose, he found that the result of C1/C6 exchange in glucose was a new sugar, which did not exist in nature and was given the name gulose. On the other hand, exchange of C1 and C6 in mannose returned mannose, unchanged. Examination of structures 7 and 8 reveals why this is so and gives us a glimpse of Fischer’s genius. If we perform a C1/C6 exchange in 8 and then rotate the resulting Fischer projection by 180°, we realize that the initial and final structures are identical: The exchange procedure gives the original sugar back. Thus 8 is identified as the structure of d-mannose, and 7, in which C1/C6 exchange gives a new structure, must correspond to d-glucose.

Exercise 24-26

Was the gulose that Fischer synthesized from d-glucose a d-sugar or an l-sugar? (Caution: In a very uncharacteristic oversight, Fischer himself got the wrong answer at first, and that confused everybody for years.)
Chapter 24  Carbohydrates

With the synthesis of gulose, one of the two remaining hexoses (the products of chain lengthening of d-xylose) was identified as structure 9. By process of elimination, the other, d-idose, could be assigned structure 10, thus completing the exercise.

**In Summary**  Step-by-step one-carbon chain lengthening or shortening, in conjunction with the symmetry properties of the various aldaric acids, allows the stereochemical assignments of the aldoses.

24-11 Complex Sugars in Nature: Disaccharides

A substantial fraction of the natural sugars occur in dimeric, trimeric, higher oligomeric (between 2 and 10 sugar units), and polymeric forms. The sugar most familiar to us, so-called table sugar, is a dimer.

**Sucrose is a disaccharide derived from glucose and fructose**

Sucrose, ordinary table sugar (see Chapter Opening), is one of the few natural chemicals consumed in unmodified form (water and NaCl are examples of others). Its average yearly consumption in the United States is about 175 pounds per person. Sugar is isolated from sugar cane and sugar beets, in which it is particularly abundant (about 14–20% by weight), although it is present in many plants in smaller concentrations. World production is about 150 million tons a year.

Sucrose has not been considered in this chapter so far, because it is not a simple monosaccharide; rather, it is a disaccharide composed of two units, glucose and fructose. The structure of sucrose can be deduced from its chemical behavior. Acidic hydrolysis splits it into glucose and fructose. It is a nonreducing sugar. It does not form an osazone. It does not undergo mutarotation. These findings suggest that the component monosaccharide units are linked by an acetal bridge (Section 17-7) connecting the two anomeric carbons; in this way, the two cyclic hemiacetal functions block each other. X-ray structural analysis confirms this hypothesis: Sucrose is a disaccharide in which the \(\alpha\)-d-glucopyranose form of glucose is attached to \(\beta\)-d-fructofuranose in this way.

 Sucrose is a pure chemical compound and forms large crystals from saturated aqueous solutions.

Both anomic carbons in sucrose are parts of acetal functional groups.

Fischer proved that his structural reasoning was correct by comparing the nitric acid oxidation of d-glucose to that of his synthetic gulose. What do these two reactions produce?

With the synthesis of gulose, one of the two remaining hexoses (the products of chain lengthening of d-xylose) was identified as structure 9. By process of elimination, the other, d-idose, could be assigned structure 10, thus completing the exercise.

**Exercise 24-28**

In the preceding discussion, we assigned the structures of d-ribose and d-arabinose by virtue of the fact that, upon oxidation, the first gives a meso diacid, the second an optically active diastereomer. Could you arrive at the same result by \(^{13}\)C NMR spectroscopy?

**Sucrose has a specific rotation of** \(+66.5\). Treatment with aqueous acid decreases the rotation until it reaches a value of \(-20\). The same effect is observed with the enzyme invertase. The phenomenon, known as the inversion of sucrose, is related to mutarotation
of monosaccharides. It includes three separate reactions: hydrolysis of the disaccharide to the component monosaccharides α-D-glucopyranose and β-D-fructofuranose; mutarotation of α-D-glucopyranose to the equilibrium mixture with the β form; and mutarotation of β-D-fructofuranose to the slightly more stable β-D-fructopyranose. Because the value for the specific rotation of fructose (−92) is more negative than the value for glucose (+52.7) is positive, the resulting mixture, sometimes called invert sugar, has a net negative rotation, inverted from that of the original sucrose solution.

Inversion of Sucrose

The noncaloric, edible fat substitute olestra (Chemical Highlight 21-1) consists of a mixture of sucroses esterified with seven or eight fatty acids obtained from vegetable oils, such as hexadecanoic (palmitic) acid. The fatty acids shield the sucrose core of olestra so effectively that it is completely immune to attack by digestive enzymes and passes through the digestive tract unchanged.

Exercise 24-29

Write the products (if any) of the reaction of sucrose with excess \((\text{CH}_3)_2\text{SO}_4, \text{NaOH}\).

**Strategy**
The chemistry of disaccharides and other more complex carbohydrates is largely the same as that of monosaccharides. Identify the functional groups present and consider processes comparable to those described earlier for simple sugars.

**Solution**
- Dimethyl sulfate is a reagent that is commonly used to convert alcohols into methyl ethers via the Williamson ether synthesis (Sections 9-6 and 22-8). (Iodomethane would be equally effective but is more costly.)
- As illustrated by the example in Section 24-8, dimethyl sulfate methylates all free −OH groups in a molecule, converting them into −OCH₃ groups by SN₂ processes. Carrying out this reaction with sucrose gives the product

For the follow-up Exercise 24-30, see next page.
Acetals link the components of complex sugars

Sucrose contains an acetal linkage between the anomeric carbons of the component sugars. One could imagine other acetal linkages with other hydroxy groups. Indeed, maltose (malt sugar), which is obtained in 80% yield by enzymatic (amylase) degradation of starch (to be discussed in the next section), is a dimer of glucose in which the hemiacetal oxygen of one glucose molecule (in the α anomeric form) is bound to C4 of the second.
The most recent successful entrant into the artificial sweetener marketplace is sucralose (marketed in the United States as Splenda®). A trichlorinated derivative of sucrose, sucralose is 600 times as sweet as sucrose. It has the benefit of sufficient heat stability to be usable in cooking and baking, and it is available in a variety of forms appropriate to its diverse potential uses. Sucralose is absorbed to a limited extent by the digestive tract, but there is no evidence of any ill effects in humans. Sucralose has been approved for safe consumption in dozens of countries, including the United States and Canada.

Exercise 24-31

Draw the structure of the initial product of β-maltose when it is subjected to (a) Br₂ oxidation; (b) phenylhydrazine (3 equivalents); (c) conditions that effect mutarotation.
Another common disaccharide is cellobiose, obtained by the hydrolysis of cellulose (to be discussed in the next section). Its chemical properties are almost identical with those of maltose, and so is its structure, which differs only in the stereochemistry at the acetal linkage—\(\beta\) instead of \(\alpha\).

Aqueous acid cleaves cellobiose into two glucose molecules just as efficiently as it hydrolyzes maltose. However, enzymatic hydrolysis requires a different enzyme, \(\beta\)-glucosidase, which specifically attacks only the \(\beta\)-acetal bridge. In contrast, maltase is specific for \(\alpha\)-acetal units of the type found in maltose.

After sucrose, the most abundant natural disaccharide is lactose (milk sugar). It is found in human and most animal milk (about 5% solution), constituting more than one-third of the solid residue remaining on evaporation of all volatiles. Its structure is made up of galactose and glucose units, connected in the form of a \(\beta\)-d-galactopyranosyl-\(\alpha\)-d-glucopyranose. Crystallization from water furnishes only the \(\alpha\) anomer.

Lactose contains an unprotected hemiacetal unit and is therefore a reducing sugar that undergoes mutarotation. The first step of its degradation in the body is hydrolysis of the glycosidic bond by the enzyme lactase to give galactose and glucose. Lack of this enzyme causes lactose intolerance, a condition that is associated with abdominal cramps and diarrhea after the consumption of milk and other dairy products.

In Summary Sucrose is a dimer derived from linking \(\alpha\)-d-glucopyranose with \(\beta\)-d-fructofuranose at the anomeric centers. It shows inversion of its optical rotation on hydrolysis to its mutarotating component sugars. The disaccharide maltose is a glucose dimer in which the components are linked by a carbon–oxygen bond between an \(\alpha\) anomeric carbon of a glucose molecule and C4 of the second. Cellobiose is almost identical with maltose but has \(\alpha\ \beta\) configuration at the acetal carbon. Lactose has a \(\beta\)-d-galactose linked to glucose in the same manner as in cellobiose.

24-12 Polysaccharides and Other Sugars in Nature

Polysaccharides are the polymers of monosaccharides. Their possible structural diversity exceeds that of alkene polymers (Sections 12-14 and 12-15), particularly in variations of chain length and branching. Nature, however, has been remarkably conservative in its construction of such macromolecules. The three most abundant natural polysaccharides—cellulose, starch, and glycogen—are derived from the same monomer: glucose.

Cellulose and starch are unbranched polymers

Cellulose is a poly-\(\beta\)-glucopyranoside linked at C4, containing about 3000 monomeric units and having a molecular weight of about 500,000. It is largely linear.
Individual strands of cellulose tend to align with one another and are connected by multiple hydrogen bonds. The development of so many hydrogen bonds is responsible for the highly rigid structure of cellulose and its effective use as the cell-wall material in organisms. Thus, cellulose is abundant in trees and other plants. Cotton fiber is almost pure cellulose, as is filter paper. Wood and straw contain about 50% of the polysaccharide.

Like cellulose, starch is a polyglucose, but its subunits are connected by $\alpha$-acetal linkages. It functions as a food reserve in plants and (like cellulose) is readily cleaved by aqueous acid into glucose. Major sources of starch are corn, potatoes, wheat, and rice. Hot water swells granular starch and allows the separation of the two major components: amylose (~20%) and amylopectin (~80%). Both are soluble in hot water, but amylose is less soluble in cold water. Amylose contains a few hundred glucose units per molecule (molecular weight, 150,000–600,000). Its structure is different from that of cellulose, even though both polymers are unbranched. The difference in the stereochemistry at the anomeric carbons leads to the strong tendency of amylose to form a helical polymer arrangement (not the straight chain shown in the formula). Note that the disaccharide units in amylose are the same as those in maltose.

In contrast with amylose, amylopectin is branched, mainly at C6, about once every 20 to 25 glucose units. Its molecular weight runs into the millions.
Glycogen is a source of energy

Another polysaccharide similar to amylopectin but with greater branching (1 per 10 glucose units) and of much larger size (as much as 100 million molecular weight) is glycogen. This compound is of considerable biological importance because it is one of the major energy-storage polysaccharides in humans and animals and because it provides an immediate source of glucose between meals and during (strenuous) physical activity. It is accumulated in the liver and in rested skeletal muscle in relatively large amounts. The manner in which cells make use of this energy storage is a fascinating story in biochemistry.

A special enzyme, glycogen phosphorylase, first breaks glycogen down to give a derivative of glucose, $\alpha$-D-glucopyranosyl 1-phosphate. This transformation takes place at one of the nonreducing terminal sugar groups of the glycogen molecule and proceeds step by step—one glucose molecule at a time. Because glycogen is so highly branched, there are many such end groups at which the enzyme can “nibble” away, making sure that, at a time of high-energy requirements, a sufficient amount of glucose becomes available quickly.
Chapter 24

Phosphorylase cannot break $\alpha$-1,6-glycosidic bonds. As soon as it gets close to such a branching point (in fact, as soon as it reaches a terminal residue four units away from that point), it stops (Figure 24-4). At this stage, a different enzyme comes into play, transferase, which can shift blocks of three terminal glucosyl residues from one branch to another. One glucose substituent remains at the branching point. Now a third enzyme is required to remove this last obstacle to obtaining a new straight chain. This enzyme is specific for the kind of bond at which cleavage is needed; it is $\alpha$-1,6-glucosidase, also known as the debranching enzyme. When this enzyme has completed its task, phosphorylase can continue degrading the glucose chain until it reaches another branch, and so forth.

**Cell-surface carbohydrates mediate cell-recognition processes**

For multicellular organisms to function, each of the great variety of cells must be able to recognize and interact specifically with other cells and with various chemical species. These specific interactions are described as cell-recognition processes. Cell recognition usually involves noncovalent binding, commonly by means of hydrogen bonds, with molecules on the exterior surface of the cell. After binding takes place, movement of extracellular material into the interior of the cell may occur.

Cell recognition is central to virtually every cell function. Examples of recognition in cell–cell interactions include the response of the immune system to invasion by “foreign” cells, infection of cells by bacteria or viruses, and fertilization of ova by sperm. Certain bacteria, such as cholera and pertussis (“whooping cough”), do not invade cells directly, but the toxins they produce bind to cell surfaces and are subsequently “escorted” inside.

These recognition processes are based on carbohydrates that are present on cell surfaces. These carbohydrates are linked either to lipids (glycolipids; Section 20-5) or to proteins (glycoproteins; Chapter 26) that are embedded in the cell wall (Figure 24-5). Glucosyl cerebroside is the simplest of the glycolipids and illustrates key features of this class of
Carbohydrates compounds: a polar carbohydrate “head” that resides on the cell surface, attached to two virtually nonpolar “tails” that embed in the cell membrane. Differences in carbohydrate composition at the “head” give rise to the different functions that these species display. For example, cholera toxin binds specifically to a glycolipid called GM1 pentasaccharide. This substance is found naturally at the surface of the cells of the intestine that are responsible for water absorption. The result is disruption of this function and severe diarrhea.

The human blood groups—O, A, B, and AB—are each characterized by different oligosaccharides on the red blood cell surface. When an incompatible blood type is introduced by transfusion, the body’s immune system produces antibodies that bind to the oligosaccharides on the surfaces of the foreign red cells, causing them to clump together. The result is widespread clogging of blood vessels and death. Type O cells are “coated” with a hexasaccharide whose structure is common to all four blood groups; therefore, type O cells are not recognized as “foreign” by any recipient, regardless of blood type. In type A and type B blood cells, two different additional saccharides are linked to the type O hexasaccharide. It is this “seventh” saccharide that triggers the immune response. Therefore, persons of types A and B cannot donate to each other, and neither can donate to someone of type O. By contrast, type AB cells

Figure 24-5 Schematic drawing illustrating carbohydrate recognition at the cell surface, enabling cell–cell binding, in addition to adhesion of other species, such as microbes (bacteria, viruses, and bacterial toxins). The sugar chains can be linked to proteins (red ribbons).
contain both the type A and type B saccharides, and therefore individuals with type AB blood can receive transfusions from any donor without risk of immune system reaction.

Oddly enough, the biological purpose (if any) of the blood cell surface oligosaccharides is a mystery. Some scientists speculate that the presence of different blood groups (and the associated antibodies) may play a role in inhibiting viral infection: Viruses transmitted between persons with different blood groups might have a greater likelihood of being recognized as “foreign” and destroyed by the recipient’s immune system. Nevertheless, people with a rare genetic abnormality that prevents their blood cells from forming any surface oligosaccharides are still capable of living normal, healthy lives.

Modified sugars may contain nitrogen

Many of the naturally occurring sugars have a modified structure or are attached to some other organic molecule. In one large class of sugars, at least one of the hydroxy groups has been replaced by an amine function. They are called glycosylamines when the nitrogen is attached to the anomeric carbon and amino deoxy sugars when it is located elsewhere.

When a sugar is attached by its anomeric carbon to the hydroxy group of another complex residue, it is called a glycosyl group. The remainder of the molecule (or the product after removal of the sugar by hydrolysis) is called the aglycon. An example is adriamycin, a member of the anthracycline family of antibiotics. Adriamycin and its deoxy analog daunomycin have been remarkably effective in the treatment of a wide variety of human cancers. They now constitute a cornerstone of combination cancer chemotherapy. The aglycon part of these systems is a linear tetracyclic framework incorporating an anthraquinone moiety (derived from anthracene; see Section 15-5). The amino sugar is called daunosamine.

An unusual group of antibiotics, the aminoglycoside antibiotics, is based on oligosaccharide structures almost exclusively. Of particular therapeutic importance is streptomycin (an antituberculosis agent), isolated in 1944 from cultures of the mold Streptomyces griseus. The molecule consists of three subunits: the furanose streptose, the glucose derivative 2-deoxy-2-methylamino-D-glucose (an example of the rare D form), and streptidine, which is actually a hexasubstituted cyclohexane.

In Summary The polysaccharides cellulose, starch, and glycogen are polyglucosides. Cellulose consists of repeating dimeric cellobiose units. Starch may be regarded as a polymaltose derivative. Its occasional branching poses a challenge to enzymatic degradation, as does
Carbohydrates

Chapter 24

Glycogen. Metabolism of these polymers first gives monomeric glucose, which is then further degraded. Finally, many sugars exist in nature in modified form or as simple appendages to other structures. Examples include cell-surface carbohydrates and amino sugars. The amino-glycoside antibiotics consist entirely of saccharide molecules, modified and unmodified.

THE BIG PICTURE

The carbohydrates are a broad and diverse class of compounds, responsible for countless functions in biological chemistry. Nonetheless, their chemical behavior and their biological activity arise directly from their structures as polyfunctional molecules with well-defined shapes, which in turn result from their stereochemical characteristics. Their study provides an excellent opportunity to review the properties of the carbonyl and hydroxy functional groups, and to explore how such simple structural components can give rise to a rich array of molecular properties.

We continue in Chapter 25 with a look at heterocyclic compounds, also powerful contributors to biological function, but with structures built around rings. These systems contain oxygen, sulfur, or nitrogen atoms in addition to carbon. In Chapter 26, we will return to systems in which carbohydrates play an important role when we discuss the nucleic acids.

CHEMICAL HIGHLIGHT 24-4

Sialic Acid, “Bird Flu,” and Rational Drug Design

In 1918 an influenza strain of unprecedented virulence jumped from its normal avian hosts to humans. By the time the outbreak subsided a year later, this “flu” killed as many as 100 million people—the numbers were so staggering that only estimates are possible—nearly 5% of the world’s population. The flu virus is a simple entity, its biochemistry governed by a half-dozen or so segments of RNA (Chapter 26) that control the synthesis of a handful of proteins. Two proteins in particular, hemagglutinin (HA) and neuraminidase (NA), determine the virus’s ability to bind to and infect cells and to reproduce by release of new virus particles from infected cells, respectively.

Influenza viruses mutate rapidly, giving rise to strains that generate modified versions of HA and NA. The flu responsible for the 1918–1919 pandemic is labeled H1N1. In all, 16 forms of HA and 9 of NA have been identified. The H5N1 strain is of most current concern: It infects vast populations of birds worldwide, especially in Southeast Asia. At present, H5N1 rarely jumps to humans, but, like H1N1, it is highly lethal when it does. The fear that a mutant variety of H5N1 will gain the ability of human-to-human transmission has sparked considerable research into vaccines to prevent infection, as well as antiviral drugs that inhibit the function of viral proteins such as NA once infection has occurred. The vaccine route is made more difficult by the tendency of the virus to mutate in almost every reproductive cycle. The antiviral strategy relies on the known biochemistry of a carbohydrate that occurs naturally in the blood and tissues of all vertebrate animals: sialic acid.

Sialic acid describes not one but a group of compounds, N- or O-substituted derivatives of neuraminic acid, a monosaccharide with a nine-carbon backbone. These compounds have essential biological functions in the blood, in the brain (especially for learning and memory), and elsewhere. The term “sialic acid” is often used to refer to the most common member of the family, N-acetylneuraminic acid (Neu5Ac). Sialic acid also protects organisms from invading pathogens; paradoxically, however, its presence on cell surfaces facilitates the binding of HA of the influenza virus, which leads to infection.

In the 1970s, studies identified a sialic acid derivative, DANA, that bound to NA and inhibited viral reproduction. An X-ray crystal structure study of the DANA–NA complex showed that the hydroxy group at C4 of the bound derivative was located close to a negatively charged carboxylate ion that was essential for NA activity. Carboxylic acids have a pK_a of about 4 (Section 19-4); therefore, at the nearly neutral pH of the body’s fluids, an acid will be in the form of its conjugate base. In an effort to make this binding stronger, a group of Australian chemists converted the C4 hydroxy into an amino group, which would be mostly protonated at pH = 7 (Section 21-4). The amine analog was found to bind to and inhibit NA 100 times more strongly. In a final modification, this substituent was converted to a guanidino function.

In 1918 an influenza strain of unprecedented virulence jumped from its normal avian hosts to humans. By the time the outbreak subsided a year later, this “flu” killed as many as 100 million people—the numbers were so staggering that only estimates are possible—nearly 5% of the world’s population. The amine analog was found to bind to and inhibit NA 100 times more strongly. In a final modification, this substituent was converted to a guanidino function,
Rutinose is a sugar that is part of several bioflavonoids, compounds found in many plants that have significant therapeutic value in maintaining cardiovascular health in general and the strength of the walls of blood vessels in particular. Rutin is one rutinose-containing bioflavonoid found in buckwheat and eucalyptus. Hesperidin is another, derived from the peels of lemons and oranges. Each contains rutinose bound to a tricyclic aglycon (Section 24-12).

Use the following information to deduce a structure for the sugar rutinose.
a. Rutinose is a reducing sugar that, upon acid hydrolysis, gives one equivalent each of d-glucose and a sugar A with the formula C₆H₁₂O₅. Sugar A reacts with four equivalents of HIO₄ to give four equivalents of formic acid and one equivalent of acetaldehyde. What can we conclude regarding sugar A at this stage?

**SOLUTION**

What does the result of HIO₄ degradation tell us? Each equivalent of HIO₄ cleaves a bond between two oxygen-bearing carbon atoms. As the examples in Section 24-5 illustrate, formic acid can arise from either a terminal formyl group or an internal secondary hydroxy group. Acetaldehyde is an unusual degradation product. Its formation implies a terminal methyl substituent, attached to a secondary hydroxy carbon. A logical reconstruction of sugar A from this information may look like this:

```
  HCOOH → CHO
  HCOOH → CHO
  HCOOH → CHO
  HCOOH → CHO
  CH₃
```

As a check, we note that our structure does indeed have the molecular formula C₆H₁₂O₅.

b. Sugar A can be synthesized from L-(-)-mannose as shown in the margin. Step 3 (noted by an asterisk) is a special reaction that converts the terminal primary alcohol into a carboxylic acid group. What does this result reveal about the stereocenters in sugar A?

**SOLUTION**

We follow the reaction sequence step by step to obtain the full open-chain structure of sugar A:

```
1. HSCH₂CH₂SH, ZnCl₂
2. Raney Ni
(Section 17-8)
3. O₂, Pt
(Section 24-4)
4. Δ (→H₂O)
(Section 24-4)
5. [(CH₃)₂CHCH₂]₂AlH
(Section 20-4)
```

Sugar A has the name 6-deoxy-L-mannose.

c. Complete methylation of rutinose with the use of excess dimethyl sulfate (Section 24-8) gives a heptamethylated derivative. On subsequent mild acid hydrolysis, one equivalent of 2,3,4-tri-O-methyl-d-glucose and one equivalent of the 2,3,4-tri-O-methyl derivative of sugar A are obtained. What possible structure(s) of rutinose is consistent with these data?

**SOLUTION**

Dimethyl sulfate treatment converts all free –OH groups into –OCH₃ moieties (Section 24-8). Therefore, we may conclude that rutinose possesses seven hydroxy substituents, and (at least) one must be
part of a cyclic hemiacetal function. Recall that rutinose is a reducing sugar (Section 24-4). We may also conclude that both monosaccharide components of rutinose are in cyclic forms. Why? The open-chain forms of glucose and sugar A contain a total of nine –OH groups. For rutinose to possess only seven, two of the original nine must be built into a cyclic glycosidic acetal function linking the sugars, similar to the linkages in the disaccharides maltose, cellobiose, and lactose (Section 24-11).

Acid hydrolysis of the heptamethylated rutinose gives two trimethylated monosaccharides. Acid cleaves the glycoside linkage between the two sugars (Section 24-11), but where did the seventh methyl group go? It must have been attached to a hemiacetal oxygen, in the form of a methyl glycoside—an acetal—which we know is cleaved by acid much more easily than an ordinary methyl ether (Section 24-8). The six methyl groups (at carbons 2, 3, and 4 in the two resulting monosaccharides) must be bound to oxygen atoms that are *not* part of either the glycosidic linkage between the sugars or their rings. Only the oxygen atoms left unmethylated by dimethyl sulfate treatment can constitute these parts of rutinose. Thus, we may conclude that the oxygens at C5 in both methylated monosaccharide products are contained in pyranose (six-membered) rings, because five-membered rings would have contained the oxygens at C4 instead. We are almost finished. There remain three hydroxy groups that are candidates for the linkage between the sugars: the hemiacetal –OH at C1 of sugar A and either the C1 hemiacetal hydroxy or the C6 primary –OH of the glucose. To summarize:

In fact, we already have the answer: Rutinose is a reducing sugar and must therefore possess at least one hemiacetal function. The only option therefore is to assign the latter to the glucose moiety and the glycoside bond to C6–OH and C1 of sugar A. We conclude by redrawing the structures in more descriptive Haworth projections and chair conformations (the stereochemistry at C1 of sugar A is not defined) by following the procedures in Section 24-2. In the following three drawings, the glucopyranose moieties are below the sugar A plane. Because A is an l sugar, care is necessary to preserve the proper absolute stereochemistry. One method is to follow the same procedure as for d sugars: Place the ether linkage in back and rotate the Fischer projection 90° clockwise, such that groups originally on the right in the Fischer projection now point downward and those on the left point upward. Indicators d and l refer to the configuration at C5. Whereas the substituent (C6) at this position points upward in a d sugar, with C5 inverted, this group must now point downward. The two structures I and II below result. An equally correct alternative is to rotate the Fischer projection of an l sugar the opposite way—counterclockwise. In this manner structure III at the right is obtained. Notice that the C6 methyl group now points upward, the anomeric carbon (C1) is to the left, and the structure of sugar A is presented in a view rotated by 180° about an axis perpendicular to the page, relative to the drawings at the right. Build models!

\text{H} &\text{OH} &\text{CH}_2\text{OH}
\end{align*}
\]

Important Concepts

1. Carbohydrates are naturally occurring polyhydroxycarbonyl compounds that can exist as monomers, dimers, oligomers, and polymers.

2. Monosaccharides are called aldoses if they are aldehydes and ketoses if they are ketones. The chain length is indicated by the prefix tri-, tet-, pent-, hex-, and so forth.

3. Most natural carbohydrates belong to the D family; that is, the stereocenter farthest from the carbonyl group has the same configuration as that in (+)-2,3-dihydroxypropanal [D-(+)-glyceraldehyde].

4. The keto forms of carbohydrates exist in equilibrium with the corresponding five-membered (furanoses) or six-membered (pyranoses) cyclic hemiacetals. The new stereocenter formed by cyclization is called the anomeric carbon, and the two anomers are designated α and β.

5. Haworth projections of D sugars depict the cyclic ether in line notation as a pentagon or a hexagon, the anomeric carbon placed on the right and the ether oxygen at the top. The substituents located above or below the ring are attached to vertical lines. The ring bond at the bottom (between C2 and C3) is understood to be in front of the plane of the paper, and the ring bonds containing the oxygen are understood to be in back. The α anomer has the OH group at the anomeric carbon pointing downward, whereas the β anomer has it pointing upward.

6. Equilibration between anomers in solution gives rise to changes in the measured optical rotation called mutarotation.

7. The reactions of the saccharides are characteristic of carbonyl, alcohol, and hemiacetal groups. They include oxidation of the aldehyde to the carboxy function of aldonic acids, double oxidation to aldaric acids, oxidative cleavage of vicinal diol units, reduction to alditols, condensations, esterifications, and acetal formations.
8. Sugars containing hemiacetal functions are called reducing sugars, because they readily reduce Tollens’ and Fehling’s solutions. Sugars in which the anomeric carbon is acetalized are nonreducing.

9. The synthesis of higher sugars is based on chain lengthening, the new carbon being introduced by cyanide ion. The synthesis of lower sugars relies on Ruff chain shortening, a terminal carbon being expelled as CO₂.

10. The Fischer proof uses the techniques of chain lengthening and shortening together with the symmetry properties of aldaric acids to determine the structures of the alsoses.

11. Di- and higher saccharides are formed by the combination of hemiacetal and alcohol hydroxy groups of two sugars to give an acetal linkage.

12. The change in optical rotation observed in acidic aqueous solutions of sucrose, called the inversion of sucrose, is due to the equilibration of the starting sugar with the various cyclic and anomeric forms of its component monomers.

13. Many sugars contain modified backbones. Amino groups may have replaced hydroxy groups, there may be substituents of various complexity (aglycons), the backbone carbon atoms of a sugar may lack oxygens, and (rarely) the sugar may adopt the l configuration.

Problems

33. The designations d and l as applied to sugars refer to the configuration of the highest-numbered stereocenter. If the configuration of the highest numbered stereocenter of d-ribose (Figure 24-1) is switched from d to l, is the product l-ribose? If not, what is the product? How is it related to d-ribose (i.e., what kind of isomers are they)?

34. To which classes of sugars do the following monosaccharides belong? Which are d and which are l?

(a) HOCH₂-OH  
   (b) HOH  
   (c) CH₃  
   (+)-Apiose  
   (-)-Rhamnose  
   (+)-Mannoheptulose

35. Draw open-chain (Fischer-projection) structures for l-(+)-ribose and l-(−)-glucose (see Exercise 24-2). What are their systematic names?

36. Identify the following sugars, which are represented by unconventionally drawn Fischer projections. (Hint: It will be necessary to convert these projections into more conventional representations without inverting any of the stereocenters.)
37. Redraw each of the following sugars in open-chain form as a Fischer projection, and find its common name.

(a) ![Fischer projection of threose](image)
(b) ![Fischer projection of allose](image)
(c) ![Fischer projection of ribulose](image)
(d) ![Fischer projection of sorbose](image)

38. For each of the following sugars, draw all reasonable cyclic structures, using either Haworth or conformational formulas; indicate which structures are pyranoses and which are furanoses; and label $\alpha$ and $\beta$ anomers.

(a) (-)-Threose; (b) (-)-allose; (c) (-)-ribulose; (d) (+)-sorbose; (e) (+)-mannoheptulose (Problem 34).

39. Are any of the sugars in Problem 38 incapable of mutarotation? Explain your answer.

40. Draw the most stable pyranose conformation of each of the following sugars. (a) $\alpha$-d-Arabinose; (b) $\beta$-d-galactose; (c) $\beta$-d-mannose; (d) $\alpha$-d-idose.

41. Ketoses show positive Fehling’s and Tollens’s tests not only by oxidation to $\alpha$-dicarbonyl compounds, but through a second process: Ketoses isomerize to aldoses in the presence of base. The aldose then undergoes oxidation by the Fehling’s or Tollens’s solution. Using any ketose in Figure 24-2, propose a base-catalyzed mechanism pathway to the corresponding aldose. [Hint: Review Section 18-2.]

42. What are the products (and their ratios) of periodate cleavage of each of the following substances: (a) 1,3-dihydroxyacetone; (b) rhamnose (Problem 34); (c) glucitol.

43. Write the expected products of the reaction of each of the following sugars with (i) Br$_2$, H$_2$O; (ii) HNO$_3$, H$_2$O, 60°C; (iii) NaBH$_4$, CH$_3$OH; and (iv) excess C$_6$H$_5$NHNH$_2$, CH$_3$CH$_2$OH, D. Find the common names of all the products. (a) d-(-)-Threose; (b) d-(-)-xylose; (c) d-(-)-galactose.

44. Draw the Fischer projection of an aldohexose that will give the same osazone as (a) d-(-)-idose and (b) l-(-)-altrose.

45. (a) Which of the aldopentoses (Figure 24-1) would give optically active alditols upon reduction with NaBH$_4$? (b) Using d-fructose, illustrate the results of NaBH$_4$ reduction of a ketose. Is the situation more complicated than reduction of an aldose? Explain.

46. Which of the following glucoses and glucose derivatives are capable of undergoing mutarotation? (a) $\alpha$-d-Glucopyranose; (b) methyl $\alpha$-d-glucopyranoside; (c) methyl $\alpha$-2,3,4,6-tetra-O-methyl-d-glucopyranoside (i.e., the tetramethyl ether at carbon 2, 3, 4, and 6); (d) $\alpha$-2,3,4,6-tetra-O-methyl-d-glucopyranose; (e) $\alpha$-d-glucopyranose 1,2-acetone acetal.

47. (a) Explain why the oxygen at C1 of an aldopyranose can be methylated so much more easily than the other oxygens in the molecule. (b) Explain why the methyl ether unit at C1 of a fully methylated aldopyranose can be hydrolyzed so much more easily than the other methyl ether functions in the molecule. (c) Write the expected product(s) of the following reaction.

![D-Fructose reaction](image)

48. Of the four aldopentoses, two form diacetals readily when treated with excess acidic acetone, but the other two form only monoacetals. Explain.
49. d-Sedoheptulose is a sugar intermediate in a metabolic cycle (the pentose oxidation cycle) that ultimately converts glucose into 2,3-dihydroxypropanal (glyceraldehyde) plus three equivalents of CO₂. Determine the structure of d-sedoheptulose from the following information.

$$d\text{-Sedoheptulose} \xrightarrow{\text{HIO}_4} 4\text{ HCOH} + 2\text{ HCH + CO}_2$$

$$d\text{-Sedoheptulose} \xrightarrow{\text{Ruff degradation}} \text{an osazone identical with that formed by another sugar, aldohexose A}$$

$$\text{Aldohexose A} \xrightarrow{\text{Ruff degradation}} \text{aldohexose B}$$

$$\text{Aldohexose B} \xrightarrow{\text{HNO}_3, \text{H}_2\text{O}} \text{an optically active product}$$

$$\text{Aldohexose B} \xrightarrow{\text{Ruff degradation}} \text{D-ribose}$$

50. Is it possible for two different diastereomeric aldoses to give the same product upon Kiliani-Fischer chain elongation? Why or why not?

51. In each of the following groups of three d aldoses, identify the two that give the same product upon Ruff degradation. (a) Galactose, gulose, talose; (b) glucose, gulose, idose; (c) allose, altrose, mannose.

52. Illustrate the results of chain elongation of D-talose through a cyanohydrin. How many products are formed? Draw them. After treatment with warm HNO₃, does the product(s) give optically active or inactive dicarboxylic acids?

53. (a) Write a detailed mechanism for the isomerization of β-d-fructofuranose from the hydrolysis of sucrose into an equilibrium mixture of the β-pyranose and β-furanose forms. (b) Although fructose usually appears as a furanose when it is part of a polysaccharide, in the pure crystalline form, fructose adopts a β-pyranose structure. Draw β-d-fructopyranose in its most stable conformation. In water at 20°C, the equilibrium mixture contains about 68% β-d-pyranose and 32% β-d-furanose. (c) What is the free-energy difference between the pyranose and furanose forms at this temperature? (d) Pure β-d-fructopyranose has $[\alpha]_D^{20°C} = -132$. The equilibrium pyranose–furanose mixture has $[\alpha]_D^{20°C} = -92$. Calculate $[\alpha]_D^{20°C}$ for pure β-d-fructofuranose.

54. Classify each of the following sugars and sugar derivatives as either reducing or nonreducing. (a) d-Glyceraldehyde; (b) d-arabinose; (c) β-d-arabinopyranose 3,4-acetone acetal; (d) β-d-arabinopyranose acetone diacetal; (e) d-ribulose; (f) d-galactose; (g) methyl β-d-galactopyranoside; (h) β-d-galactaruronic acid (as shown in the margin); (i) β-cellobiose; (j) α-lactose.

55. Is α-lactose capable of mutarotation? Write an equation to illustrate your answer.

56. Trehalose, sophorose, and turanose are disaccharides. Trehalose is found in the cocoons of some insects, sophorose turns up in a few bean varieties, and turanose is an ingredient in low-grade honey made by bees with indigestion from a diet of pine tree sap. Identify among the following structures those that correspond to trehalose, sophorose, and turanose on the basis of the following information: (i) Turanose and sophorose are reducing sugars. Trehalose is nonreducing. (ii) Upon hydrolysis, sophorose and trehalose give two molecules each of aldoses. Turanose gives one molecule of an aldose and one molecule of a ketose. (iii) The two aldoses that constitute sophorose are anomers of each other.
57. Identify and, using the information in Sections 24-1 and 24-11, provide names for the carbohydrates that are contained in the structure of stevioside (Chemical Highlight 24-3).

58. The disaccharide at the terminus of the oligosaccharide attached to the surface of type B red blood cells is an \( \alpha\)-d-galactopyranosyl-\( \beta\)-d-galactopyranose. The linkage is an acetal from C1 of the first galactose to the C3 hydroxy group of the second. In other words, the full name is 3-(\( \alpha\)-d-galactopyranos-1-yl)-\( \beta\)-d-galactopyranose. Draw the structure of this disaccharide, using conformationally accurate chairs for the six-membered rings.

59. Glucose reacts with ammonia in the presence of a trace of acid to give predominantly \( \beta\)-d-glucopyranosylamine (Section 24-12). Propose a reasonable mechanism for this transformation. Why is only the hydroxy group at C1 replaced?

60. (a) A mixture of (R)-2,3-dihydroxypropanal (d-glyceraldehyde) and 1,3-dihydroxyacetone that is treated with aqueous NaOH rapidly yields a mixture of three sugars: d-fructose, d-sorbose, and racemic dendroketose (only one enantiomer is shown here). Explain this result by means of a detailed mechanism. (b) The same product mixture is also obtained if either the aldehyde or the ketone alone is treated with base. Explain. [Hint: Closely examine the intermediates in your answer to (a).]

61. Write or draw the missing reagents and structures (a) through (g). What is the common name of (g)?

\[
\begin{align*}
\text{(a)} & \quad \text{D- (+)-Xylose} \quad \text{NaOH} \\
\text{(b)} & \quad \text{Methyl D-xylonate} \\
\text{(c)} & \quad \text{Methyl D-glucuronoside} \\
\text{(d)} & \quad \text{D-Glucuronic acid} \\
\text{(e)} & \quad \text{Gulonic acid} \\
\text{(f)} & \quad \text{Gulonolactone} \\
\text{(g)} & \quad \text{Gulose}
\end{align*}
\]

The preceding sequence (called the Weerman degradation) achieves the same end as what procedure described in this chapter?

62. Fischer’s solution to the problem of sugar structures was actually much more difficult to achieve experimentally than Section 24-10 implies. For one thing, the only sugars that he could readily obtain from natural sources were glucose, mannose, and arabinose. (Erythrose and threose were, in fact, not then available at all, either naturally or synthetically.) His ingenious solution required a way to exchange the functionalities at C1 and C6 of glucose and mannose in order to make the critical distinction described at the end of the section. (Of course, had gulose existed in nature, all this effort would have been unnecessary, but Fischer wasn’t so lucky.) Fischer’s plan led to unexpected difficulties, because at a key stage he got a troublesome mixture of products. Nowadays we solve the problem in the manner shown below. Fill in the missing reagents and structures (a) through (g). Use Fischer projections for all structures. Follow the instructions and hints in parentheses.
63. **Challenge** Vitamin C (ascorbic acid, Section 22-9) is present almost universally in the plant and animal kingdoms. (According to Linus Pauling, mountain goats biosynthesize from 12 to 14 g of it per day.) Animals produce it from d-glucose in the liver by the four-step sequence d-glucose → d-glucuronic acid (see Problem 62) → d-glucuronic acid γ-lactone → l-gulonic acid γ-lactone → vitamin C.

![Chemical structure of Vitamin C](image)

The enzyme that catalyzes the last reaction, l-gulonolactone oxidase, is absent from humans, some monkeys, guinea pigs, and birds, presumably because of a defective gene resulting from a mutation that may have occurred some 60 million years ago. As a result, we have to get our vitamin C from food or make it in the laboratory. In fact, the ascorbic acid in almost all vitamin supplements is synthetic. An outline of one of the major commercial syntheses follows. Draw the missing reagents and products (a) through (f).

![Synthesis outline](image)

Team Problem

64. This problem is meant to encourage you to think as a team about how you might establish the structure of a simple disaccharide, with some additional information at your disposal. Consider d-lactose (Section 24-11) and assume you do not know its structure. You are given the knowledge that it is a disaccharide, linked in a β manner to the anomeric carbon of only one of the sugars, and you are given the structures of all of the aldohexoses (Table 24-1), as well as all of their possible methyl ethers. Deal with the following questions as a team or by dividing the work, before joint discussion, as appropriate.

(a) Mild acid hydrolyzes your “unknown” to d-galactose and d-glucose. How much information can you derive from that result?
(b) Propose an experiment that tells you that the two sugars are not connected through their respective anomeric centers.
(c) Propose an experiment that tells you which one of the two sugars contains an acetal group used to bind the other. (Hint: The functional group chemistry of the monosaccharides described in the chapter can be applied to higher sugars as well. Specifically, consider Section 24-4 here.)
(d) Making use of the knowledge of the structure of all possible methyl ethers of the component monosaccharides, design experiments that will tell you which (nonanomeric) hydroxy group is responsible for the disaccharide linkage.
(e) Similarly, can you use this approach to distinguish between a furanose and pyranose structure for the component of the disaccharide that can mutarotate?
Preprofessional Problems

65. Most natural sugars have a stereocenter that is identical to that in (\(R\))-2,3-dihydroxypropanal, shown as a Fischer projection in the margin. What is the (very popular) common name for this compound? (a) d-(\(+\))-Glyceraldehyde; (b) d-(\(-\))-glyceraldehyde; (c) l-(\(+\))-glyceraldehyde; (d) l-(\(-\))-glyceraldehyde

66. What kind of sugar is the compound shown in the margin? (a) An aldopentose; (b) a ketopentose; (c) an aldohexose; (d) a ketohexose

67. Which one of the following statements is true about the oxacyclohexane conformer of the sugar \(\beta\-\text{d-(+)}\)-glucopyranose?
   (a) One OH group is axial, but all remaining substituents are equatorial.
   (b) The CH\(_2\)OH group is axial, but all remaining groups are equatorial.
   (c) All groups are axial.
   (d) All groups are equatorial.

68. The methyl glycoside of mannose is made by treating the sugar with (a) AlBr\(_3\), CH\(_3\)Br; (b) dilute aqueous CH\(_3\)OH; (c) CH\(_3\)OCH\(_3\) and LiAlH\(_4\); (d) CH\(_3\)OH, HCl; (e) oxacyclopropane, AlCl\(_3\)

69. One of the statements below is correct about the sugar shown. Which one?

(a) It is a nonreducing sugar. (b) It forms an osazone. (c) It exists in two anomic forms. (d) It undergoes mutarotation.
Look at the list of the world’s top ten prescription drugs (Table 25-1). What do their structures have in common? Apart from the presence of heteroatoms, such as oxygen, nitrogen, and sulfur, they all contain at least two rings. Moreover, in all but two cases, these rings are made up not solely of carbon, called carbocycles (Chapter 4), but also of heteroatoms and are thus called heterocycles.

This chapter describes the naming, syntheses, and reactions of some saturated and aromatic heterocyclic compounds in order of increasing ring size, starting with the heterocyclopropanes. Some of this chemistry is a simple extension of transformations presented earlier for carbocycles. However, the heteroatom often causes heterocyclic compounds to exhibit special chemical behavior.

Most physiologically active compounds owe their biological properties to the presence of heteroatoms, mainly in the form of heterocycles. A majority of the known natural products are heterocyclic. It is therefore not surprising that more than half the published chemical literature deals with such compounds—their synthesis, isolation, and interconversions. Indeed, we have already encountered many examples—the cyclic ethers (Section 9-6), acetics (Sections 17-8, 23-4, and 24-8), carboxylic acid derivatives (Chapters 19 and 20), and amines (Chapter 21). The bases in DNA, whose sequence stores hereditary information, are heterocycles (Section 26-9); so are many vitamins, such as B₁ (thiamine, Chemical Highlight 23-2), B₂ (riboflavin, Chemical Highlight 25-3), B₆ (pyridoxine), the spectacularly complex B₁₂, and vitamins C and E (Section 22-9). The structures of vitamins B₆ and B₁₂, as well as additional examples of heterocyclic systems and their varied uses, are depicted here.

25-1 Naming the Heterocycles

Like all other classes of compounds we have encountered, the heterocycles contain many members bearing common names. Moreover, there are several competing systems for naming heterocycles, which is sometimes confusing. We shall adhere to the simplest system. We regard saturated heterocycles as derivatives of the related carbocycles and use a prefix to denote the presence and identity of the heteroatom: aza- for nitrogen, oxa- for oxygen, thia- for sulfur, phospha- for phosphorus, and so forth. Other widely used names will be given in parentheses. The location of substituents is indicated by numbering the ring atoms, starting with the heteroatom. In the following examples, space-filling renditions of the most representative ring sizes, from three to six membered, give you a perspective of their actual shape.
The common names of unsaturated heterocycles are so firmly entrenched in the literature that we shall use them here.

The common names of unsaturated heterocycles are so firmly entrenched in the literature that we shall use them here.

**Exercise 25-1**

Name or draw the following compounds. (a) trans-2,4-Dimethyloxacyclopentane (trans-2,4-Dimethyltetrahydrofuran); (b) N-ethylazacyclopropane;

(c) O,N

(d) Br

**25-2 Nonaromatic Heterocycles**

As illustrated by the chemistry of the oxacyclopropanes (Section 9-9), ring strain allows the three- and four-membered heterocycles to undergo nucleophilic ring opening readily. In contrast, the larger, unstrained systems are relatively inert to attack.
Ring strain makes heterocyclopropanes and heterocyclobutanes reactive

Heterocyclopropanes are relatively reactive because ring strain is released by nucleophilic ring opening. Under basic conditions, this process gives rise to inversion at the less substituted center (Section 9-9).

\[
\begin{align*}
\text{2-Phenyl oxacyclopropane} & \xrightarrow{\text{Attack at less substituted carbon}} \text{2-Methoxy-1-phenylethanol} \\
\text{N-Ethyl-(2S,3S)-trans-2,3-dimethylazacyclopropane} & \xrightarrow{\text{Attack with inversion}} \text{meso-N,N'-Diethyl-2,3-butanediamine}
\end{align*}
\]

Exercise 25-2

Explain the following result by a mechanism. (Caution: This is not an oxidation. Hints: Calculate the molecular formulas of starting material and product. Try a ring opening catalyzed by the Lewis acid and consider the options available to the resulting intermediate. See Section 9-3.)

\[
\text{H} \xrightarrow{\text{MgBr}_2, (CH_3CH_2)_2O} \text{O
\]

Exercise 25-3

2-(Chloromethyl)oxacyclopropane reacts with hydrogen sulfide ion (HS\(^-\)) to give thiacyclobutan-3-ol. Explain by a mechanism.

Exercise 25-4

Working with the Concepts: Practicing Mechanisms That Involve Heterocycles

Isomeric cylindricines A and B, isolated in 1993, are the two main alkaloids (Section 25-8) present in extracts from the Australian marine plant *Clavelina cylindrica*. The two compounds equilibrate to a 3:2 mixture. Formulate a mechanism for this process. (Hint: Check Exercise 9-25.)
CHEMICAL HIGHLIGHT 25-1

Smoking, Nicotine, Cancer, and Medicinal Chemistry

Nicotine is an azacyclopentane derivative that is responsible for the addictive character of cigarette smoking. Like other drugs of abuse, its presence activates the brain’s pleasure centers by stimulating the release of the neurotransmitter dopamine, while its absence activates the body’s stress systems (“withdrawal”). The causal link between smoking and cancer is well established, and there are over 40 known carcinogens among the thousands of compounds contained in cigarette smoke, among them benz[a]pyrene (Section 16-7).

Nicotine appears to play a dual contributory role, because its metabolites are outright carcinogens and because the parent system itself, while not causing cancer, is a tumor promoter.

The metabolic pathway has as the initial step the N-nitrosation of the azacyclopentane (pyrrolidine) nitrogen. Oxidation and ring opening (compare Chemical Highlight 21-3) then take place, giving a mixture of two N-nitrosodialkanamines (N-nitrosamines), each of which is a known powerful carcinogen.

Upon protonation of the oxygen in the nitroso group, these substances become reactive alkylating agents, capable of transferring methyl groups to nucleophilic sites in biological molecules such as DNA, as shown below. The diazohydroxide that remains decomposes through a diazonium ion to a carbocation, which may inflict additional molecular damage (Section 21-10).

The ability of nicotine to act as a tumor promoter has surfaced in several studies. For example, certain human lung cancer cells show 50% acceleration in their rate of division if nicotine is added to the culture medium. Nicotine also inhibits the “suicide” of malignant cells, one of the main repair and clean-up mechanisms of the body in case of cell damage. Thus, nicotine actually helps cells with genetic damage to

Strategy

Following the hint, Exercise 9-25 points out that a 2-chloroethylsulfide can undergo intramolecular S\textsubscript{N}2 reaction to an intermediate sulfonyl ion, which is subject to opening by external nucleophilic attack. Recognizing that the “action” part of cylindricine A is a 2-chloroethylamine substructure, we can apply the same principle here.

Solution

- Intramolecular attack by the amino nitrogen on the chlorine-bearing carbon produces reactive intermediate ammonium ion A (next page).
- The activated azacyclopropane ring may be attacked at either of its two carbons by the chloride ion liberated in the first step.
- Ring opening via the primary carbon regenerates starting material (a).
- However, attack on the neighboring position (b) unravels A to cylindricine B.
- Build a model!

Nicotine patches are used to wean individuals from their addiction to cigarette smoking.
survive and, presumably, proliferate. This finding has caused concern, because nicotine is the crucial ingredient in a number of smoking-cessation therapies that feature gums, patches, lozenges, and inhalators.

There are about 1.3 billion smokers worldwide, a staggering number, to which the United States contributes 60 million. Among them, the majority wants to and has tried to quit. Because tobacco-related illnesses are the second leading cause of death (after heart disease), there is a tremendous need for new therapies. A new concept in this vein is the new drug varenicline (Chantix), which came on the market in 2006. It is a nicotine receptor “partial agonist,” that is, this molecule targets the same receptors site of the central nervous system as nicotine, but with only partial efficacy. As such, it both reduces the craving for “a smoke” and decreases the pleasure associated with it, but not completely, thus minimizing the chances of a relapse.

The synthesis of varenicline is a showcase of reactions that you have encountered in this book, as practiced by medicinal chemists.
Chapter 25  
Heterocycles

The reactivity of the four-membered heterocycloalkanes bears out expectations based on ring strain: They undergo ring opening, as do their three-membered cyclic counterparts, but more stringent reaction conditions are usually required. The reaction of oxacyclobutane with CH₃NH₂ is typical.

\[ \text{O} \quad \text{CH₃NH₂} \quad \text{CH₃NH(CH₂)₃OH} \quad 45\% \]

\[ \text{N-Methyl-3-amino-1-propanol} \]

The β-lactam antibiotic penicillin functions through related ring-opening processes (see Chemical Highlight 20-2).

Exercise 25-5

Try It Yourself

Treatment of thiacyclobutane with chlorine in CHCl₃ at −70°C gives ClCH₂CH₂CH₂SCl in 30% yield. Suggest a mechanism for this transformation. [Hint: The sulfur in sulfides is nucleophilic (Section 9-10).]

The reactivity of the four-membered heterocycloalkanes bears out expectations based on ring strain: They undergo ring opening, as do their three-membered cyclic counterparts, but more stringent reaction conditions are usually required. The reaction of oxacyclobutane with CH₃NH₂ is typical.

\[ \square \quad \text{O} \quad + \quad \text{CH₃NH₂} \quad \xrightarrow{150°C} \quad \text{CH₃NH(CH₂)₃OH} \quad 45\% \]

\[ \text{N-Methyl-3-amino-1-propanol} \]

The β-lactam antibiotic penicillin functions through related ring-opening processes (see Chemical Highlight 20-2).

Exercise 25-6

2-Methyloxacyclobutane reacts with HCl to give two products. Write their structures.

Heterocyclopentanes and heterocyclohexanes are relatively unreactive

The unstrained heterocyclopentanes and heterocyclohexanes are relatively inert. Recall that oxacyclopentane (tetrahydrofuran, THF) is used as a solvent. However, the heteroatoms in aza- and thiacyclobutanes allow for characteristic transformations (see Sections 9-10, 17-8, 18-4, and Chapter 21). In general, ring opening occurs by conversion of the heteroatom into a good leaving group.

Exercise 25-7

Treatment of azacyclopentane (pyrrolidine) with sodium nitrite in acetic acid gives a liquid, b.p. 99–100°C (15 mm Hg), that has the composition C₄H₈N₂O. Propose a structure for this compound. [Hint: Review Section 21-10.]

In Summary The reactivity of heterocyclopropanes and heterocyclobutanes results from the release of strain by ring opening. The five- and six-membered heterocycloalkanes are less reactive than their smaller-ring counterparts.

25-3 Structure and Properties of Aromatic Heterocyclopentadienes

Pyrrole, furan, and thiophene are 1-hetero-2,4-cyclopentadienes. Each contains a butadiene unit bridged by an sp²-hybridized heteroatom bearing lone electron pairs. These systems contain delocalized π electrons in an aromatic six-electron framework. This section considers the structures and methods of preparation of these compounds.

Pyrrole, furan, and thiophene contain delocalized lone electron pairs

The electronic structure of the three heterocycles pyrrole, furan, and thiophene is similar to that of the aromatic cyclopentadienyl anion (Section 15-7). The cyclopentadienyl anion may
be viewed as a butadiene bridged by a negatively charged carbon whose electron pair is
delocalized over the other four carbons. The heterocyclic analogs contain a neutral atom in
that place, again bearing lone electron pairs. One of these pairs is similarly delocalized,
furnishing the two electrons needed to satisfy the $4n + 2$ rule (Section 15-7). To maximize
overlap, the heteroatoms are hybridized $sp^2$ (Figure 25-1), the delocalized electron pair
being assigned to the remaining $p$ orbital. In pyrrole, the $sp^2$-hybridized nitrogen bears a
hydrogen substituent in the plane of the molecule. For furan and thiophene, the second lone
electron pair is placed into one of the $sp^2$ hybrid orbitals, again in the plane and therefore
with no opportunity to achieve overlap. This arrangement is much like that in the phenyl
anion (Section 22-4). As a consequence of delocalization, pyrrole, furan, and thiophene
exhibit properties that are typical of aromatic compounds, such as unusual stability,
deshielded protons in the $^1H$ NMR spectra due to the presence of ring currents, and the
ability to undergo electrophilic aromatic substitution (Section 25-4).

The delocalization of the lone pair in the 1-hetero-2,4-cyclopentadienes can be described
by charge-separated resonance forms, as shown for pyrrole.

**Resonance Forms of Pyrrole**

![Resonance Forms of Pyrrole](image)

Notice that there are four dipolar forms in which a positive charge is placed on the hetero-
amon and a negative charge successively on each of the carbons. This picture suggests that
the heteroatom should be relatively electron poor and the carbons relatively electron rich.
The electrostatic potential maps below confirm this expectation. Thus (on the same scale),
the nitrogen in pyrrole is less electron rich (orange) than that in its saturated counterpart
azacyclopentane (red), whereas the diene portion in pyrrole is more electron rich (red) than
that in 1,3-cyclopentadiene (yellow).
As this description suggests, the extent of aromaticity in these systems depends on the relative ability of the heteroatom to donate its lone electron pair, in turn described by its respective electronegativity (Table 1-2). Consequently, the aromatic character increases along the series furan < pyrrole < thiophene, a trend that is reflected in relative reactivity and stability.

**Aromaticity in Heterocyclopentadienes**

\[
\text{O} < \text{N} < \text{S}
\]

**Increasing aromaticity**

---

**Exercise 25-8**

Azacyclopentane and pyrrole are both polar molecules. However, the dipole vectors in the two molecules point in opposite directions. What is the sense of direction of this vector in each structure? Explain your answer.

---

**Pyrroles, furans, and thiophenes are prepared from \(\gamma\)-dicarbonyl compounds**

Syntheses of the heterocyclopentadienes use a variety of cyclization strategies. A general approach is the Paal-Knorr* synthesis (for pyrroles) and its variations (for the other heterocycles). The target molecule is made from an enolizable \(\gamma\)-dicarbonyl compound that is treated with an amine derivative (for pyrroles) or \(\text{P}_2\text{O}_5\) (for furans) or \(\text{P}_2\text{S}_5\) (for thiophenes).

---

**Cyclization of a \(\gamma\)-Dicarbonyl Compound to a 1-Hetero-2,4-Cyclopentadiene**

\[
\text{CH}_3\text{CCH}_2\text{CH}_2\text{CCH}_3 + (\text{CH}_3)_2\text{CHNH}_2 \xrightarrow{\text{CH}_3\text{COOH}, \Delta, 17 \text{ h}} \text{C}_6\text{H}_5\text{C}_6\text{H}_5\text{C}_6\text{H}_5\text{C}_6\text{H}_5
\]

\(\text{N-(1-Methylethyl)-2,5-dimethylpyrrole}\)

*Professor Karl Paal (1860–1935), University of Erlangen, Germany; Professor Ludwig Knorr (1859–1921), University of Jena, Germany.*
In Summary  
Pyrrole, furan, and thiophene contain delocalized aromatic $\pi$ systems analogous to that of the cyclopentadienyl anion. A general method for the preparation of 1-hetero-2,4-cyclopentadienes is based on the cyclization of enolizable $\gamma$-dicarbonyl compounds.

25-4 Reactions of the Aromatic Heterocyclopentadienes

The reactivity of pyrrole, furan, and thiophene and their derivatives is governed largely by their aromaticity and is based on the chemistry of benzene. This section describes some of their reactions, particularly electrophilic aromatic substitution, and introduces indole, a benzofused analog of pyrrole.
Pyrroles, furans, and thiophenes undergo electrophilic aromatic substitution

As expected for aromatic systems, the 1-hetero-2,4-cyclopentadienes undergo electrophilic substitution. There are two sites of possible attack, at C2 and at C3. Which one should be more reactive? An answer can be found by the same procedure used to predict the regioselectivity of electrophilic aromatic substitution of substituted benzenes (Chapter 16): enumeration of all the possible resonance forms for the two modes of reaction.

Consequences of Electrophilic Attack at C2 and C3 in the Aromatic Heterocyclopentadienes

Attack at C2

Three resonance forms

Attack at C3

Two resonance forms

Both modes benefit from the presence of the resonance-contributing heteroatom, but attack at C2 leads to an intermediate with an additional resonance form, thus indicating this position to be the preferred site of substitution. Indeed, such selectivity is generally observed. However, because C3 also is activated to electrophilic attack, mixtures of products can form, depending on conditions, substrates, and electrophiles.

Electrophilic Aromatic Substitution of Pyrrole, Furan, and Thiophene

Electrophilic Aromatic Substitution of Pyrrole

2-Chloropyrrole

Electrophilic Aromatic Substitution of Furan

2-Chlorofuran

Electrophilic Aromatic Substitution of Thiophene

2-Acetyl-5-methylthiophene
The relative reactivity of benzene and the three heterocycles in electrophilic substitutions is the result of contributions from the aromaticity of the respective rings and the stabilization of the intermediate cations. It increases in the order benzene $<$ thiophene $<$ furan $<$ pyrrole.

**Exercise 25-12**

**Working with the Concepts: Predicting the Position of Electrophilic Aromatic Substitution of Substituted Thiophene**

The monobromination of thiophene-3-carboxylic acid gives only one product. What is its structure, and why is it the only product formed?

**Strategy**
The two preferred sites of reaction should be at the carbon atoms next to sulfur, in our unsymmetrical thiophene C2 and C5. To see which one of these is more active, we need to compare the respective resonance forms of the intermediate cation resulting from electrophilic attack at either position.

**Solution**
• Attack at C2

\[
\begin{align*}
\text{Br}_2 & \rightarrow \text{COOH} \\
\text{Br} & \rightarrow \text{COOH} \\
\text{Br} & \rightarrow \text{COOH} \\
\text{Br} & \rightarrow \text{COOH} \\
\end{align*}
\]

• Attack at C5

\[
\begin{align*}
\text{Br}_2 & \rightarrow \text{COOH} \\
\text{Br} & \rightarrow \text{COOH} \\
\text{Br} & \rightarrow \text{COOH} \\
\text{Br} & \rightarrow \text{COOH} \\
\end{align*}
\]

• Result: Attack on C5 avoids placing the positive charge on C3, as in A, bearing the electron-withdrawing carboxy function. Therefore, the only product is 5-bromo-3-thiophenecarboxylic acid.

**Exercise 25-13**

**Try It Yourself**
The monobromination of 3-methylfuran gives only one product. What is its structure, and why is it the only product formed?

Pyrrrole is extremely nonbasic compared to ordinary amines (Section 21-4), because the lone electron pair on nitrogen is tied up by conjugation. Very strong acid is required to effect protonation, and it takes place on C2, not on the nitrogen.

**The Protonation of Pyrrole Occurs on Carbon**

\[
\begin{align*}
\text{N} & \rightarrow \text{H}^+ + \text{H} \\
\text{pK}_a = -4.4 \\
\end{align*}
\]

Pyrrroles are not only very nonbasic, they are, in fact, relatively acidic. Thus, while azacyclopentane has a $pK_a = 35$ (normal for an amine, Section 21-4), the corresponding value for pyrrole is 16.5! The reasons for this increase in acidity are the change in hybridization from $sp^3$ to $sp^2$ (see Section 11-3) and the delocalization of the negative charge (as in cyclopentadienyl anion, Section 15-7).
Chapter 25  Heterocycles

**Pyrrole Is Relatively Acidic**

N\(\text{H}^+\) \(pK_a = 35\)

Azacyclopentane

N\(\text{H}^+\) \(pK_a = 16.5\)

Five resonance forms

**Exercise 25-14**

Explain why pyrrole is protonated at C2 rather than on the nitrogen.

1-Hetero-2,4-cyclopentadienes can undergo ring opening and cycloaddition reactions

Furans can be hydrolyzed under mild conditions to \(\gamma\)-dicarbonyl compounds. The reaction may be viewed as the reverse of the Paal-Knorr-type synthesis of furans. Pyrrole polymerizes under these reaction conditions, whereas thiophene is stable.

**Hydrolysis of a Furan to a \(\gamma\)-Dicarbonyl Compound**

\[
\begin{align*}
\text{CH}_3\text{COOH, H}_2\text{SO}_4, \text{H}_2\text{O, }\Delta & \quad \text{\rightarrow} \quad \text{CH}_3\text{CCH}_2\text{CH}_2\text{CCH}_3 \\
\text{50\%} & \quad \text{2,5-Hexanedione}
\end{align*}
\]

Raney nickel desulfurization (Section 17-8) of thiophene derivatives results in sulfur-free acyclic saturated compounds.

\[
\begin{align*}
\text{Raney Ni, (CH}_3\text{CH}_2\text{)_2O, }\Delta & \quad \text{\rightarrow} \quad \text{CH}_3\text{(CH}_2\text{)}_3\text{CH(OCH}_2\text{CH}_3\text{)_2} \\
\text{50\%} & \quad \text{(CH}_3\text{CH}_2\text{)_2O}
\end{align*}
\]

Being least aromatic (Section 25-3), the \(\pi\) system of furan (but not of pyrrole or thiophene) possesses sufficient diene character to undergo Diels-Alder cycloadditions (Section 14-8).

**Indole is a benzopyrrole**

Indole is the most important \(\text{benzannulated}\) (fused-ring) derivative of the 1-hetero-2,4-cyclopentadienes. It forms part of many natural products, including the amino acid tryptophan (Section 26-1).

Indole is related to pyrrole in the same way that naphthalene is related to benzene. Its electronic makeup is indicated by the various possible resonance forms that can be formulated for the molecule. Although those resonance forms that disturb the cyclic six-\(\pi\)-electron
system of the fused benzene ring are less important, they indicate the electron-donating effect of the heteroatom.

**Resonance in Indole**

![Resonance in Indole](image)

**Exercise 25-15**

Predict the preferred site of electrophilic aromatic substitution in indole. Explain your choice.

**Exercise 25-16**

Irradiation of compound A in ethoxyethane (diethyl ether) at \(-100^\circ C\) generates the enol form, B, of acetylbenzene and a new compound, C, which isomerizes to indole upon warming to room temperature.

![Exercise 25-16](image)

The \(^1\)H NMR spectrum of compound C shows signals at \(\delta = 3.79\) (d, 2 H) and \(8.40\) (t, 1 H) ppm in addition to four aromatic absorptions. Indole has peaks at \(\delta = 6.34\) (d, 1 H), \(6.54\) (broad d, 1 H), and \(7.00\) (broad s, 1 H) ppm. What is compound C? (**Hint:** This reaction proceeds by a mechanism similar to the mass spectral McLafferty rearrangement, Section 17-3.)

**In Summary** The donation of the lone electron pair on the heteroatom to the diene unit in pyrrole, furan, and thiophene makes the carbon atoms in these systems electron rich and therefore more susceptible to electrophilic aromatic substitution than the carbons in benzene. Electrophilic attack is frequently favored at C2, but substitution at C3 is also observed, depending on conditions, substrates, and electrophiles. Some rings can be opened by hydrolysis or by desulfurization (for thiophenes). The diene unit in furan is reactive enough to undergo Diels-Alder cycloadditions. Indole is a benzopyrrole containing a delocalized \(\pi\) system.

### 25-5 Structure and Preparation of Pyridine: An Azabenzene

**Pyridine** can be regarded as a benzene derivative—an azabenzene—in which an \(sp^2\)-hybridized nitrogen atom replaces a CH unit. The pyridine ring is therefore aromatic, but its electronic structure is perturbed by the presence of the electronegative nitrogen atom. This section describes the structure, spectroscopy, and preparation of this simple azabenzene.

**Pyridine is aromatic**

Pyridine contains an \(sp^2\)-hybridized nitrogen atom like that in an imine (Section 17-9). In contrast to pyrrole, only one electron in the \(p\) orbital completes the aromatic \(\pi\)-electron arrangement of the aromatic ring; as in the phenyl anion, the lone electron pair is located...
in one of the \( sp^2 \) hybrid atomic orbitals in the molecular plane (Figure 25-2). Therefore, in pyridine, the nitrogen does not donate excess electron density to the remainder of the molecule. Quite the contrary: Because nitrogen is more electronegative than carbon (Table 1-2), it withdraws electron density from the ring, both inductively and by resonance.

**Resonance in Pyridine**

### Exercise 25-17

Azacyclohexane (piperidine) is polarized because of the presence of the relatively electronegative nitrogen. The polarization in pyridine is twice as large. Explain.

Aromatic delocalization in pyridine is evident in the \(^1\text{H}\) NMR spectrum, which reveals the presence of a ring current. The electron-withdrawing capability of the nitrogen is manifest in larger chemical shifts (more deshielding) at C2 and C4, as expected from the resonance picture.

### \(^1\text{H}\) NMR Chemical Shifts (ppm) in Pyridine and Benzene

Because the lone pair on nitrogen is not tied up by conjugation (as it is in pyrrole, Exercise 25-14), pyridine is a weak base. (It is used as such in numerous organic transformations.) Compared with alkanamines \( (\text{pK}_a \text{ of ammonium salts} < 10; \text{Section 21-4}) \), the pyridinium ion has a low \( \text{pK}_a \), because the nitrogen is \( sp^2 \) and not \( sp^3 \) hybridized (see Section 11-3 for the effect of hybridization on acidity).

Pyridine is the simplest azabenzenes. Some of its higher aza analogs are shown here. They behave like pyridine but show the increasing effect of aza substitution—in particular, increasing electron deficiency. Minute quantities of several 1,4-diazabenzene (pyrazine) derivatives are responsible for the characteristic odors of many vegetables. One drop of 2-methoxy-3-(1-methylethyl)-1,4-diazabenzene (2-isopropyl-3-methoxypyrazine) in a large
swimming pool would be more than adequate to give the entire pool the odor of raw potatoes.

Pyridines are made by condensation reactions

Pyridine and simple alkylpyridines are obtained from coal tar. Many of the more highly substituted pyridines are in turn made by both electrophilic and nucleophilic substitution of the simpler derivatives.

Pyridines can be made by condensation reactions of acyclic starting materials such as carbonyl compounds with ammonia. The most general of these methods is the Hantzsch\(^*\) pyridine synthesis. In this reaction, two molecules of a \(\beta\)-dicarbonyl compound, an aldehyde, and ammonia combine in several steps (Chapter Integration Problem 25-28) to give a substituted dihydropyridine, which is readily oxidized by nitric acid to the aromatic system. When the \(\beta\)-dicarbonyl compound is a 3-ketoester, the resulting product is a 3,5-pyridinedicarboxylic ester. Hydrolysis followed by pyrolysis of the calcium salt of the acid causes decarboxylation.

**Hantzsch Synthesis of 2,6-Dimethylpyridine**

\[
\begin{align*}
\text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)} & \quad \overset{\Delta, -3 \text{ H2O}}{\rightarrow} \quad \text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)} \\
\text{H2C\(\text{O}^\prime\text{C}\)C\(\text{O}^\prime\text{C}\)C\(\text{NH3}\)} & \quad \overset{\text{HNO3, H2SO4}}{\rightarrow} \quad \text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)}
\end{align*}
\]

Diethyl 1,4-dihydro-2,6-dimethyl-3,5-pyridinedicarboxylate

\[
\begin{align*}
\text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)} & \quad \overset{1. \text{ KOH, H2O, 2. CaO, \Delta, -2 CH3CH2OH, -2 CaCO3}}{\rightarrow} \quad \text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)}
\end{align*}
\]

Diethyl 2,6-dimethyl-3,5-pyridinedicarboxylate

\[
\begin{align*}
\text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)} & \quad \overset{1. \text{ KOH, H2O, 2. CaO, \Delta}}{\rightarrow} \quad \text{CH\(\text{CH2CH3}\))C\(\text{CO2CH2CH3}\)}
\end{align*}
\]

2,6-Dimethylpyridine

\(^*\)Professor Arthur R. Hantzsch (1857–1935), University of Leipzig, Germany.
Chapter 25

Heterocycles

The first step of the Hantzsch pyridine synthesis is an example of a four-component reaction: Four molecules combine in a specific fashion to form a single product. This is remarkable considering the number of possible condensation pathways that are available to the starting materials. The reason for its success is the reversibility of channels that do not lead to the observed dihydropyridine and the careful tuning of reactivity of the participating molecules: ammonia (or ammonium acetate); a relatively reactive aldehyde; and a $\beta$-dicarbonyl constituent that is used twice. (For a stepwise tour through the mechanism, see Chapter Integration Problem 25-28). Multicomponent reactions of this type, in which water is the only by-product, are by their very nature atom economical and hence “green” (Chemical Highlight 3-1). Even more environmentally friendly is the use of water as a solvent and, in the aromatization step to the substituted pyridine, simply oxygen in the presence of activated carbon (a form of highly porous carbon derived from charcoal).

A “Super Green” Hantzsch Pyridine Synthesis

Exercise 25-18

What starting materials would you use in the Hantzsch synthesis of the following pyridines?

(a) CH$_3$CHO

2 CH$_3$CCH$_2$COCH$_2$CH$_3$ + \( \text{NH}_4^+\text{OCCH}_3 \)

\( \overset{\text{H}_2\text{O}}{\text{80\%}} \)

\( \overset{\text{OCCH}_3}{\text{O}} \)

\( \overset{\text{O}}{\text{O}} \)

\( \overset{\text{H}_3\text{C}}{\text{N}} \)

\( \text{O} \)

\( \text{N} \)

\( \text{O} \)

\( \text{O} \)

\( \text{O} \)

\( \text{CH}_3 \)

\( \text{CH}_3 \)

Exercise 25-19

Working with the Concepts: Practicing Mechanisms of Pyridine Syntheses

The Hantzsch synthesis of pyridines features 1,4-dihydropyridines in the first step. A variant of the method uses hydroxylamine (Table 17-5), which can be regarded as an oxidized version of ammonia. With this reagent, pyridines are formed directly from 1,5-dicarbonyl compounds, in turn readily made by Michael additions of enolates to $\alpha,\beta$-unsaturated aldehydes and ketones (Section 18-11). Formulate the mechanisms of the two steps in the pyridine synthesis shown.

H$_2$N$\text{O}_2$, HCl, CH$_3$CH$_2$OH
**Strategy**

Looking at the first step of the reaction, you should recognize a Michael addition of cyclohexanone to an unsaturated ketone. (You can review this reaction in Section 18-11). The transformation in the second step looks similar to the Paal-Knorr synthesis of pyroles (Exercise 25-9), except that the result is the construction of a six-membered (not a five-membered) ring. The mechanism you are looking for should be based on the mechanisms for these two reactions.

**Solution**

• In the first step, the product is formed by C–C bond construction between the carbon next to the carbonyl in cyclohexanone and the terminal position of the enone; in other words, cyclohexanone is alkylated at the α-position. Remember that ketones are alkylated through their enolates (Section 18-4) and, in this case, alkylation occurs by attack of cyclohexanone enolate on the positively polarized enone β-carbon, as sketched below.

```
  cyclohexanone enolate
  + cyclohexanone enone
  → alkylated product
```

• For the second step, recall that primary amines react with ketones reversibly to furnish imines by loss of water (Section 17-9) and that, in fact, hydroxylamine makes oximes (Table 17-5). These condensations proceed through the intermediacy of hemiaminals by nucleophilic attack of the amine nitrogen on the carbonyl carbon.

```
  hemiaminal
  + H₂N-H₂O
  → oxime
```

• Imines (like carbonyl compounds that form enols) are in equilibrium with their tautomeric forms, enamines (Section 17-9). If we write this form for our oxime, we arrive at an aminocarbonyl compound that is poised to undergo fast intramolecular formation of another hemiaminal. Dehydration produces a new cyclic enamine, which, upon inspection, is nothing but a hydrated pyridine. Finally, the driving force of aromaticity facilitates the rapid loss of water and generation of the pyridine product.

```
  oxime
  + H⁺ - H₂O
  → enamine
  + H⁺ - H₂O
  → hydrated pyridine
```
In Summary Pyridines are aromatic but electron poor. The lone pair on nitrogen makes the heterocycle weakly basic. Pyridines are prepared by condensation of a β-dicarbonyl compound with ammonia and an aldehyde.

25-6 Reactions of Pyridine

The reactivity of pyridine derives from its dual nature as both an aromatic molecule and a cyclic imine. Both electrophilic and nucleophilic substitution processes may occur, leading to a variety of substituted derivatives.

Pyridine undergoes electrophilic aromatic substitution only under extreme conditions

Because the pyridine ring is electron poor, the system undergoes electrophilic aromatic substitution only with great difficulty, several orders of magnitude more slowly than benzene, and at C3 (see Section 15-8).

Electrophilic Aromatic Substitution of Pyridine

Exercise 25-20

Try It Yourself

Sketch a plausible mechanism by which the following condensation reaction occurs. [Hints: Start with an aldol condensation of the aldehyde with the enamine. (Review enamine alkylation, Section 18-4). Then use the resulting product as a Michael acceptor of the second enamine.]

Exercise 25-21

1,3-Diazabenzen-2,4,6-triol prefers the triketo tautomeric form (Section 22-3) by about 29 kcal mol⁻¹. It is commonly known as barbituric acid ($pK_a = 7.4$) and constitutes the basic frame of a group of sedatives and sleep inducers called barbiturates, of which veronal and phenobarbital are two examples (margin).

Propose a synthesis of veronal from diethyl propanedioate (malonic ester; Section 23-2) and urea (Section 20-6). (Hint: In the presence of a base, such as an alkoxide, amides are in equilibrium with the corresponding amidates; Section 20-7.)
Activating substituents allow for milder conditions or improved yields.

Pyridine undergoes relatively easy nucleophilic substitution

Because the pyridine ring is relatively electron deficient, it undergoes nucleophilic substitution much more readily than does benzene (Section 22-4). Attack at C2 and C4 is preferred because it leads to intermediates in which the negative charge is on the nitrogen. An example of nucleophilic substitution of pyridine is the Chichibabin* reaction, in which the heterocycle is converted into 2-aminopyridine by treatment with sodium amide in liquid ammonia.

This reaction proceeds by the addition–elimination mechanism. The first step is attack by $\cdot\text{NH}_2$ at C2, a process that resembles 1,2-addition to an imine function. Expulsion of a hydride ion, $\text{H}^-$, from C2 is followed by deprotonation of the amine nitrogen to give H$_2$ and a resonance-stabilized 2-pyridineamide ion. Protonation by aqueous work-up furnishes the final product. Note the contrast with electrophilic substitutions, which include proton loss, not expulsion of hydride as a leaving group.

Transformations related to the Chichibabin reaction take place when pyridines are treated with Grignard or organolithium reagents.

Exercise 25-22

Explain why electrophilic aromatic substitution of pyridine occurs at C3.

*Professor Alexei E. Chichibabin (1871–1945), University of Moscow, Russia.
In most nucleophilic substitutions of pyridines, halides are leaving groups, the 2- and 4-halopyridines being particularly reactive.
LiAlH₄, in carbonyl reductions, or as surrogates for catalytically activated (e.g., Pd or Pt) hydrogen in hydrogenations. Indeed, such so-called *biomimetic* reactions (because they mimic the principles applied by nature) have been achieved with “Hantzsch esters” to reduce 2-oxoesters to the corresponding alcohols. Similarly, conjugate hydride addition to α,β-unsaturated aldehydes, followed by protonation provides the saturated aldehydes.

**Hantzsch Esters in Reductions**

The first process is not quite metal free, as it requires catalytic amounts of Lewis acidic Cu²⁺ to activate the carbonyl function. This has the advantage that in the presence of chiral ligands (see Section 12-2 and Chemical Highlights 5-4 and 12-2) to the Cu²⁺, the hydride adds enantioselectively from only one side of the molecule to generate only one enantiomer of the alcohol, much as nature does it. In the second process, similar activation takes place using catalytic amounts of an ammonium salt, which converts intermittently the aldehyde function to the corresponding iminium ion, in which the positive charge serves to render the β-carbon a better hydride acceptor. Traditionally, such activations are performed with H⁺ or Lewis acids, and hydrogenation of alkenes normally uses heterogeneous metal catalysts (Section 12-2). To contrast this and related transformations from their metal-catalyzed variants, they have been termed “organocatalytic.” Because they provide great selectivity and avoid potentially toxic metal ingredients, they also fall into the category of “green” chemistry.

**The NAD⁺–NADH Redox Couple**

**Exercise 25-23**

Propose a mechanism for the reaction of 4-chloropyridine with methoxide. [**Hint:** Think of the pyridine ring as containing an α,β-unsaturated imine function (see Sections 17-9 and 18-9).]

**Exercise 25-24**

The relative rates of the reactions of 2-, 3-, and 4-chloropyridine with sodium methoxide in methanol are 3000:1:81,000. Explain.
In Summary  Pyridine undergoes slow electrophilic aromatic substitution preferentially at C3. Nucleophilic substitution reactions occur more readily to expel hydride or another leaving group from either C2 or C4.

25-7 Quinoline and Isoquinoline: The Benzopyridines

We can imagine the fusion of a benzene ring to pyridine in either of two ways, giving us quinoline and isoquinoline (1- and 2-azanaphthalene, according to our systematic nomenclature). Both are liquids with high boiling points. Many of their derivatives are found in nature or have been synthesized in the search for physiological activity. Like pyridine, quinoline and isoquinoline are readily available from coal tar.

As might be expected, because pyridine is electron poor compared with benzene, electrophilic substitutions on quinoline and isoquinoline take place at the benzene ring. As with naphthalene, substitution at the carbons next to the ring fusion predominates.

![Quinoline and Isoquinoline](image)

**CHEMICAL HIGHLIGHT 25-3**

**Folic Acid, Vitamin D, Cholesterol, and the Color of Your Skin**

Folic acid is essential to human life. Its structure incorporates a 1,3,5,8-tetraazanaphthalene (pteridine) ring system, together with 4-aminobenzoic acid (Section 15-4) and \((\text{S})\)-aminopentanedioic (glutamic) acid (Section 26-1). Folic acid is necessary for the proper development of the nervous system in the very early stages of pregnancy. One of its functions is the transfer of one-carbon fragments between biomolecules (Chapter 9, Problems 69 and 70). A deficiency of this substance, which must be obtained from the diet, is associated with crippling and often fatal birth defects such as spina bifida (“open spine”) and anencephaly (a failure of the brain to develop normally). The U.S. Public Health Service recommends that all women of child-bearing age take 400 μg (0.4 mg) of folic acid daily.

![Folic Acid](image)

Vitamin D is also an essential nutrient for good health. It supports the growth of healthy bones in children, and its lack leads to a deforming condition known as rickets. Throughout our lives, vitamin D plays a crucial role in maintaining proper levels of calcium and phosphorus in the body. Unlike folic acid, your body can manufacture vitamin D. The starting material is cholesterol (Chemical Highlight 4-2), and the other indispensable ingredient is sunlight—specifically, the ultraviolet B radiation (the range from 280 to 315 nm) that falls on the Earth’s surface when the sun is high in the sky. From these facts derives a truly remarkable story.
Chapter 25

25-7 Quinoline and Isoquinoline: The Benzopyridines

In contrast with electrophiles, nucleophiles prefer reaction at the electron-poor pyridine nucleus. These reactions are quite analogous to those with pyridine.

Chichibabin Reaction of Quinoline and Isoquinoline

The Peruvian fire stick secretes quinoline from glands behind the head as a chemical defense against predators, such as frogs, cockroaches, spiders, and ants.

The diversity of the interplay between folic acid and vitamin D production: Thuram (top), Henry, Lama, and Petit of the French national soccer team on the way to winning the World Cup in 1998.

The shades of human skin range from nearly jet black in some tropical populations to the palest of skin tones in redheads from northern Europe (the United Kingdom in particular). How and why is this the case?

The extended aromatic \( \pi \) system in the tetraazanaphthalene ring of folic acid absorbs ultraviolet light strongly (Section 15-5) and undergoes subsequent structural changes; in short, sunlight, which is necessary for the production of vitamin D, destroys the body’s stores of folic acid. The variations in human skin color around Earth represent the response of human evolution to the varying amounts of UV light to which humans are exposed. At the evolutionary dawn of humanity, as the amount of protective hair covering the body diminished, individuals who possessed greater amounts of skin-darkening pigments had a higher likelihood of giving birth to healthy babies. Their slightly darker skin provided some protection for the folic acid in their bodies, while still allowing the synthesis of adequate amounts of vitamin D.

What about lighter-skinned populations? Assuming the accuracy of the “out of Africa” hypothesis, humans moving northward to latitudes with less direct sunlight would have faced vitamin D deficiencies as a function of the darkness of their skin. In this situation, individuals with slightly lighter skin would have had the advantage, their increased vitamin D production increasing the odds of reaching reproductive age. Over the generations of northward human migration, the lightening of the skin would have reached the present balance that allows both the preservation of necessary amounts of folic acid and the synthesis of adequate quantities of vitamin D.

How do the darkest-skinned individuals synthesize enough vitamin D, when their skin permits only very little UV light to penetrate? An adaptation developed in this population, which favored individuals who produced higher levels of cholesterol, the precursor of vitamin D, in their blood. We see the consequences of this modification in the higher incidence of cholesterol-related heart disease and stroke in this group.
Exercise 25-25

Quinoline and isoquinoline react with organometallic reagents exactly as pyridine does (Section 25-6). Give the products of their reaction with 2-propenylmagnesium bromide (allylmagnesium bromide).

Exercise 25-26

Working with the Concepts: Recognizing Retrosynthetic Disconnections in the Azanaphthalenes

As described in Section 25-5, some pyridine syntheses are based on a variety of condensation reactions, typically aldol (Section 18-5) and imine condensations (Section 17-9). Bearing this in mind, how would you dissect the pyridine ring of quinoline A retrosynthetically to two appropriate starting materials for its construction?

Strategy

The most obvious disconnection is the imine linkage, which could arise from the corresponding amine and carbonyl component. The latter reveals an \( \alpha,\beta \)-unsaturated ketone that might be assembled by an aldol condensation.

Solution

• First, we disconnect the imine double bond (step 1). This produces a benzenamine on one side and a carbonyl group on the other.
• Second, we apply a retroaldol step to the remaining double bond (step 2) to generate 2-acetylbenzeneamine and 2,4-pentanedione.
• Are these two materials suitable starting materials for the synthesis of A? The answer is yes: This reaction is an example of the so-called Friedländer synthesis of quinolines, and it proceeds with either acid or base catalysis. While one can envisage several competing condensations of the starting materials, they are reversible and there is considerable driving force toward the aromatic cyclization product. Moreover, the aminoketone component contains the two functions in conjugation, thus preventing its self-condensation (write the dipolar ammonium enolate resonance form).
In Summary The azanaphthalenes quinoline and isoquinoline may be regarded as benzo-pyridines. Electrophiles attack the benzene ring, nucleophiles attack the pyridine ring.

25-8 Alkaloids: Physiologically Potent Nitrogen Heterocycles in Nature

The alkaloids are bitter-tasting, natural nitrogen-containing compounds found particularly in plants. The name is derived from their characteristic basic properties (alkali-like), which are induced by the lone electron pair of nitrogen.

As with acyclic amines (Chapter 21), the (Lewis) basic nature of the alkaloids, in conjunction with their particular three-dimensional architecture, gives rise to often potent physiological activity. We have already noted some examples of this behavior in the narcotics morphine and heroin (Section 9-11), the psychoactive lysergic acid and LSD (Section 19-13), and the antibiotic penicillins (Chemical Highlight 20-2).

Nicotine (see also Chemical Highlight 25-1), present in dried tobacco leaves in 2–8% concentration, is the stimulating ingredient in cigarettes and other tobacco products.

Exercise 25-27

Try It Yourself

Sketch plausible retrosynthetic disconnections for the following molecules. [Hints: For (b), see Section 17-10; for (c), see Problem 17-43.]

Lysergic acid diethylamide, LSD  
[\(X = (CH_3CH_2)_2N\)]  

Heroin (R = CH$_3$C)  

Nicotine (see also Chemical Highlight 25-1), present in dried tobacco leaves in 2–8% concentration, is the stimulating ingredient in cigarettes and other tobacco products.
Nature Is Not Always Green: Natural Pesticides

Many people believe that everything synthetic is somehow suspect and “bad,” and that all of nature’s chemicals are benign. As pointed out by Ames* and others, this is a misconception. While we have seen that, indeed, many manufactured chemicals have problems with toxicity and adverse effects on the environment, nature’s chemicals are not any different from synthetic ones. Nature has its own highly productive laboratory, which puts out compounds by the millions, many of which are highly toxic, such as quite a few of the alkaloids found in plants. Consequently, there are numerous (sometimes lethal) cases of poisoning (especially of children) due to the accidental ingestion of plant material, the eating of green potatoes (exposed to sunlight, which increases their toxin level), the drinking of herbal teas, the consumption of “poison” mushrooms, and so forth. Abraham Lincoln’s mother died from drinking milk from a cow that had grazed on the toxic snakeroot plant. The issue strikes at the heart of the argument that “organic” food, especially fruits and vegetables, is more healthy than conventional produce. Proponents advocate that organic products are better because they are grown without added synthetic pesticides, and critics claim that this very fact makes them prone to be contaminated with higher levels of bacteria and natural toxins.

In addition to the problem of immediate potential toxicity of plant chemicals, there is a growing body of evidence that points to adverse interactions between foods and pharmaceuticals. For example, bergamottin in grapefruit juice is responsible for the “grapefruit juice effect” on the bioavailability of several prescription drugs. This can cause the effective concentration of a drug to be greatly increased, reaching dangerous levels, or to be decreased, making the treatment less effective. Another example is the herbal antidepressant hypericum (St. John’s wort), which can cause abortions and also interferes with the action of the birth control pill (Chemical Highlight 4-3).

What is the purpose of these compounds in plant life? Plants cannot run away from predators and invading organisms, such as fungi, insects, animals, and humans, and they have no organs with which to defend themselves. Instead, they have developed an array of chemical weapons, “natural pesticides,” with which to mount an effective defense strategy. Tens of thousands of these chemicals are now known. They are either already present in the existing plant or are generated in a primitive “immune response” to external damage, such as by caterpillars or herbivorous insects. For example, in the tomato plant, a small polypeptide (Section 26-4) containing 18 amino acids, systemin, is the chemical alarm signal for external attack. The molecule travels rapidly through the plant, initiating a cascade of reactions that produce chemical poisons. The effect is either to fend off attackers completely or to slow them down sufficiently so that other predators will consume them. Interestingly, one of these compounds is salicylic acid, the core of aspirin (Chemical Highlight 22-2), which prevents the point of damage (much like a wound) from being infected. Plants in distress have evolved to use chemicals as alarm pheromones (Section 12-17), activating the chemical weapons complex of (as yet) undamaged neighbors by air- or waterborne molecular signals. They may also develop resistance (immunity) by chemical pathways.

Americans consume about 1.5 g of natural pesticides per person per day, in the form of vegetables, fruit, tea, coffee, and so forth—10,000 times more than their intake of.

*Professor Bruce N. Ames (b. 1928), University of California at Berkeley.
synthetic pesticide residues. The concentration of these natural compounds ranges in the parts per million (ppm), orders of magnitude above the levels at which water pollutants (e.g., chlorinated hydrocarbons) and other synthetic pollutants (e.g., detergents, Chemical Highlight 19-1) are usually measured (parts per billion, or ppb). Few of these plant toxins have been tested for carcinogenicity but, of those tested (in rodents), roughly half are carcinogenic, the same proportion as that of synthetic chemicals. Many have proven toxicity. The table gives examples of some (potentially) toxic pesticides in common foods.

Why, then, have we all not been exterminated by these poisons? One reason is that the level of our exposure to any one of these natural pesticides is very small. More important, we, like plants, have evolved to defend ourselves against this barrage of chemical projectiles. Thus, for starters, our first line of defense, the surface layers of the mouth, esophagus, stomach, intestine, skin, and lungs, is discarded once every few days as “cannon fodder.” In addition, we have multiple detoxifying mechanisms, rendering ingested poisons nontoxic; we excrete a lot of material before it does any harm; our DNA has many ways of repairing damage; and finally, our ability to smell and taste “repugnant” substances (such as the “bitter” alkaloids, rotten food, milk that is “off,” eggs that smell of “sulfur”) serves as an advance warning signal. In the final analysis, we each must judge what we put into our bodies, but the age-old wisdoms still hold: Avoid anything in excess, and maintain variety in your diet.

Even more stimulating than nicotine are caffeine and theobromine, present in coffee and tea or cocoa (chocolate), respectively. Perhaps the most dangerous stimulant is cocaine, extracted from the leaves of the coca shrub, which is cultivated mainly in South America for the purpose of illegal drug trafficking. Cocaine is shipped and sold in the form of the water-soluble hydrochloride salt ("street cocaine"), which may be ingested through the nasal passages by "snorting" or orally and intravenously. The actual alkaloid is known as "freebase" or "crack" and is inhaled by smoking. There are severe physical and psychological side effects of the drug, such as brain seizures, respiratory collapse, heart attack, paranoia, and depression. The compound has some good uses, nevertheless. For example, it functions as a very effective topical anesthetic in eye operations.

Quinine, isolated from cinchona bark (as much as 8% concentration), is the oldest known effective antimalarial agent. A malaria attack consists of a chill accompanied or followed by a fever, which terminates in a sweating stage. Such attacks may recur regularly. The name “malaria” is derived from the Italian *malo*, bad, and *aria*, air, referring to the old belief that the disease was caused by noxious effluent gases from marshland. The actual culprit is a protozoan parasite (*Plasmodium* species) transmitted by the bite of an infected female mosquito of the genus *Anopheles* (see Chemical Highlight 3-2). It is estimated that from 300 to 500 million people are affected by this disease, which kills over 2 million each year, more than half of them children.

Strychnine is a powerful poison (the lethal dose in animals is about 5–8 mg kg\(^{-1}\)), the lethal ingredient of many a detective novel.

The isoquinoline and 1,2,3,4-tetrahydroisoquinoline nuclei are abundant among the alkaloids, and their derivatives are physiologically active, for example, as hallucinogens, central nervous system agents (depressants and stimulants), and hypotensives. Note that the pharmacophoric 2-phenylethanamine unit (see Chemical Highlight 21-1) is part of these nuclei and is also present in most of the other alkaloids considered in this section. (Find it in morphine, lysergic acid, quinine—there is a quirk here—and strychnine.)

**In Summary** The alkaloids are natural nitrogen-containing compounds, many of which are physiologically active.

**THE BIG PICTURE**

The discussion of saturated and aromatic heterocycles pulls together several concepts and applications in this book—in particular, the ring opening of strained heterocycles; the extension of the principles of aromaticity to heteroaromatic systems, including electrophilic and nucleophilic aromatic substitution; the use of condensation methodology in the construction of heteroaromatic systems; and a glimpse at their structural diversity in nature and as synthetic drugs. The field of heterocyclic chemistry is vast, and this chapter has only highlighted a few of its aspects. We shall see in the next and final chapter that heterocycles are integral parts of the nucleic acids DNA and RNA.
CHAPTER INTEGRATION PROBLEMS

25-28. As we have seen for the heterocyclopentadienes (Section 25-3) and pyridine (Section 25-5), heteroaromatic compounds can almost invariably be made by condensation reactions of carbonyl substrates with appropriate heterofunctions.

a. Write a plausible mechanism for the first step of the Hantzsch synthesis of 2,6-dimethylpyridine (Section 25-5), shown again here.

\[
\begin{align*}
\text{CH}_3\text{CONH}_2 + \text{CO}_2\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}_2\text{C} & \rightarrow \text{CH}_3\text{CH}_2\text{CONH}_2 + \text{CO}_2\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}_2\text{C} \\
\text{H}_3\text{C}=\text{C}\text{H}_2\text{CO}_2\text{CH}_3 + \text{CH}_3\text{CH}_2\text{O}_2\text{C} & \rightarrow \text{CH}_3\text{CH}_2\text{C}=$$
\]

SOLUTION

By following the fate of the four components in the starting mixture, you can see that the ammonia has reacted at the two keto carbonyl carbons, presumably by imine and then enamine formation (Section 17-9), whereas the formaldehyde component has made bonds to the acidic methylene of the 3-oxobutanoates (Section 23-2), presumably initially by an aldol-like condensation process (Section 18-5). Let us formulate these steps one at a time.

**Step 1.** Aldol-like condensation of formaldehyde with ethyl 3-oxobutanoate

\[
\text{H}_2\text{C}=\text{O} + \text{CH}_3\text{CCH}_2\text{CO}_2\text{CH}_3 \rightarrow \text{H}_2\text{C}=\text{C}\text{CH}_3 + \text{H}_2\text{O}
\]

**Michael acceptor**

**Step 2.** Enamine formation of ammonia with ethyl 3-oxobutanoate

\[
\text{CH}_3\text{CCH}_2\text{CO}_2\text{CH}_3 + \text{NH}_3 \rightarrow \text{CH}_3\text{C}=\text{CHCO}_2\text{CH}_3 + \text{H}_2\text{O}
\]

We note that step 1 furnishes a Michael acceptor, whereas step 2 results in an enamine. The latter can react with the former, in analogy to the reaction of enolates, by Michael addition, in this case to a neutral oxoenamine.

**Step 3.** Michael addition of the enamine

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{O}_2\text{C} & \rightarrow \text{CH}_3\text{CH}_2\text{O}_2\text{C} \\
\text{H}_3\text{C} & \rightarrow \text{H} \rightarrow \text{CH}_3\text{C} \rightarrow \text{H}_2\text{O}
\end{align*}
\]

This species is now perfectly set up to undergo an intramolecular imine condensation of the 3,4-dihydropyridine, which tautomerizes (Sections 13-7 and 18-2) to the more stable 1,4-dihydro product.
Step 4. Intramolecular imine formation and tautomerization

\[
\begin{align*}
\text{Oxoenamine} & \quad \xrightarrow{-\text{H}_2\text{O}} \quad \text{Diethyl 3,4-dihydro-2,6-dimethyl-3,5-pyridinedicarboxylate} \\
\end{align*}
\]

b. On the basis of the discussion of (a) and Exercises 25-11 and 25-14, suggest some simple retro-synthetic (recondensation) reactions to indole, quinoline, and 1,4-diazanaphthalene (quinoxaline) from ortho-disubstituted benzenes.

SOLUTION

You can view indole as a benzofused enamine. The enamine part is retrosynthetically connected to the corresponding enolizable carbonyl and amino function (Section 17-9).

\[
\begin{align*}
\text{Indole} & \quad \xrightarrow{\text{H}_2\text{NNH}_2, \text{H}_2\text{O}} \quad \text{H}_2\text{NCH} = \text{CH}_2
\end{align*}
\]

Quinoline can be viewed as a benzofused \(\alpha,\beta\)-unsaturated imine. The imine nucleus is retrosynthetically opened to the corresponding amine and \(\alpha,\beta\)-unsaturated carbonyl fragments (Section 17-9), which can be constructed by an aldol condensation (Section 18-5) employing acetaldehyde.

\[
\begin{align*}
\text{Quinoline} & \quad \xrightarrow{\text{CH}_3\text{OSOCH}_3} \quad \text{H}_2\text{NCH} = \text{CH}_2 + \text{CH}_3\text{CHO}
\end{align*}
\]

1,4-Diazanaphthalene can be dissected by retrosynthetic hydrolysis of the two imine functions (Section 17-9) to 1,2-benzenediamine and ethanedione (glyoxal).

\[
\begin{align*}
\text{1,4-Diazanaphthalene (Quinoxaline)} & \quad \xrightarrow{\text{NaOH, H}_2\text{O}} \quad \text{H}_2\text{NCH} = \text{CH}_2 + \text{CH} = \text{CH}_2 \quad \text{glyoxal}
\end{align*}
\]

25-29. Viagra (sildenafil citrate) was introduced in 1998 as an effective way to treat male erectile dysfunction (MED). It was discovered accidentally during clinical trials of the compound as a treatment for coronary heart disease and works by enhancing the production of nitric oxide (NO) in erectile tissue, ultimately leading to vasodilation (see Chemical Highlight 26-1). The route by which Viagra was made originally in the research laboratory is shown below.
With your current knowledge of synthetic chemistry, you should be able to understand each of the 12 steps in this synthesis, even though some of the functional units are new to you. Identify the essential features of each step and rationalize its outcome.

**SOLUTION**

This problem is typical of what the practitioner of organic synthesis might encounter while reading the literature. He or she may not be versed in the particular class of substances described, or the specific reagents employed, but will nevertheless be able to follow the narrative by extrapolating from basic principles.

**Step 1.** We can see topologically that the N₂ unit in the reagent hydrazine, H₂NNH₂, has been added across the β-dicarbonyl function (Chapter 23) in some way. Comparison of the respective molecular formulas reveals that two molecules of water are lost on going from starting materials to product, suggestive of a double condensation. Substituted hydrazines undergo just that with ketones (Section 17-10; see also Exercise 25-27b), normally only once; here we do it twice. Application to a 1,3-dione produces a diazacyclopentadiene, which aromatizes by deprotonation (to an aromatic anion, see Section 15-7), followed by reprotonation. The resulting 2-azapyrrole (Section 25-4) is called pyrazole, and this is one way of making it.

**General Pyrazole Synthesis**

**Step 2.** Dimethylsulfate, (CH₃O)₂SO₂, is a methylating agent (Section 6-7) and serves to alkylate the pyrazole nitrogen.

**Step 3.** This step is a simple base-mediated ester hydrolysis (Section 20-4).
Step 4. The product of the sequence 4–7 contains an additional amino substituent on the pyrazole ring. The requisite nitrogen is introduced by way of an electrophilic nitration (Sections 15-10 and 25-4).

Steps 5 and 6. This sequence converts the carboxylic acid to the carboxylic amide via the acid chloride (Sections 19-8 and 20-2).

Step 7. We now convert the nitro substituent introduced in step 4 into the amino function by catalytic hydrogenation (Section 16-5).

Step 8. Next, we introduce the 2-ethoxybenzoyl fragment by amide formation (Section 20-2).

Step 9. This condensation is unusual, as it involves deactivated amino and carbonyl groups. It is facilitated by its intramolecular nature, much like that of cyclic imide formation (Section 19-10), and the dipolar (Section 20-1) aromatic resonance stabilization of the product, shown in a general way below.

Step 10. This step is a variant of aromatic sulfonation (Section 15-10) and simultaneous sulfonyl chloride generation, using chlorosulfonic acid, ClSO$_3$H, the acid chloride of sulfuric acid.

Step 11. We arrive at sildenafil, the active ingredient of Viagra, by sulfonamide production (Section 15-10).

Step 12. To allow for water solubility, sildenafil is administered in the protonated form of the ammonium salt of citric acid, the drug Viagra itself.

New Reactions

1. Reactions of Heterocyclopropanes (Section 25-2)

   \[
   \begin{align*}
   X & \quad \overset{1. \cdot \cdot \cdot \text{Nu or HNu}}{\xrightarrow{1. \cdot \cdot \cdot \text{Nu or HNu}}} \quad HX \quad \overset{2. \text{H}_2\text{O}}{\longrightarrow} \quad \text{Nu} \\
   \end{align*}
   \]

2. Ring Opening of Heterocyclobutanes (Section 25-2)

   \[
   \begin{align*}
   X & \quad \overset{1. \cdot \cdot \cdot \text{Nu or HNu}}{\xrightarrow{1. \cdot \cdot \cdot \text{Nu or HNu}}} \quad HX \quad \overset{2. \text{H}_2\text{O}}{\longrightarrow} \quad \text{Nu} \\
   \text{Less reactive than heterocyclopropanes} \\
   \end{align*}
   \]

3. Paal-Knorr Synthesis of 1-Hetero-2,4-cyclopentadienes (Section 25-3)

   \[
   \begin{align*}
   \text{P}_2\text{S}_5, \Delta & \quad \overset{\text{P}_2\text{S}_5, \Delta}{\xrightarrow{\text{P}_2\text{S}_5, \Delta}} \quad R \quad \overset{\text{P}_2\text{O}_5, \Delta}{\longrightarrow} \quad R \\
   \overset{\text{(NH}_4\text{)}_2\text{CO}_3, \Delta}{\downarrow} & \quad \overset{\text{(NH}_4\text{)}_2\text{CO}_3, \Delta}{\downarrow} \quad R \\
   \text{N} & \quad \overset{\text{N}}{\xrightarrow{\text{N}} \quad \text{R}} \\
   \end{align*}
   \]

4. Reactions of 1-Hetero-2,4-cyclopentadienes (Section 25-4)

   Electrophilic substitution

   \[
   \begin{align*}
   E^- & \quad \overset{\text{E}^-}{\xrightarrow{\text{E}^-}} \quad \text{X} \quad \text{through} \quad \text{X} \quad \text{E}^- \\
   \text{Relative reactivity} & \quad \text{Main product} \\
   \text{S} & \quad \text{O} \quad \text{N} \\
   \end{align*}
   \]
Ring opening

\[
\text{H}_3\text{C} - \text{O} - \text{CH}_3 + \text{H}^+ + \text{H}_2\text{O} \rightarrow \text{H}_3\text{C} - \text{O} - \text{CH}_3
\]

Cycloaddition

\[
\text{C} = \text{C} + \text{C} = \text{O} \rightarrow \text{C} = \text{C} - \text{O} - \text{C} = \text{O}
\]

5. Hantzsch Synthesis of Pyridines (Section 25-5)

\[
\text{RO} - \text{C} - \text{CH}_2 + \text{H}_2\text{C} - \text{C} = \text{O} + \text{NH}_3 \rightarrow \text{RO}_2\text{C} - \text{N} - \text{H} - \text{R} + \text{H}_2\text{O} + \text{HNO}_3
\]

6. Reactions of Pyridine (Sections 25-5 and 25-6)

Protonation (Section 25-5)

\[
\text{H}^+ + \text{Pyridine} \rightleftharpoons \text{Pyridinium ion}
\]

Pyridinium ion

\[
(pK_a = 5.29)
\]

Electrophilic substitution (Section 25-6)

\[
\text{E}^- + \text{Pyridine} \rightarrow \text{E} - \text{Pyridine}
\]

Ring is deactivated relative to benzene.

Nucleophilic substitution (Section 25-6)

\[
\text{NaNH}_2, \text{liquid NH}_3 \rightarrow \text{Pyridine} + \text{NH}_2\text{NH}_2
\]

\[
\text{RLi, Organometallic reagent} \rightarrow \text{Pyridine} \rightarrow \text{Halopyridine}
\]

\[
(X = \text{Br, Cl})
\]
7. Reactions of Quinoline and Isoquinoline (Section 25-7)

Electrophilic substitution

**Important Concepts**

1. The **heterocycloalkanes** can be named using cycloalkane nomenclature. The prefix aza- for nitrogen, oxa- for oxygen, thia- for sulfur, and so forth, indicates the heteroatom. Other systematic and common names abound in the literature, particularly for the aromatic heterocycles.

2. The **strained three- and four-membered heterocycloalkanes** undergo **ring opening** with nucleophiles easily.

3. The **1-hetero-2,4-cyclopentadienes** are **aromatic** and have an arrangement of six $\pi$ electrons, similar to that in the cyclopentadienyl anion. The heteroatom is $sp^2$ hybridized, the $p$ orbital contributing two electrons to the $\pi$ system. As a consequence, the diene unit is electron rich and reactive in electrophilic aromatic substitutions.

4. Replacement of one (or more) of the CH units in benzene by an $sp^2$-hybridized nitrogen gives rise to **pyridine** (and other azabenzenes). The $p$ orbital on the heteroatom contributes one electron to the $\pi$ system; the lone electron pair is located in an $sp^2$ hybrid atomic orbital in the molecular plane. Azabenzenes are **electron poor**, because the electronegative nitrogen withdraws electron density from the ring by induction and by resonance. Electrophilic aromatic substitution of azabenzenes is sluggish. Conversely, nucleophilic aromatic substitution occurs readily; this is shown by the Chichibabin reaction, substitutions by organometallic reagents next to the nitrogen, and the displacement of halide ion from halopyridines by nucleophiles.

5. The azanaphthalenes (benzopyridines) **quinoline** and **isoquinoline** contain an electron-poor pyridine ring, susceptible to nucleophilic attack, and an electron-rich benzene ring that enters into electrophilic aromatic substitution reactions, usually at the positions closest to the heterocyclic unit.

**Problems**

30. Name or draw the following compounds. (a) *cis*-2,3-Diphenyloxacyclopropane; (b) 3-azacyclobutanone; (c) 1,3-oxathiacyclopentane; (d) 2-butanoyl-1,3-dithiacyclohexane;

31. Identify by name (either IUPAC or common) as many of the heterocyclic rings contained in the structures shown in Table 25-1 as you can.

32. Give the expected product of each of the following reaction sequences.
33. The penicillins are a class of antibiotics containing two heterocyclic rings that interfere with the construction of cell walls by bacteria (Chemical Highlight 20-2). The interference results from reaction of the penicillin with an amino group of a protein that closes gaps that develop during construction of the cell wall. The insides of the cell leak out, and the organism dies. (a) Suggest a reasonable product for the reactions of penicillin G with the amino group of a protein (protein–NH₂). (Hint: First identify the most reactive electrophilic site in penicillin.)

(b) Penicillin-resistant bacteria secrete an enzyme (penicillinase) that catalyzes hydrolysis of the antibiotic faster than the antibiotic can attack the cell-wall proteins. Propose a structure for the product of this hydrolysis and suggest a reason why hydrolysis destroys the antibiotic properties of penicillin.

34. Propose reasonable mechanisms for the following transformations.

(a) 1. SnCl₄ (a Lewis acid), CH₂Cl₂
    2. H⁺, H₂O

(b) 1. CH₃CH₂CH₂CH₂Li, BF₃–O(CH₂CH₃)₂, THF
    2. H⁺, H₂O

(c) H₃C
    O
    H
    CH₃
    MgBr₂, CH₃COCCH₃
    (Hint: See Section 15-13.)

35. Rank the following compounds in increasing order of basicity: water, hydroxide, pyridine, pyrrole, ammonia.

36. Each of the heterocyclopentadienes in the margin contains more than one heteroatom. For each one, identify the orbitals occupied by all lone electron pairs on the heteroatoms and determine whether the molecule qualifies as aromatic. Are any of these heterocycles a stronger base than pyrrole?

37. Give the product of each of the following reactions.

(a) O
    CH₃NH₂

(b) O
    P₂O₅,
    /H₁₁₀₀₁

38. 1-Hetero-2,4-cyclopentadienes can be prepared by condensation of an α-dicarbonyl compound and certain heteroatom-containing diesters. Propose a mechanism for the following pyrrole synthesis.

C₆H₃CCC₆H₅ + CH₃COCH₂NCH₂COCH₃
NaOCH₂, CH₂OH, Δ

How would you use a similar approach to synthesize 2,5-thiophenedicarboxylic acid?
39. Give the expected major product(s) of each of the following reactions. Explain how you chose the position of substitution in each case.

(a) \( \text{COOCH}_3 \text{O} \) \( \text{Cl}_2 \)  
(b) \( \text{HNO}_3, \text{H}_2\text{SO}_4 \)  
(c) \( \text{CH}_3\text{S} \text{CH}_3 \text{CH}_2\text{CH}_3, \text{AlCl}_3 \)  
(d) \( \text{Br}_2 \)  
(e) \( \text{N}_2\text{Cl}^- \text{, NaOH, H}_2\text{O} \)  

(Hint: basic conditions. First deprotonate nitrogen.)

40. Give the products expected of each of the following reactions.

(a) \( \text{H}_3\text{C} \text{C}_3 \text{N} \) \( \text{Fuming H}_2\text{SO}_4, 270^\circ\text{C} \)  
(b) \( \text{O} \) \( \text{O} \) \( \text{O} \) \( \text{H}_9\text{O}_4, \text{pressure} \)  
(c) \( \text{KSH, CH}_3\text{OH, } \Delta \)  
(d) \( \text{S} \) \( \text{1. C}_6\text{H}_5\text{COCl, SnCl}_4 \) \( \text{2. Raney Ni, } \text{H}_9\text{O}_4 \)  
(e) \( \text{N(C}_3\text{H}_3)\text{Cl}_2 \text{Li, THF, } \text{H}_9\text{O}_4 \)  

41. Propose a synthesis of each of the following substituted heterocycles, using synthetic sequences presented in this chapter.

(a) \( \text{H}_3\text{C} \text{C}_3 \text{H}_3 \text{O} \) \( \text{H}_3\text{C} \text{C}_3 \text{H}_3 \text{O} \)  
(b) \( \text{H}_3\text{C}_6 \text{C}_3 \text{N} \text{C}_3\text{H}_5 \)  
(c) \( \text{H}_3\text{C} \text{N} \text{H} \text{C}_3\text{H}_3 \)  
(d) \( \text{H}_3\text{C} \text{S} \text{H}_3\text{C} \text{H}_3 \)  

42. The structures of caffeine, the principal stimulant in coffee, and theobromine, its close relative in chocolate, are given in Section 25-8. Propose an efficient synthetic method to convert theobromine into caffeine.

43. Melamine, or 2,4,6-triaminotriazine, is a toxic heterocyclic compound that has been implicated in the illnesses and deaths of both house pets and humans who ingested melamine-contaminated food. As its formula shows, melamine has a very high nitrogen content. Proteins (Chapter 26) are the main natural source of nitrogen in foods, and nitrogen analysis is commonly used to determine protein content in foods. The illegal addition of melamine to packaged foods increases their nitrogen content and makes them appear richer in protein; in reality, they are deadly. (a) A typical protein in food contains about 15% nitrogen. What is the % N in melamine? Does this result explain the motivation behind the melamine “doping” of packaged foods? (b) Melamine is synthesized by addition of ammonia to cyanuric chloride (2,4,6-trichlorotriazine, see equation in the margin). What kind of reaction is this? Formulate a mechanism and explain why cyanuric chloride displays this type of chemistry.

44. Chelidonic acid, a 4-oxacyclohexanone (common name, γ-pyrone), is found in a number of plants and is synthesized from acetone and diethyl ethanedioate. Formulate a mechanism for this transformation.
45. Porphyrins are polyheterocyclic constituents of hemoglobin and myoglobin, the molecules that transport molecular oxygen in living systems (Section 26-8), of the cytochromes, which also play central roles in biological redox processes (Section 22-9), and of chlorophyll (Chemical Highlight 24-2), which mediates photosynthesis in all green plants.

Porphyrins are the products of a remarkable reaction between pyrrole and an aldehyde in the presence of acid:

This reaction is complicated and has many steps. The simpler condensation of one molecule of benzaldehyde and two of pyrrole to give the product shown below, a dipyrrylmethane, is illustrative of the first stage in porphyrin formation. Propose a step-by-step mechanism for this process.

46. Isoxazoles (Problem 36) have taken on increased significance as synthetic targets, because they are found in the structures of some recently discovered naturally occurring molecules that show promise as antibiotics (see Chemical Highlight 20-2). Isoxazoles may be prepared by reaction of alkynes with compounds containing the unusual nitrile oxide functional group:

Suggest a mechanism for this process.

47. Reserpine is a naturally occurring indole alkaloid with powerful tranquilizing and antihypertensive activity. Many such compounds possess a characteristic structural feature: one nitrogen atom at a ring fusion separated by two carbons from another nitrogen atom.

A series of compounds with modified versions of this structural feature have been synthesized and also shown to have antihypertensive activity, as well as antifibrillatory properties. One such synthesis is shown here. Name or draw the missing reagents and products (a) through (c).
48. Starting with benzenamine (aniline) and pyridine, propose a synthesis for the antimicrobial sulfa drug sulfapyridine.

\[
\text{N} \quad \text{CO}_2\text{CH}_2\text{CH}_3
\]

\[
\text{H} \quad \text{CO}_2\text{CH}_2\text{CH}_3
\]

\[
\text{H}_2\text{C} \quad \text{CH}_2 \quad \Delta \quad \text{CH}_2\text{CH}_3\text{OH}
\]

\[
\text{LiAIH}_4 \quad \text{C}_6\text{H}_4\text{N}_2\text{O}
\]

\[
\text{C}_6\text{H}_{16}\text{N}_2
\]

49. Derivatives of benzimidazole possess biological activity somewhat like that of indoles and purines (of which adenine, Section 25-1, is an example). Benzimidazoles are commonly prepared from benzene-1,2-diamine. Devise a short synthesis of 2-methylbenzimidazole from benzene-1,2-diamine.

\[
\text{NH}_2 \quad \text{NH}_2
\]

\[
\text{Benzene-1,2-diamine} \quad \text{2-Methylbenzimidazole}
\]

50. The Darzens condensation is one of the older methods (1904) for the synthesis of three-membered heterocycles. It is most commonly the reaction of a 2-halo ester with a carbonyl derivative in the presence of base. The following examples of the Darzens condensation show how it is applied to the synthesis of oxacyclopropane and azacyclopropane rings. Suggest a reasonable mechanism for each of these reactions.

\[(a) \quad \text{C}_6\text{H}_5\text{CHO} + \text{C}_6\text{H}_5\text{CHCOOCH}_2\text{CH}_3 \xrightarrow{\text{KOC(CH}_3)_3, \text{(CH}_3)_3\text{COH}} \text{H}_2\text{C}_6\text{C} \quad \text{C}_6\text{H}_6 \quad \text{COOCH}_2\text{CH}_3\]

\[(b) \quad \text{C}_6\text{H}_5\text{CH} = \text{NC}_6\text{H}_5 + \text{ClICH}_2\text{COOCH}_2\text{CH}_3 \xrightarrow{\text{KOC(CH}_3)_3, \text{CH}_3\text{OCH}_2\text{CH}_2\text{OCH}_3} \text{C}_6\text{H}_6\text{CH} \quad \text{CHCOOCH}_2\text{CH}_3\]

51. (a) The compound shown in the margin, with the common name 1,3-dibromo-5,5-dimethylhydantoin, is useful as a source of electrophilic bromine (Br⁺) for addition reactions. Give a more systematic name for this heterocyclic compound. (b) An even more remarkable heterocyclic compound (ii) is prepared by the following reaction sequence. Using the given information, deduce structures for compounds i and ii, and name the latter.

\[
\text{H}_3\text{C} \quad \text{N} \quad \text{O} \quad \text{Br}
\]

\[
\text{H}_3\text{C} \quad \text{N} \quad \text{O} \quad \text{Br}
\]

Heterocycle ii is a yellow, crystalline, sweet-smelling compound that decomposes upon gentle heating into two molecules of acetone, one of which is formed directly in its \(n \rightarrow \pi^*\) excited state (Sections 14-11 and 17-3). This electronically excited product is chemiluminescent.

\[
\text{ii} \quad \text{CH}_2\text{CCH}_3 + \left[ \text{CH}_3\text{CCH}_3 \right] \xrightarrow{\pi^*} \text{hv} + 2 \text{CH}_3\text{CCH}_3
\]

Heterocycles similar to compound ii are responsible for the chemiluminescence produced by a number of species [e.g., fireflies (see Chemical Highlight 9-1) and several deep-sea fish]; they also serve as the energy sources in commercial chemiluminescent products.
52. Azacyclohexanes (piperidines) can be synthesized by reaction of ammonia with *cross-conjugated dienones*: ketones conjugated on both sides with double bonds. Propose a mechanism for the following synthesis of 2,2,6,6-tetramethylaza-4-cyclohexanone.

$$\text{(CH}_3\text{)}_2\text{C} = \text{CHCH} = \text{C} \text{(CH}_3\text{)}_2 \xrightarrow{\text{NH}_3} \text{H}_3\text{C} \text{H}_3\text{N} \text{H} \text{CH}_3 \text{CH}_3$$

53. Quinolines (Section 25-7) are heterocycles that are widely used in medicinal chemistry because of the diversity of biological activity—including anticancer utility—that their derivatives display. A short synthesis of 3-acylidihydroquinolines (which may be converted into 3-acylquinolines by mild oxidation) is shown below. Propose a mechanism for this process. **(Hint: Review Section 18-10.)**

54. **Challenge** At which position(s) do you expect 3-acetylquinoline (margin) to undergo nitration in the presence of a mixture of sulfuric and fuming nitric acids? Will this reaction be faster or slower than nitration of quinoline itself?

55. Compound A, C₈H₈O, exhibits ¹H NMR spectrum A. Upon treatment with concentrated aqueous HCl, it is converted almost instantaneously into a compound that exhibits spectrum B (p. 1206). What is compound A, and what is the product of its treatment with aqueous acid?

**¹H NMR**

```
5 H

7.4 7.3
3.9 3.8
1 H

3.2 3.1 2.8

(CH₃)₄Si
```

300-MHz ¹H NMR spectrum ppm (δ)
56. Heterocycle C, C₅H₆O, exhibits ¦H NMR spectrum C and is converted by H₂ and Raney nickel into compound D, C₅H₁₀O, with spectrum D (p. 1207). Identify compounds C and D. (Note: The coupling constants of the compounds in this problem and the next one are rather small; they are therefore not nearly as useful in structure elucidation as those around a benzene ring.)
57. **Challenge** The commercial synthesis of a useful heterocyclic derivative requires treatment of a mixture of aldopentoses (derived from corncobs, straw, etc.) with hot acid under dehydrating conditions. The product, E, has \(^1H\) NMR spectrum E, shows a strong IR band at 1670 cm\(^{-1}\), and is formed in nearly quantitative yield. Identify compound E and formulate a mechanism for its formation.
Aldopentoses $\xrightarrow{H^+, \Delta} C_3H_4O_2$

Compound E is a valuable synthetic starting material. The following sequence converts it into furethonium, which is useful in the treatment of glaucoma. What is the structure of furethonium?

$$E \xrightarrow{1. NH_2, NaBH_3CN} \xrightarrow{2. Excess CH_3I, (CH_3CH_2)_2O} \text{furethonium}$$

**Challenge** Treatment of a 3-acylindole with LiAlH_4 in (CH_3CH_2)_2O reduces the carbonyl all the way to a CH_2 group. Explain by a plausible mechanism. (Hint: Direct S_N2 displacement of alkoxide by hydride is not plausible.)

**59.** The sequence in the margin is a rapid synthesis of one of the heterocycles in this chapter. Draw the structure of the product, which has $^1H$ NMR spectrum F.

**Team Problem**

**60.** This problem introduces two literature syntheses of indole derivatives, and you are asked to come up with plausible mechanisms for them. Divide your team in two, each group concentrating on one of the methods.
Fischer Indole Synthesis of 2-Phenylindole

In this procedure, a hydrazone of an enolizable aldehyde or ketone is heated in strong acid, causing ring closure with simultaneous expulsion of ammonia to furnish the indole nucleus. [Hints: The mechanism of the reaction proceeds in three stages: (1) an imine–enamine tautomerization (recall Section 17-9); (2) an electrocyclic reaction (a “diaza-Cope” rearrangement; recall Section 22-7); (3) another imine–enamine (in this case, benzenamine) tautomerization; (4) ring closure to the heterocycle; and (5) elimination of NH₃.]

Reissert Indole Synthesis of Ethyl Indole-2-carboxylate

In this sequence, a 2-methylnitrobenzene (o-nitrotoluene) is first converted into an ethyl 2-oxopropanoate (pyruvate, Chemical Highlight 23-2) ester, which, on reduction, is transformed into the target indole. [Hints: (1) The nitro group is essential for the success of the first step. Why? Does this step remind you of another reaction? Which one? (2) Which functional group is the target of the reduction step (recall Section 16-5)? (3) The ring closure to the heterocycle requires a condensation reaction.]
64. This reaction yields one main organic product. Which of the following compounds is it?

\[
\text{2-Phenylthiophene} \xrightarrow{\text{SnCl}_4, \text{CH}_3\text{CCl}_2} \]

(a) ![Molecule A](image)
(b) ![Molecule B](image)
(c) ![Molecule C](image)
(d) ![Molecule D](image)
n page 1 of this text we defined organic chemistry as the chemistry of carbon-containing compounds. We then went on to point out that organic molecules constitute the chemical bricks of life. Indeed, a historical definition of organic chemistry restricts it to living organisms. What is life and how do we, as organic chemists, approach its study? A functional definition of life refers to it as a condition of matter manifested by growth, metabolism, reproduction, and evolution. The underlying basic processes are chemical, and researchers hope to decipher their complexity by investigating specific reactions or reaction sequences. The “whole,” however, is much more complex than these individual pieces, because they interact by multiple feedback loops in a manner that makes it impossible to show that each effect has a simple cause. This final chapter will provide a glimpse of that complexity by taking you from amino acids to their polymers, the polypeptides—in particular, the large natural polypeptides called proteins—and to their biological origin, DNA.

Proteins have an astounding diversity of functions in living systems. As enzymes, they catalyze transformations ranging in complexity from the simple hydration of carbon dioxide to the replication of entire chromosomes—great coiled strands of DNA, the genetic material in living cells. Enzymes can accelerate certain reactions many millionfold.

We have already encountered the protein rhodopsin, the photoreceptor that generates and transmits nerve impulses in retinal cells (Chemical Highlight 18-3). Other proteins serve for transport and storage. Thus, hemoglobin carries oxygen; iron is transported in the blood by transferrin and stored in the liver by ferritin. Proteins play a crucial role in coordinated motion, such as muscle contraction. They give mechanical support to skin and bone; they are the antibodies responsible for our immune protection; and they control growth and differentiation—that is, which part of the information stored in DNA is to be used at any given time.

We begin with the structure and preparation of the 20 most common amino acids, the building blocks of proteins. We then show how amino acids are linked by peptide bonds in the three-dimensional structure of hemoglobin and other polypeptides. Some proteins contain thousands of amino acids, but we shall see how to determine the sequence of amino acids in many polypeptides and synthesize these molecules in the laboratory. Finally, we consider how other polymers, the nucleic acids DNA and RNA, direct the synthesis of proteins in nature.
26-1 Structure and Properties of Amino Acids

Amino acids are carboxylic acids that bear an amine group. The most common of these in nature are the 2-amino acids, or α-amino acids, which have the general formula RCH(NH₂)COOH; that is, the amino function is located at C2, the α-carbon. The R group can be alkyl or aryl, and it can contain hydroxy, amino, mercapto, sulfide, carboxy, guanidino, or imidazolyl groups. Because of the presence of both amino and carboxy functions, amino acids are both acidic and basic.

The stereocenter of common 2-amino acids has the S configuration

More than 500 amino acids exist in nature, but the proteins in all species, from bacteria to humans, consist mainly of only 20. Adult humans can synthesize all but eight, and two only in insufficient quantities. This group is often called the essential amino acids because they must be included in our diet. Although amino acids can be named in a systematic manner, they rarely are; so we shall use their common names. Table 26-1 lists the 20 most common amino acids, along with their structures, their \( pK_a \) values, and the three- and (the newer) one-letter codes that abbreviate their names. We shall see later how to use these codes to describe peptides conveniently.

<sup>a</sup>Essential amino acids. <sup>b</sup>Entire structure. <sup>c</sup>pK<sub>a</sub> of conjugate acid. <sup>d</sup>The stereocenter is R because the CH<sub>3</sub>SH substituent has higher priority than the COOH group.

Amino acids may be depicted by either hashed-wedged line structures or by Fischer projections.

### How to Draw L-Amino Acids and Their Relation to the L-Sugars

In all but glycine, the simplest of the amino acids, C2 is a stereocenter and usually adopts the S configuration. Other stereocenters located in the substituent R may have either R (as in threonine) or S configuration (as in isoleucine).

As in the names of the sugars (Section 24-1), an older amino acid nomenclature uses the prefixes D and L, which relate all the L-amino acids to (S)-2,3-dihydroxypropanal (L-glyceraldehyde). As emphasized in the discussion of the natural D sugars, a molecule belonging to the L family is not necessarily levorotatory. For example, both valine ([α]<sub>D</sub><sup>25</sup> = +13.9) and isoleucine ([α]<sub>D</sub><sup>25</sup> = +11.9) are dextrorotatory.
Amino acids are acidic and basic: zwitterions

Because of their two functional groups, the amino acids are both acidic and basic; that is, they are amphoteric (Section 8-3). The carboxylic acid group protonates the amine function, thus forming a zwitterion. This ammonium carboxylate form is favored because an ammonium ion is much less acidic (\( pK_a < 10^{-11} \)) than a carboxylic acid (\( pK_a < 2^{-5} \)). The highly polar zwitterionic structure allows amino acids to form particularly strong crystal lattices. Most of them therefore are fairly insoluble in organic solvents, and they decompose rather than melt when heated. The electrostatic potential map of glycine in the margin depicts its highly dipolar nature, originating from the juxtaposition of the electron-rich (red) carboxylate function with the electron-poor (blue) ammonium group.

The structure of an amino acid in aqueous solution depends on the pH. Consider, for example, the simplest member of the series, glycine. The major form in neutral solution is the zwitterion. However, in strong acid (pH \(< 1\)), glycine exists predominantly as the cationic ammonium carboxylic acid, whereas strongly basic solutions (pH \( > 13 \)) contain mainly the deprotonated \( \alpha \)-aminocarboxylate ion. These forms interconvert by acid-base equilibria (Section 2-2).

\[
\begin{align*}
\text{An ammonium ion} & \quad \text{predominates at pH < 1} \\
\text{A neutral zwitterion} & \quad \text{predominates at pH ? 6} \\
\text{A carboxylate ion} & \quad \text{predominates at pH > 13}
\end{align*}
\]

Increasing pH

Table 26-1 records \( pK_a \) values for each functional group of the amino acids. For glycine, the first value (2.3) refers to the equilibrium

\[
\frac{\text{\text{H}_2\text{NCH}_2\text{COOH}}}{\text{\text{H}_2\text{NCH}_2\text{COO}^- + \text{H}_3\text{O}^+}} = K_1 = 10^{2.3}
\]

Note that this \( pK_a \) is more than two units less than that of an ordinary carboxylic acid (\( pK_a \) \( \text{CH}_3\text{COOH} = 4.74 \)), an observation that is true for all the other \( \alpha \)-aminocarboxy groups in
Table 26-1. This difference is a consequence of the electron-withdrawing effect of the protonated amino group. The second $pK_a$ value (9.6) describes the second deprotonation step:

$$
\text{H}_2\text{NCH}_2\text{COO}^- + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{NCH}_2\text{COO}^- + \text{H}_2\text{O}$$

\[ pK_a = 9.6 \]

\[ K_2 = \frac{[\text{H}_2\text{NCH}_2\text{COO}^-][\text{H}_2\text{O}]}{[\text{H}_2\text{NCH}_2\text{COO}^-]} = 10^{-9.6} \]

**At the isoelectric point, the net charge is zero**

The pH at which the extent of protonation equals that of deprotonation is called the isoelectric pH or the isoelectric point ($pI$; Table 26-1). At this pH, the amount of positive charge balances that of negative charge and the concentration of the charge-neutralized zwitterionic form is at its greatest. For an amino acid without any additional acidic or basic groups, such as glycine, the value of its $pI$ is the average of its two $pK_a$ values.

\[ pI = \frac{pK_{a-COOH} + pK_{a-NH_2}}{2} \]

(for glycine) \[ \frac{2.3 + 9.6}{2} = 6.0 \]

When the side chain of the acid bears an additional acidic or basic function, the $pI$ is either decreased or increased, respectively, as one would expect. Table 26-1 shows seven amino acids in which this is the case. Specifically, for the four amino acids with an acidic side chain, the $pI$ is the average of its two lowest $pK_a$ values. Conversely, for the three amino acids with a basic side chain, the $pI$ is the average of its two highest $pK_a$ values.

**Assignment of $pK_a$ Values in Selected Amino Acids**

Why is this so? Picture these amino acids in their fully protonated form and then raise the pH (in other words, add base) to observe what happens to their net charge. For example, the amino dicarboxylic acid, aspartic acid, will be positively charged at low pH due to the presence of the ammonium substituent. To reach a charge-neutral form, on average one of the carboxy functions has to be deprotonated. This will happen at a pH midpoint between the two respective $pK_a$ values (1.9 and 3.7), at $pI = 2.8$. The similar glutamic acid has the corresponding value at 3.2. At physiological pH, both of the carboxy functions are deprotonated, and the molecules exist as the zwitterionic anions aspartate and glutamate. (Monosodium glutamate, MSG, is used as a flavor enhancer in various foods.) Tyrosine, which bears the relatively nonacidic neutral phenol substituent (at low pH), has a $pI = 5.7$, which is midway between the $pK_a$’s of the other two more acidic groups.
In contrast to the above examples, lysine bears an additional basic amino group that is protonated in a strongly acidic medium to furnish a dication. When the pH of the solution is raised, deprotonation of the carboxy group occurs first, followed by respective proton loss from the nitrogen at C2 and the remote ammonium function. The isoelectric point is located halfway between the last two pKₐ values, at pI = 9.7. Arginine carries a substituent new to us: the relatively basic guanidino group, -NH₂CNH₂, derived from the molecule guanidine (margin). The pKₐ of its conjugate acid is 12.5, almost three units greater than that of the ammonium ion (Section 21-4). The pI of arginine lies midway between that of the guanidinium and ammonium groups, at 10.8.

In the late 1980s and early 1990s, scientists, among them the 1998 Nobelists (medicine) Furchgott, Ignarro, and Murad,* made a series of startling discoveries. The simple but highly reactive and exceedingly toxic molecule nitric oxide, N=O₂, is synthesized in a wide variety of cells in mammals, including humans.

In the body, nitric oxide performs several critical biological functions as diverse as control of blood pressure, inhibition of platelet aggregation, cell differentiation, neurotransmission, and penile erection. It also plays a major role in the activity of the immune system. For example, macrophages (cells associated with the body’s immune system) destroy bacteria and tumor cells by exposing them to nitric oxide.

Nitric oxide is released by cells on the inner walls of blood vessels and causes adjacent muscle fibers to relax. This 1987 discovery explains the effectiveness of nitroglycerin and other organic nitrates as treatments for angina and heart attacks, a nearly century-old mystery: These substances are metabolically converted into NO, which dilates the blood vessels (see also Chapter Integration Problem 25-29).

Paradoxically, considering the essential benefits of NO, its overproduction leads to septic shock. Uncontrolled release may also be the cause of brain damage after a stroke and disorders such as Alzheimer’s and Huntington’s diseases. The occurrence of high levels of nitrite ion, NO₂⁻, in the joints of people with rheumatoid arthritis indicates overproduction of NO as a response to inflammation. Similar associations have been established for schizophrenia, urinary disorders, and multiple sclerosis. The rapidly evolving story of NO is an example of how little we still know about the functions of the body, but also how rapidly a discovery leads to the evolution of an entire field.

*Professor Robert F. Furchgott (b. 1916), State University of New York, Brooklyn; Professor Louis J. Ignarro (b. 1941), University of California at Los Angeles; Professor Ferid Murad (b. 1936), University of Texas, Dallas.
Chapter 26

1217

The imidazole ring is relatively basic because the protonated species is stabilized by resonance.

\[ \text{pK}_a = 7.0 \]

Guanidine is found in turnip juice, mushrooms, corn germ, rice hulls, mussels, and earthworms. Its basicity is due to the formation of a highly resonance-stabilized conjugate acid. Draw its resonance forms. (Hint: Review Section 20-1.)

Histidine (margin) contains another new substituent, the basic imidazole ring (see Problem 6 of Chapter 25). In this aromatic heterocycle, one of the nitrogen atoms is hybridized as in pyridine and the other is hybridized as in pyrrole.

Exercise 26-4

Guanidine is found in turnip juice, mushrooms, corn germ, rice hulls, mussels, and earthworms. Its basicity is due to the formation of a highly resonance-stabilized conjugate acid. Draw its resonance forms. (Hint: Review Section 20-1.)

Histidine (margin) contains another new substituent, the basic imidazole ring (see Problem 6 of Chapter 25). In this aromatic heterocycle, one of the nitrogen atoms is hybridized as in pyridine and the other is hybridized as in pyrrole.

Exercise 26-5

Draw an orbital picture of imidazole. (Hint: Use Figure 25-1 as a model.)

The imidazole ring is relatively basic because the protonated species is stabilized by resonance.

Resonance in Protonated Imidazole

\[ \text{pK}_a = 7.0 \]

This resonance stabilization is related to that in amides (Sections 20-1 and 26-4). Imidazole is significantly protonated at physiological pH (pI = 7.6). It can therefore function as a proton acceptor and donor at the active site of a variety of enzymes (see, e.g., chymotrypsin, Section 26-4).

The amino acid cysteine bears a relatively acidic mercapto substituent (pK_a = 8.2, pI = 5.1). Recall that, apart from their acidic character, thiols can be oxidized to disulfides under mild conditions (Section 9-10). In nature, various enzymes are capable of oxidatively coupling and reductively decoupling the mercapto groups in the cysteines of proteins and peptides, thereby reversibly linking peptide strands (Section 9-10).

In Summary There are 20 elementary L-amino acids, all of which have common names. Unless there are additional acid-base functions in the side chain, their acid-base behavior is governed by two pK_a values, the lower one describing the deprotonation of the carboxy group. At the isoelectric point, the number of amino acid molecules with net zero charge is maximized. Some amino acids contain additional acidic or basic functions, such as hydroxy, amino, guanidino, imidazolyl, mercapto, and carboxy.

26-2 Synthesis of Amino Acids: A Combination of Amine and Carboxylic Acid Chemistry

Chapter 21 treated the chemistry of amines, Chapters 19 and 20 that of carboxylic acids and their derivatives. We use both in preparing 2-amino acids.

Hell-Volhard-Zelinsky bromination followed by amination converts carboxylic acids to 2-amino acids

What would be the quickest way of introducing a 2-amino substituent into a carboxylic acid? Section 19-12 pointed out that simple 2-functionalization of an acid is possible by
the Hell-Volhard-Zelinsky bromination. Furthermore, the bromine in the product can be
displaced by nucleophiles, such as ammonia. In these two steps, propanoic acid can be
converted into racemic alanine.

\[
\begin{align*}
\text{Propanoic acid} & \quad \xrightarrow{\text{Br-Br, trace PBr}_3, \text{HBr}} \quad 2\text{-Bromopropanoic acid} \quad \xrightarrow{\text{NH}_3, \text{H}_2\text{O}, 25^\circ\text{C, 4 days}} \quad \text{Alanine} \\
\text{CH}_3\text{CH}_2\text{COOH} & \quad 80\% \quad \text{CH}_3\text{CHCOOH} & \quad 56\% \quad \text{CH}_3\text{CHCOO}^- \\
\end{align*}
\]

Unfortunately, this approach suffers frequently from relatively low yields. A better syn-
thesis utilizes Gabriel’s procedure for the preparation of primary amines (Section 21-5).

**The Gabriel synthesis can be adapted to produce amino acids**

Recall that \(N\)-alkylation of 1,2-benzenedicarboxylic imide (phthalimide) anion followed
by acid hydrolysis furnishes amines (Section 21-5). To prepare an amino acid instead,
we can use diethyl 2-bromopropanedioate (diethyl 2-bromomalonate) in the first step
of the reaction sequence. This alkylating agent is readily available from the bromination
of diethyl propanedioate (malonate). Now the alkylation product can be hydrolyzed
and decarboxylated (Section 23-2). Hydrolysis of the imide group then furnishes an
amino acid.

**Gabriel Synthesis of Glycine**

\[
\begin{align*}
\text{Potassium 1,2-benzenedicarboxylic imide (Potassium phthalimide)} & \quad + \quad \text{COOCH}_2\text{CH}_3 \quad \xrightarrow{\text{K}^+, \text{H}_2\text{O}} \quad \text{Diethyl 2-bromopropanedioate (Diethyl 2-bromomalonate)} \\
\text{CH}_3\text{CH}_2\text{O} \quad \xrightarrow{\text{Na}^+, \text{CH}_3\text{CH}_2\text{OH}} \quad \text{RCHCOO}^- \quad \xrightarrow{\text{H}^+, \text{H}_2\text{O}, \Delta} \quad \text{H}_3\text{NCH}_2\text{COO}^- \quad 85\%
\end{align*}
\]

One of the advantages of this approach is the versatility of the initially formed
2-substituted propanedioate. This product can itself be alkylated, thus allowing for the
preparation of a variety of substituted amino acids.
Exercise 26-6

Propose Gabriel syntheses of methionine, aspartic acid, and glutamic acid.

Exercise 26-7

Working with the Concepts: Practicing Variants of the Gabriel Amino Acid Synthesis

A variation of the Gabriel synthesis uses diethyl N-acetyl-2-aminopropanedioate (acetamidomalonic ester), A. Propose a synthesis of racemic serine from this reagent.

\[
\begin{align*}
\text{NH}_2 & \quad \text{NH}_2 \\
\text{CO}_2\text{CH}_2\text{CH}_3 & \quad \text{CO}_2\text{CH}_2\text{CH}_3 \\
\text{OH} & \quad \text{HOCH}_2\text{CHCOO}^- \\
\end{align*}
\]

Strategy

We are starting with a substituted malonic ester. You should be asking yourself the following questions: What synthesis should I be looking at? What substituent needs to be introduced? How do I achieve this substitution?

Solution

- We apply the principles of the malonic ester synthesis of substituted carboxylic acids (Section 23-2).
- The substituent to be introduced is hydroxymethyl.
- Hydroxymethylation is achieved by crossed aldol addition reaction (Section 18-6) of the malonic ester enolate with formaldehyde.
- Decarboxylation (Section 23-2) and amide hydrolysis (Section 20-6) is achieved with aqueous acid.

Exercise 26-8

Try It Yourself

In the search for lead compounds for the treatment of certain neurodegenerative disorders, medicinal chemists used diethyl N-acetyl-2-aminopropanedioate (acetamidomalonic ester, reagent A in Exercise 26-7) for the synthesis of the heterocyclic amino acid B from starting compound A. Suggest how they might have done so. **[Caution: You need to introduce a leaving group into A. Hint: The heterocycle is aromatic (Section 25-3) and therefore attached carbons are reactive (Section 22-1).]**
Amino acids are prepared from aldehydes by the Strecker synthesis

The crucial step in the Strecker synthesis is a variation of the cyanohydrin formation from aldehydes and hydrogen cyanide (Section 17-11).

\[
\text{O} \quad \text{RCH} \quad + \quad \text{HCN} \quad \rightleftharpoons \quad \text{OH} \quad \text{R} \quad \text{C} \quad \text{CN} \\
\text{H} \quad \text{Cyanohydrin}
\]

When the same reaction is carried out in the presence of ammonia or ammonium cyanide, \(\text{H}_3\text{N}^+\text{CN}^-\), it is the intermediate imine that undergoes addition of hydrogen cyanide, to furnish the corresponding 2-amino nitriles. Subsequent acidic or basic hydrolysis (Section 20-8) results in the desired amino acids.

**Exercise 26-9**

Propose Strecker syntheses of glycine (from formaldehyde) and methionine (from 2-propenal). (**Hint:** Review Section 18-9.)

**In Summary** Racemic amino acids are made by the amination of 2-bromocarboxylic acids, applications of the Gabriel synthesis of amines, and the Strecker synthesis. The last method proceeds through an imine variation of the preparation of cyanohydrins, followed by hydrolysis.

26-3 Synthesis of Enantiomerically Pure Amino Acids

All the methods of the preceding section produce amino acids in racemic form. However, we noted that most of the amino acids in natural polypeptides have the \(S\) configuration. Thus, many synthetic procedures—in particular, peptide and protein syntheses—require enantiomerically pure compounds. To meet this requirement, either the racemic amino acids must be resolved (Section 5-8) or a single enantiomer must be prepared by enantioselective reactions.

A conceptually straightforward approach to the preparation of pure enantiomers of amino acids would be resolution of their diastereomeric salts. Typically, the amine group is first protected as an amide and the resulting product is then treated with an optically active amine, such as the inexpensive alkaloid brucine (Section 25-8 and margin). The two diastereomers formed can be separated by fractional crystallization. Unfortunately, in practice, this method can be tedious and can suffer from poor yields.

*Professor Adolf Strecker (1822–1871), University of Würzburg, Germany.*
Resolution of Racemic Valine

\[
\begin{align*}
\text{(R,S)-Valine} & \quad \xrightarrow{\text{Protection}} \quad \text{(R,S)-N-Formylvaline} \\
\text{Racemate} & \quad \xrightarrow{\text{Brucine (abbreviated B*), CH}_3\text{OH, 0°C}} \quad \text{Diastereomers} \\
& \quad \xrightarrow{\text{NaOH, H}_2\text{O, 0°C}} \quad \text{Separate by fractional crystallization} \\
& \quad \xrightarrow{\text{NaOH, H}_2\text{O, 0°C}} \quad \text{Remove brucine and hydrolyze amide} \\
& \quad \xrightarrow{\text{70% 70%}} \quad \text{Enantiomer} \\
& \quad \text{(S)-Valine} \quad \text{Enantiomer} \\
& \quad \text{(R)-Valine}
\end{align*}
\]

In an alternative approach, the stereocenter at C2 is formed enantioselectively, such as in enantioselective hydrogenations of \(\alpha,\beta\)-unsaturated amino acids (Section 12-2). Nature makes use of this strategy in the biosynthesis of amino acids. Thus, the enzyme glutamate dehydrogenase converts the carbonyl group in 2-oxopentanedioic acid into the amine substituent in (S)-glutamic acid by a biological reductive amination (for chemical reductive aminations, see Section 21-6). The reducing agent is NADH (Chemical Highlight 25-2).

\[
\text{HOOCCH}_2\text{CH}_2\text{CCOO}^- + \text{NH}_3 + \text{H}^+ \xrightarrow{\text{NADH, glutamate dehydrogenase}} \text{HOOCCH}_2\text{CH}_2\text{CHCOO}^- + \text{H}_2\text{O}
\]

(S)-Glutamic acid is the biosynthetic precursor of glutamine, proline, and arginine. Moreover, it functions to aminate other 2-oxo acids, with the help of another type of enzyme, a transaminase, making additional amino acids available.

In Summary Optically pure amino acids can be obtained by resolution of a racemic mixture or by enantioselective formation of the C2 stereocenter.
Peptides and Proteins: Amino Acid Oligomers and Polymers

Amino acids are very versatile biologically because they can be polymerized. In this section, we describe the structure and properties of such polypeptide chains. Long polypeptide chains are called proteins (somewhat arbitrarily defined as >50 amino acids) and are one of the major constituents of biological structures. Proteins serve an enormous variety of biological functions; these functions are often facilitated by the twists and folds of the component chains.

Amino acids form peptide bonds

2-Amino acids are the monomer units in polypeptides. The polymer forms by repeated reaction of the carboxylic acid function of one amino acid with the amine group in another to make a chain of amides (Section 20-6). The amide linkage joining amino acids is also called a peptide bond.

\[
2n \text{ HN} - \text{C} - \text{COH} \rightarrow -(\text{NH} - \text{C} - \text{C} - \text{NH} - \text{C} - \text{C})_n + 2n \text{ H}_2\text{O}
\]

The oligomers formed by linking amino acids in this way are called peptides. For example, two amino acids give rise to a dipeptide, three to a tripeptide, and so forth. The individual amino acid units forming the peptide are referred to as residues. In some proteins, two or more polypeptide chains are linked by disulfide bridges (Sections 9-10 and 26-1).
Of great importance for the structure of polypeptides is the fact that the peptide bond is fairly rigid at room temperature and planar, a result of the conjugation of the amide nitrogen lone electron pair with the carbonyl group (Section 20-1). The N–H hydrogen is almost always located trans to the carbonyl oxygen, and rotation about the C–N bond is slow because the C–N bond has partial double-bond character. The result is a relatively short bond (1.32 Å), between the length of a pure C–N single bond (1.47 Å, Figure 21-1) and that of a C–N double bond (1.27 Å). On the other hand, the bonds adjacent to the amide function enjoy free rotation. Thus, polypeptides are relatively rigid but nevertheless sufficiently mobile to adopt a variety of conformations. Hence, they may fold in many different ways. Most biological activity is due to such folded arrangements; straight chains are usually inactive.

Of great importance for the structure of polypeptides is the fact that the peptide bond is fairly rigid at room temperature and planar, a result of the conjugation of the amide nitrogen lone electron pair with the carbonyl group (Section 20-1). The N–H hydrogen is almost always located trans to the carbonyl oxygen, and rotation about the C–N bond is slow because the C–N bond has partial double-bond character. The result is a relatively short bond (1.32 Å), between the length of a pure C–N single bond (1.47 Å, Figure 21-1) and that of a C–N double bond (1.27 Å). On the other hand, the bonds adjacent to the amide function enjoy free rotation. Thus, polypeptides are relatively rigid but nevertheless sufficiently mobile to adopt a variety of conformations. Hence, they may fold in many different ways. Most biological activity is due to such folded arrangements; straight chains are usually inactive.

**Planarity Induced by Resonance in the Peptide Bond**

Polypeptides are characterized by their sequence of amino acid residues

In drawing a polypeptide chain, the amino end, or N-terminal amino acid, is placed at the left. The carboxy end, or C-terminal amino acid, appears at the right. The configuration at the C2 stereocenters is usually presumed to be S.
How to Draw the Structure of a Tripeptide

The chain incorporating the amide (peptide) bonds is called the **main chain**, the substituents $R$, $R'$, and so forth, are the **side chains**.

The naming of peptides is straightforward. Starting from the amino end, the names of the individual residues are simply connected in sequence, each regarded as a substituent to the next amino acid, ending with the C-terminal residue. Because this procedure rapidly becomes cumbersome, the three-letter abbreviations listed in Table 26-1 are used for larger peptides.

Let us look at some examples of peptides and their structural variety. A dipeptide ester, aspartame, is a low-calorie artificial sweetener (NutraSweet; see Chapter Integration Problem 26-28). In the three-letter notation, the ester end is denoted by $OCH_3$. Glutathione, a tripeptide, is found in all living cells, and in particularly high concentrations in the lens of the eye. It is unusual in that its glutamic acid residue is linked at the $\gamma$-carboxy group (denoted $\gamma$-Glu) to the rest of the peptide. It functions as a biological reducing agent by being readily oxidized enzymatically at the cysteine mercapto unit to the disulfide-bridged dimer.
Gramicidin S is a cyclic peptide antibiotic constructed out of two identical pentapeptides that have been joined head to tail. It contains phenylalanine in the \( R \) configuration and a rare amino acid, ornithine [Orn, a lower homolog (one less \( \text{CH}_2 \) group) of lysine]. In the short notation in which gramicidin S is shown in the margin, the sense in which the amino acids are linked (amino-to-carboxy direction) is indicated by arrows.

Gramicidin S. (Computer-generated model, courtesy Professor Evan R. Williams and Dr. Richard L. Wong, University of California at Berkeley. The red dashed lines represent hydrogen bonds.)

Insulin illustrates the three-dimensional structure adopted by a complex sequence of amino acids (Figure 26-1). This protein hormone is an important drug in the treatment of diabetes because of its ability to regulate glucose metabolism. Insulin contains 51 amino acid residues incorporated into two chains, denoted A and B. The chains are connected by two disulfide bridges, and there is an additional disulfide linkage connecting the cysteine residues at positions 6 and 11 of the A chain, causing it to loop. Both chains fold up in a way that minimizes steric interference and maximizes electrostatic, London, and hydrogen-bonding attractions. These forces give rise to a fairly condensed three-dimensional structure (Figure 26-2).

Because synthetic methods gave only low yields, insulin used to be isolated from the pancreas of slaughtered cows and pigs, purified, and sold as such. In the 1980s, the development of genetic engineering methods (Section 26-11) allowed the cloning of the human gene that codes for insulin. The gene was placed into bacteria modified to produce the drug continuously. In this way, enough material is generated to treat millions of diabetics throughout the world.

\]
Proteins fold into pleated sheets and helices: secondary and tertiary structure

Insulin and other polypeptide chains adopt well-defined three-dimensional structures. Whereas the sequence of amino acids in the chain defines the primary structure, the folding pattern of the chain induced by the spatial arrangement of close-lying amino acid residues gives rise to the secondary structure of the polypeptide. The secondary structure results mainly from the rigidity of the amide bond and from hydrogen (and other noncovalent) bonding (margin) along the chain(s). Two important arrangements are the pleated sheet, or \( \beta \) configuration, and the \( \alpha \) helix.

In the pleated sheet (also called \( \beta \) sheet; Figure 26-3), two chains line up with the amino groups of one peptide opposite the carbonyl groups of a second, thereby allowing hydrogen bonds to form. Such bonds can also develop within a single chain if it loops back on itself. Multiple hydrogen bonding of this type can impart considerable rigidity to a system. The planes of adjacent amide linkages form a specific angle, a geometry that produces the observed pleated-sheet structure, in which the R groups protrude above and below at each kink.

The \( \alpha \) helix, as shown in Figure 26-4, allows for intramolecular hydrogen bonding between nearby amino acids in the chain. The carbonyl oxygen of each amino acid is interacting with the amide hydrogen four residues ahead. There are 3.6 amino acids per turn of the helix, two equivalent points in neighboring turns being about 5.4 Å apart. The C=O and N—H bonds point in opposite directions and are roughly aligned with the helical axis. On the other hand, the (hydrophobic) R groups point away from the helix.

Not all polypeptides adopt idealized structures such as these. If too much charge of the same kind builds up along the chain, charge repulsion will enforce a more random orientation. In addition, the rigid proline, because its amino nitrogen is part of the substituent ring and has no N—H available for hydrogen bonding, can cause a kink or bend in an \( \alpha \) helix.

Further folding, coiling, and aggregation of polypeptides is induced by distant residues in the chain end and give rise to their tertiary structure. A variety of forces, all arising from the R group, come into play to stabilize such molecules, including disulfide bridges, hydrogen

Exercise 26-10

Vasopressin, also known as antidiuretic hormone, controls the excretion of water from the body. Draw its complete structure. (Caution: There is a disulfide bridge between the two cysteine residues.)

\[

\]

bonds, London forces, and electrostatic attraction and repulsion. There are also micellar effects (Chemical Highlight 19-1 and Section 20-5): The polymer adopts a structure that maximizes exposure of polar groups to the aqueous environment while minimizing exposure of hydrophobic groups (e.g., alkyl and phenyl), the “hydrophobic effect” (Section 8-2, Chemical Highlight 19-1). Pronounced folding is observed in the globular proteins, many of which perform chemical transport and catalysis (e.g., myoglobin and hemoglobin, Section 26-8, Figure 26-8). In the
fibrous proteins, such as myosin (in muscle), fibrin (in blood clots), and \( \alpha \)-keratin (in hair, nails, and wool), several \( \alpha \) helices are coiled to produce a superhelix (Figure 26-5).

The tertiary structures of enzymes and transport proteins (proteins that carry molecules from place to place) usually give rise to three-dimensional pockets, called active sites or binding sites. The size and shape of the active site provide a highly specific “fit” for the substrate or ligand, the molecule on which the protein carries out its intended function. The inner surface of the pocket typically contains a specific arrangement of the side chains of polar amino acids that attracts functional groups in the substrate by hydrogen bonding or ionic interactions. In enzymes, the active site aligns functional groups and additional molecules in a way that promotes their reactions with the substrate.

An example is the active site of chymotrypsin, a mammalian digestive enzyme responsible for the degradation of proteins in food. Chymotrypsin accomplishes the hydrolysis of peptide bonds at body temperature and at physiological pH. Recall that ordinary amide hydrolysis requires much more drastic conditions (Section 20-6). Moreover, the enzyme also recognizes specific peptide linkages that are targeted for selective cleavage, such as the carboxy end of phenylalanine residues (see Section 26-5, Table 26-2). How does it do that?

A simplified picture of the active part of this large molecule (of dimensions 51 \( \times \) 40 \( \times \) 40 Å) in this process is shown in the following scheme.

### Peptide Hydrolysis in the Active Site of Chymotrypsin

![Diagram of Peptide Hydrolysis in the Active Site of Chymotrypsin](image)
The enzyme has four important, close-lying parts, all of which work together to facilitate the hydrolysis reaction: a hydrophobic pocket, and the residues of aspartic acid, histidine, and serine. The hydrophobic pocket (see Section 8-2) helps to bind the polypeptide to be “digested” by attraction of the hydrophobic phenyl substituent of one of its component phenylalanine residues. With the phenyl group held in this pocket, the three amino acid residues cooperate in a proton-transfer relay sequence to effect nucleophilic addition–elimination (Sections 19-7 and 20-6) of the serine hydroxy group to the carbonyl function of Phe, releasing the amine part of the cleaved polypeptide. The remainder of the substrate is held by an ester linkage to the enzyme, positioned to undergo ester hydrolysis (Section 20-4) by a water molecule. This reaction is aided by a tandem proton-transfer sequence similar to that used for hydrolyzing the peptide bond. With the link to the enzyme broken, the carboxy segment of the original substrate is now free to leave the intact active site of chymotrypsin, making room for another polypeptide.

**Exercise 26-11**

The scheme just shown omits the respective elimination steps of the two nucleophilic addition–elimination reactions. Show how the enzyme aids in accelerating them as well. [Hint: Draw the result of the “electron pushing” depicted in the first (or second) picture of the scheme and think about how a reversed electron and proton flow might help.]

Denaturation, or breakdown of the tertiary structure of a protein, usually causes precipitation of the protein and destroys its catalytic activity. Denaturation is caused by exposure to excessive heat or extreme pH values. Think, for example, of what happens to clear egg white when it is poured into a hot frying pan or to milk when it is added to lemon tea.

Some molecules, such as hemoglobin (Section 26-8), also adopt a quaternary structure (see Figure 26-9), in which two or more polypeptide chains, each with its own tertiary structure, combine to form a larger assembly. A simplified picture of the progression from primary to quaternary structures is given below.

### The Progression from Primary to Secondary, Tertiary, and Quaternary Polypeptide Structures

The three-dimensional constellation of polypeptides is a direct consequence of primary structure: In other words, the amino acid sequence specifies in which way the chain will coil, aggregate, and otherwise interact with internal and external molecular units. Therefore, knowledge of this sequence is of paramount importance in the understanding of protein structure and function. How to obtain this knowledge is the subject of the next section.

**In Summary** Polypeptides are polymers of amino acids linked by amide bonds. Their amino acid sequences can be described in a shorthand notation using the three- or one-letter abbreviations compiled in Table 26-1. The amino end group is placed at the left, the carboxy end at the right. Polypeptides can be cyclic and can also be linked by disulfide and hydrogen bonds. The sequence of amino acids is the primary structure of a polypeptide, folding gives rise to its secondary structure, further folding and coiling produce its tertiary structure, and aggregation of several polypeptides results in the quaternary structure.
26-5 Determination of Primary Structure: Amino Acid Sequencing

Biological function in polypeptides and proteins requires a specific three-dimensional shape and arrangement of functional groups, which, in turn, necessitate a definite amino acid sequence. One “monkey wrench” residue in an otherwise normal protein can completely alter its behavior. For example, sickle-cell anemia, a potentially lethal condition, is the result of changing a single amino acid in hemoglobin (Section 26-8). The determination of the primary structure of a protein, called amino acid or polypeptide sequencing, can help us to understand the protein’s mechanism of action.

In the late 1950s and early 1960s, amino acid sequences were discovered to be predetermined by DNA, the molecule containing our hereditary information (Section 26-9). Thus, through a knowledge of protein primary structure, we can learn how genetic material expresses itself. Functionally similar proteins in related species should, and do, have similar primary structures. The closer their sequences of amino acids, the more closely the species are related. Polypeptide sequencing therefore strikes at the heart of the question of the evolution of life itself. This section shows how chemical means, together with analytical techniques, allow us to obtain this information.

First, purify the polypeptide

The problem of polypeptide purification is an enormous one, and attempts at its solution consume many days in the laboratory. Several techniques can separate polypeptides on the basis of size, solubility in a particular solvent, charge, or ability to bind to a support. Although detailed discussions are beyond the scope of this book, we shall briefly describe some of the more widely used methods.

In dialysis, the polypeptide is separated from smaller fragments by filtration through a semipermeable membrane. A second method, gel-filtration chromatography, uses a carbohydrate polymer in the form of a column of beads as a support. Smaller molecules diffuse more easily into the beads, spending a longer time on the column than large ones do; thus, they emerge from the column later than the large molecules. In ion-exchange chromatography, a charged support separates molecules according to the amount of charge that they carry. Another method based on electric charge is electrophoresis. A spot of the mixture to be separated is placed on a plate covered with a thin layer of chromatographic material (such as polyacrylamide) that is attached to two electrodes. When the voltage is turned on, positively charged species (e.g., polypeptides rich in protonated amine groups) migrate toward the cathode, negatively charged species (carboxy-rich peptides) toward the anode. The separating power of this technique is extraordinary. More than a thousand different proteins from one species of bacterium have been resolved in a single experiment.

Finally, affinity chromatography exploits the tendency of polypeptides to bind very specifically to certain supports by hydrogen bonds and other attractive forces. Peptides of differing sizes and shapes have differing retention times in a column containing such a support.

Second, determine which amino acids are present

When the polypeptide strand has been purified, the next step in structural analysis is to establish its composition. To determine which amino acids and how much of each is present in the polypeptide, the entire chain is degraded by amide hydrolysis (6 N HCl, 110°C, 24 h) to give a mixture of the free amino acids. The mixture is then separated and its composition recorded by an automated amino acid analyzer.

This instrument consists of a column bearing a negatively charged support, usually containing carboxylate or sulfonate ions. The amino acids pass through the column in slightly acidic solution. They are protonated to a greater or lesser degree, depending on their structure, and therefore are more or less retained on the column. This differential retention separates the amino acids, and they come off the column in a specific order, beginning with the most acidic and ending with the most basic. At the end of the column is a reservoir containing a special indicator. Each amino acid produces a violet color (see Chapter Integration Problem 26-29) whose intensity is proportional to the amount of that...
The area under each peak is a measure of the relative amount of a specific amino acid in the mixture. The amino acid analyzer can readily establish the composition of a polypeptide. For example, the chromatogram of hydrolyzed glutathione (Section 26-4) gives three equal-sized peaks, corresponding to Glu, Gly, and Cys.

**Exercise 26-12**

Hydrolysis of the A chain in insulin (Figure 26-1) gives a mixture of amino acids. What are they and what is their relative abundance in the mixture?

---

**Sequence the peptide from the amino (N-terminal) end**

Once we know the gross makeup of a polypeptide, we can determine the order in which the individual amino acids are bound to one another—the amino acid sequence.

Several different methods can reveal the identity of the residue at the amino end. Most exploit the uniqueness of the free amino substituent, which may enter into specific chemical reactions that serve to “tag” the N-terminal amino acid. One such procedure is the Edman* degradation, and the reagent used is phenyl isothiocyanate, \( C_6H_5N\equivC\equivS \) (a sulfur analog of an isocyanate; Section 20-7).

Recall (Section 20-7) that isocyanates are very reactive with respect to nucleophilic attack, and the same is true of their sulfur analogs. In the Edman degradation, the terminal amino group adds to the isothiocyanate reagent to give a thiourea derivative (refer to Section 20-6 for the urea function). Mild acid causes extrusion of the tagged amino acid as a phenylthiohydantoin, leaving the remainder of the polypeptide unchanged (see also Exercise 26–13). The phenylthiohydantoins of all amino acids are well known, so the N-terminal end of the original polypeptide can be readily identified. The new chain, carrying a new terminal amino acid, is now ready for another Edman degradation to tag the next residue, and so forth. The entire procedure has been automated to allow the routine identification of polypeptides containing 50 or more amino acids.

Beyond that number, the buildup of impurities becomes a serious impediment. The reason for this drawback is that each degradation round, though proceeding in high yield, is not completely quantitative, thus leaving small quantities of incompletely reacted peptide admixed with the new one. You can readily envisage that, with each step, this problem increases until the mixtures become intractable.

---

*Professor Pehr V. Edman (1916–1977), Max Planck Institute for Biochemistry, Martinsried, Germany.
Exercise 26-13

The pathway of phenylthiohydantoin formation is not quite as straightforward as indicated by the red arrow in step 2 of the preceding scheme, but rather proceeds through the intermediacy of an isomeric thiazolinone (margin), which then rearranges under acidic conditions to the more stable phenylthiohydantoin. Formulate a mechanism for the formation of this compound (R = H) from the acid treatment of the phenylthiourea of glycine amide, C_6H_5NHC(=S)NHCH_2C(=O)NH_2.

[Hint: Sulfur is more nucleophilic than nitrogen (Section 6-8).]

Exercise 26-14

Polypeptides can be cleaved into their component amino acid fragments by treatment with dry hydrazine. This method reveals the identity of the carboxy end. Explain.

The chopping up of longer chains is achieved with enzymes

The Edman procedure allows for the ready sequencing of only relatively short polypeptides. For longer ones (e.g., those with more than 50 residues), it is necessary to cleave the larger chains into shorter fragments in a selective and predictable manner. These cleavage methods
Chapter 26

Section 26-5 Amino Acid Sequencing

rely mostly on hydrolytic enzymes. For example, trypsin, a digestive enzyme of intestinal liquids, cleaves polypeptides only at the carboxy end of arginine and lysine.

Selective Hydrolysis of the B Chain of Insulin by Trypsin

Trypsin, H2O

A more selective enzyme is clostripain, which cleaves only at the carboxy end of arginine. In contrast, chymotrypsin, which, like trypsin, is found in mammalian intestines, is less selective and cleaves at the carboxy end of phenylalanine (see Section 26-4), tryptophan, and tyrosine. Other enzymes have similar selectivity (Table 26-2). In this way, a longer polypeptide is broken down into several shorter ones, which may then be sequenced by the Edman procedure.

After a first enzymatic cleavage, sequences of segments of the polypeptide under investigation are determined, but the order in which they are linked is not. For this purpose, selective hydrolysis is carried out a second time, by using a different enzyme that provides pieces in which the connectivities broken under the first conditions are left intact, so-called overlap peptides. The solution is then found by literally “piecing” together the available information like a puzzle.

Exercise 26-15

Working with the Concepts: Determining Amino Acid Sequences

A polypeptide containing 21 amino acids was hydrolyzed by thermolysin. The products of this treatment were Gly, Ile, Val-Cys-Ser, Leu-Tyr-Gln, Val-Glu-Gln-Cys-Cys-Ala-Ser, and Leu-Glu-Asn-Tyr-Cys-Asn. When the same polypeptide was hydrolyzed by chymotrypsin, the products were Cys-Asn, Gln-Leu-Glu-Asn-Tyr, and Gly-Ile-Val-Glu-Gln-Cys-Cys-Ala-Ser-Val-Cys-Ser-Leu-Tyr. Give the amino acid sequence of this molecule.

Strategy

Piecing together puzzles of this type is best done visually. First lay out all the individual products, best in order of decreasing length. Starting with the largest oligopeptide resulting from the hydrolysis of the starting material by one enzyme, look for matching partial sequences of pieces obtained in the hydrolysis by the second enzyme. One of the remaining oligopeptides should provide an overlap sequence with a second by lining it up against one of the termini of the starting large fragment, thus allowing the gradual lengthening of it, until all degradation products have been reassembled to the original polypeptide.

Protein sequencing is made possible by recombinant DNA technology

Despite the success of the techniques for polypeptide sequencing described so far, allowing for the structure elucidation of hundreds of proteins, their application to large systems (i.e., those containing more than 1000 residues) is an expensive, laborious, and time-consuming business. Progress in this field was significantly impeded until the advent of recombinant DNA technology (Section 26-11). As we shall see (Section 26-10, Table 26-3), the sequences of the four bases in DNA—adenine, thymine, guanine, and cytosine—are directly correlated to the amino acid sequences of the proteins encoded by genes or the corresponding messenger RNA. Modern developments have led to the rapid automated analysis of DNA, and the knowledge gained can be immediately translated into primary protein structure. In this way, tens of thousands of proteins have been sequenced in the past few years.

In Summary

The structure of polypeptides is established by various degradation schemes. First, the polymer is purified; then the kind and relative abundance of the component amino acids are determined by complete hydrolysis and amino acid analysis. The N-terminal residues can be identified by Edman degradation. Repeated Edman degradation gives the sequence of shorter polypeptides, which are made from longer polypeptides by specific enzymatic hydrolysis. Finally, recombinant DNA technology has made primary structure analysis of larger proteins relatively easy.

26-6 Synthesis of Polypeptides: A Challenge in the Application of Protecting Groups

In a sense, the topic of peptide synthesis is a trivial one: Only one type of bond, the amide linkage, has to be made. The formation of this linkage was described in Section 19-10. Why discuss it further? This section shows that, in fact, achieving selectivity poses great problems, for which specific solutions have to be found.

Consider even as simple a target as the dipeptide glycylalanine. Just heating glycine and alanine to make the peptide bond by dehydration would result in a complex mixture of di-, tri-, and higher peptides with random sequences. Because the two starting materials can form bonds either to their own kind or to each other, there is no way to prevent random oligomerization.
An Attempt at the Synthesis of Glycylalanine by Thermal Dehydration

\[ \text{Gly} + \text{Ala} \xrightarrow{\Delta, \text{H}_2\text{O}} \text{Gly-Gly} + \text{Ala-Gly} + \text{Gly-Ala} + \text{Ala-Ala} + \text{Gly-Gly-Ala} + \text{Ala-Gly-Ala} \text{ etc.} \]

**Selective peptide synthesis requires protecting groups**

To form peptide bonds selectively, the functional groups of the amino acids have to be protected. There are several amino- and carboxy-protecting strategies available, two of which are described on the following page (see also Problem 26-55).

The amino end is frequently blocked by a **phenylmethoxycarbonyl group** (abbreviated **carbobenzoxy** or **Cbz**), introduced by reaction of an amino acid with phenylmethyl chloroformate (benzyl chloroformate).

**Protection of the Amino Group in Glycine**

\[
\begin{align*}
\text{H}_2\text{NCH}_2\text{COO}^- & + \text{PhCH}_2\text{OCCl} \xrightarrow{\text{NaOH}, \text{NaCl}, \text{H}_2\text{O}} \text{PhCH}_2\text{OCNHCH}_2\text{COOH} \\
\text{Glycine} & \quad \text{Phenylmethyl chloroformate (Benzyl chloroformate)} & \quad \text{Phenylmethoxycarbonylglycine (Carbobenzoxyglycine, Cbz-Gly)}
\end{align*}
\]

The amino function is deprotected by hydrogenolysis (Section 22-2), which initially furnishes the carbamic acid as a reactive intermediate (Section 20-7). Decarboxylation occurs instantly to restore the free amine.

**Deprotection of the Amino Group in Glycine**

\[
\begin{align*}
\text{H}_2\text{NCH}_2\text{COO}^- & + \text{PhCH}_2\text{OCNHCH}_2\text{COOH} \xrightarrow{\text{H}_2, \text{Pd}-\text{C}} \text{H}_2\text{NCH}_2\text{COO}^- + \text{CO}_2
\end{align*}
\]

Another amino-protecting group is **1,1-dimethylethoxycarbonyl** (**tert-butoxycarbonyl**, **Boc**), introduced by reaction with bis(1,1-dimethylethyl) dicarbonate (di-**tert**-butyl dicarbonate).

**Protection of the Amino Group in Amino Acids as the Boc Derivative**

\[
\begin{align*}
\text{R} & \quad \text{H}_2\text{NCHCOO}^- & \quad \text{Bis(1,1-dimethylethyl)} \quad \text{dicarbonate} \quad \text{(Di-**tert**-butyl dicarbonate)} & \quad \text{(CH}_3\text{)}_3\text{COCOCOC(CH}_3\text{)}_3
\end{align*}
\]

Deprotection in this case is achieved by treatment with acid under conditions mild enough to leave peptide bonds untouched.

**Deprotection of Boc-Amino Acids**

\[
\begin{align*}
\text{(CH}_3\text{)}_3\text{COCNHCHCOOH} & \xrightarrow{\text{HCl or CF}_3\text{COOH, 25°C}} \text{(CH}_3\text{)}_3\text{CHNCOO}^- & \quad \text{CO}_2 & \quad \text{CH}_2\text{═C(CH}_3\text{)}_2
\end{align*}
\]
Amino Acids, Peptides, Proteins, and Nucleic Acids

The carboxy terminus of an amino acid is protected by the formation of a simple ester, such as methyl or ethyl. Deprotection results from treatment with base. Phenylmethyl (benzyl) esters can be cleaved by hydrogenolysis under neutral conditions (Section 22-2).

Peptide bonds are formed by using carboxy activation

With the ability to protect either end of the amino acid, we can synthesize peptides selectively by coupling an amino-protected unit with a carboxy-protected one. Because the protecting groups are sensitive to acid and base, the peptide bond must be formed under the mildest possible conditions. Special carboxy-activating reagents are used.

Perhaps the most general of these reagents is dicyclohexylcarbodiimide (DCC). The electrophilic reactivity of this molecule is similar to that of an isocyanate (Section 20-7); it is ultimately hydrated to \(N,N'-\)dicyclohexylurea.

\[
\text{Dicyclohexylcarbodiimide (DCC)}
\]

The role of DCC is to activate the carbonyl group of the acid to nucleophilic attack by the amine. This activation arises from the formation of an \(O\)-acyl isourea, in which the carbonyl group possesses reactivity similar to that in an anhydride (Section 20-3).

Armed with this knowledge, let us solve the problem of the synthesis of glycylalanine. We add amino-protected glycine to an alanyl ester in the presence of DCC. The resulting product is then deprotected to give the desired dipeptide.

\[
\text{Preparation of Gly-Ala}
\]

\[
\begin{align*}
\text{Boc-Gly} & \quad \text{H}_{2}\text{NCHCOCOCH}_2\text{C}_6\text{H}_5 \\
\text{Ala-OCH}_2\text{C}_6\text{H}_5 & \quad \text{Boc-Gly-Ala-OCH}_2\text{C}_6\text{H}_5
\end{align*}
\]

For the preparation of a higher peptide, deprotection of only one end is required, followed by renewed coupling, and so forth.

Exercise 26-17

The mechanism of the deprotection of Boc-amino acids is different from that of the normal ester hydrolysis (Section 20-4): It proceeds through the intermediate 1,1-dimethylethyl (tert-butyl) cation. Formulate this mechanism.
In Summary  Polypeptides are made by coupling an amino-protected amino acid with another in which the carboxy end is protected. Typical protecting groups are readily cleaved esters and related functions. Coupling proceeds under mild conditions with dicyclohexyl-carbodiimide as a dehydrating agent.
26-7 Merrifield Solid-Phase Peptide Synthesis

Polypeptide synthesis has been automated. This ingenious method, known as the Merrifield* solid-phase peptide synthesis, uses a solid support of polystyrene to anchor a peptide chain. Polystyrene is a polymer (Section 12-15) whose subunits are derived from ethenylbenzene (styrene). Although beads of polystyrene are insoluble and rigid when dry, they swell considerably in certain organic solvents, such as dichloromethane. The swollen material allows reagents to move in and out of the polymer easily. Thus, its phenyl groups may be functionalized by electrophilic aromatic substitution. For peptide synthesis, a form of Friedel-Crafts alkylation is used to chloromethylate a few percent of the phenyl rings in the polymer.

Electrophilic Chloromethylation of Polystyrene

Exercise 26-21

Formulate a plausible mechanism for the chloromethylation of the benzene rings in polystyrene. (Hint: Review Section 15-11.)

A dipeptide synthesis on chloromethylated polystyrene proceeds as follows.

Solid-Phase Synthesis of a Dipeptide

1. Attachment of protected amino acid

2. Deprotection of amino terminus

3. Coupling to protected second amino acid

*Professor Robert B. Merrifield (1921–2006), Rockefeller University, New York, Nobel Prize 1984 (chemistry).
4. Deprotection of amino terminus

5. Disconnection of dipeptide from polymer

First an amino-protected amino acid is anchored on the polystyrene by nucleophilic substitution of the benzylic chloride by carboxylate. Deprotection is then followed by coupling with a second amino-protected amino acid. Renewed deprotection and final removal of the dipeptide by treatment with hydrogen fluoride complete the sequence.

The great advantage of solid-phase synthesis is the ease with which products can be isolated. Because all the intermediates are immobilized on the polymer, the products can be purified by simple filtration and washing.

Obviously, it is not necessary to stop at the dipeptide stage. Repetition of the deprotection–coupling sequence leads to larger and larger peptides. Merrifield designed a machine that would carry out the required series of manipulations automatically, each cycle requiring only a few hours. In this way, the first total synthesis of the protein insulin was accomplished. More than 5000 separate operations were required to assemble the 51 amino acids in the two separate chains; thanks to the automated procedure, this took only several days.

Automated protein synthesis has opened up exciting possibilities. First, it is used to confirm the structure of polypeptides that have been analyzed by chain degradation and sequencing. Second, it can be used to construct synthetic proteins that might be more active and more specific than natural ones. Such proteins could be invaluable in the treatment of disease or in understanding biological function and activity.

In Summary Solid-phase synthesis is an automated procedure in which a carboxy-anchored peptide chain is built up from amino-protected monomers by cycles of coupling and deprotection.

26-8 Polypeptides in Nature: Oxygen Transport by the Proteins Myoglobin and Hemoglobin

Two natural polypeptides function as oxygen carriers in vertebrates: the proteins myoglobin and hemoglobin. Myoglobin is active in the muscle, where it stores oxygen and releases it when needed. Hemoglobin is contained in red blood cells and facilitates oxygen transport. Without its presence, blood would be able to absorb only a fraction (about 2%) of the oxygen needed by the body.

How is the oxygen bound in these proteins? The secret of the oxygen-carrying ability of myoglobin and hemoglobin is a special nonpolypeptide unit, called a heme group, attached to the protein. Heme is a cyclic organic molecule (called a porphyrin) made of four linked, substituted pyrrole units surrounding an iron atom (Figure 26-7). The complex is red, giving blood its characteristic color.

The iron in the heme is attached to four nitrogens but can accommodate two additional groups above and below the plane of the porphyrin ring. In myoglobin, one of these groups is the imidazole ring of a histidine unit attached to one of the α-helical segments of the protein (Figure 26-8A). The other is most important for the protein’s function—bound oxygen. Close to the oxygen-binding site is a second imidazole of a histidine unit, which protects this side of the heme by steric hindrance. For example, carbon monoxide, which also binds to the
iron in the heme group, and thus blocks oxygen transport, is prevented from binding as strongly as it normally would because of the presence of the second imidazole group. Consequently, CO poisoning can be reversed by administering oxygen to a person who has been exposed to the gas. The two imidazole substituents in the neighborhood of the iron atom in the heme group are brought into close proximity by the unique folding pattern of the protein. The rest of the polypeptide chain serves as a mantle, shielding and protecting the active site from unwanted intruders and controlling the kinetics of its action (Figure 26-8B and C).

Myoglobin and hemoglobin offer excellent examples of the four structural levels in proteins. The primary structure of myoglobin consists of 153 amino acid residues of known sequence. Myoglobin has eight \( \alpha \)-helical segments that constitute its secondary structure, the longest having 23 residues. The tertiary structure has the bends that give myoglobin its three-dimensional shape.

Hemoglobin contains four protein chains: two \( \alpha \) chains of 141 residues each, and two \( \beta \) chains of 146 residues each. Each chain has its own heme group and a tertiary structure similar to that of myoglobin. There are many contacts between the chains; in particular, \( \alpha_1 \) is closely attached to \( \beta_1 \), as is \( \alpha_2 \) to \( \beta_2 \). These interactions give hemoglobin its quaternary structure (Figure 26-9).

Fresh meat rapidly assumes a dark, sometimes grayish appearance. However, when it is treated with carbon monoxide, it retains its bright red color, a feature that appeals to consumers. The reason is the formation of a stable Fe–CO complex of the heme in hemoglobin.
The folding of the hemoglobin and myoglobin of several living species is strikingly similar even though the amino acid sequences differ. This finding implies that this particular tertiary structure is an optimal configuration around the heme group. The folding allows the heme to absorb oxygen as it is introduced through the lung, hang on to it as long as necessary for transport, and release it when required.

**26-9 Biosynthesis of Proteins: Nucleic Acids**

How does nature assemble proteins? The answer to this question is based on one of the most exciting discoveries in science, the nature and workings of the genetic code. All hereditary information is embedded in the deoxyribonucleic acids (DNA). The expression of this information in the synthesis of all proteins, including the many enzymes necessary for cell function, is carried out by the ribonucleic acids (RNA). After the carbohydrates and polypeptides, the nucleic acids are the third major type of biological polymer. This section describes their structure and function.

**Four heterocycles define the structure of nucleic acids**

Considering the structural diversity of natural products, the structures of DNA and RNA are simple. All their components, called nucleotides, are polyfunctional, and it is one of the wonders of nature that evolution has eliminated all but a few specific combinations. Nucleic acids are polymers in which phosphate units link sugars, which bear various heterocyclic nitrogen bases (Figure 26-10).

In DNA, the sugar units are 2-deoxyriboses, and only four bases are present: cytosine (C), thymine (T), adenine (A), and guanine (G). The sugar characteristic of RNA is ribose, and again there are four bases, but the nucleic acid incorporates uracil (U) instead of thymine.

**Nucleic Acid Sugars and Bases**

![Heme group](image)

![Figure 26-9](image) The quaternary structure of hemoglobin. Each \( \alpha \) and \( \beta \) chain has its own heme group. (After R. E. Dickerson and I. Geis, 1969, *The Structure and Action of Proteins*, Benjamin-Cummings, p. 56. Copyright © 1969 by Irving Geis.)

![Figure 26-10](image) Part of a DNA chain. The base is a nitrogen heterocycle. The sugar is 2-deoxyribose.
Exercise 26-22

Even though the preceding structures do not (except for adenine) indicate so, cytosine, thymine, guanine, and uracil are aromatic, albeit somewhat less so than the corresponding azapyridines. Explain. (Hint: Recall the discussions about amide resonance in Sections 20-1 and 26-4 and Chapter Integration Problem 25-9.)

We construct a nucleotide from three components. First, we replace the hydroxy group at C1 in the sugar with one of the base nitrogens. This combination is called a nucleoside. Second, a phosphate substituent is introduced at C5. In this way, we obtain the four nucleotides of both DNA and RNA. The positions on the sugars in nucleosides and nucleotides are designated 1’, 2’, and so forth, to distinguish them from the carbon atoms in the nitrogen heterocycles.
Chapter 26

CHEMICAL HIGHLIGHT 26-3

Synthetic Nucleic Acid Bases and Nucleosides in Medicine

The central role played by nucleic acid replication in biology has been exploited in medicine. Many hundreds of synthetically modified bases and nucleosides have been prepared and their effects on nucleic acid synthesis investigated. Some of them in clinical use include 5-fluorouracil (fluracil), an anticancer agent, 9-[(2-hydroxyethoxy)methyl]guanine (acyclovir), which is active against two strains of herpes simplex virus, 3′-azido-3′-deoxythymidine (zidovudine, or AZT), the first approved drug (in 1987) that combats the AIDS virus, and 1-β-d-ribofuranosyl-1,2,4-triazole-3-carboxamide (ribavirin), used to treat hepatitis C and respiratory viral infections.

Substances such as these may interfere with nucleic acid replication by masquerading as legitimate nucleic acid building blocks. The enzymes associated with this process are fooled into incorporating the drug molecule, and synthesis of the biological polymer cannot continue.

Nucleotides of RNA

The polymeric chain shown in Figure 26-10 is then readily derived by repeatedly forming a phosphate ester bridge from C5′ (called the 5′ end) of the sugar unit of one nucleotide to C3′ (the 3′ end) of another (Figure 26-10).

In this polymer, the bases adopt the same role as that of the 2-substituent in the amino acids of a polypeptide: Their sequence varies from one nucleic acid to another and determines the fundamental biological properties of the system. Viewed from the perspective of storing
information, polypeptides do so by using an amide polymer backbone along which differing side chains are attached, like the letters in a word. In the case of polypeptides, there are 20 such letters, for the 20 natural amino acids (Table 26-1). The same goal is achieved in nucleic acids through a sugar–phosphate polymeric array that bears a sequence of amine bases, except that now we have only four letters: C, T, A, G for DNA and C, U, A, G for RNA.

Information Storage in Polypeptides and Nucleic Acids

A nucleic acid

Nucleic acids form a double helix

Nucleic acids, especially DNA, can form extraordinarily long chains (as long as several centimeters) with molecular weights of as much as 150 billion. Like proteins, they adopt secondary and tertiary structures. In 1953, Watson and Crick* made their ingenious proposal that DNA is a double helix composed of two strands with complementary base sequences. A crucial piece of information was that, in the DNA of various species, the ratio of adenine to thymine, like that of guanine to cytosine, is always one to one. Watson and Crick concluded that two chains are held together by hydrogen bonding in such a way that adenine and guanine, respectively, in one chain always face thymine and cytosine in the other, and vice versa (Figure 26-11). Thus, if a piece of DNA in one strand has the sequence

*Professor James D. Watson (b. 1928), Harvard University, Cambridge, Massachusetts, Nobel Prize 1962 (medicine); Professor Sir Francis H. C. Crick (1916–2004), Cambridge University, England, Nobel Prize 1962 (medicine).

Because of other structural constraints, the arrangement that maximizes hydrogen bonding and minimizes steric repulsion is the double helix (Figure 26-12). The cumulative hydrogen-bonding energies involved are substantial considering that just single base pairing, as in Figure 26-11, is favorable by 5.8 kcal mol\(^{-1}\) (24 kJ mol\(^{-1}\)) for G–C and 4.3 kcal mol\(^{-1}\) (18 kJ mol\(^{-1}\)) for A–T.

**DNA replicates by unwinding and assembling new complementary strands**

There is no restriction on the variety of sequences of the bases in the nucleic acids. Watson and Crick proposed that the specific base sequence of a particular DNA contained all genetic information necessary for the duplication of a cell and, indeed, the growth and development of the organism as a whole. Moreover, the double-helical structure suggested a way in which DNA might replicate—make exact copies of itself—and so pass on the genetic code. In this mechanism, each of the two strands of DNA functions as a template. The double helix partly unwinds, and enzymes called DNA polymerases then begin to assemble the new DNA by coupling nucleotides to one another in a sequence complementary to that in the template, always juxtaposing C to G and A to T (Figure 26-13). Eventually, two complete double helices are produced from the original. This process is at work throughout the entire
human genetic material, or genome—some 2.9 billion base pairs—with an error frequency of less than 1 in 10 billion base pairs.

In Summary The nucleic acids DNA and RNA are polymers containing monomeric units called nucleotides. There are four nucleotides for each, varying only in the structure of the base: cytosine (C), thymine (T), adenine (A), and guanine (G) for DNA; cytosine, uracil (U), adenine, and guanine for RNA. The two nucleic acids differ also in the identity of the sugar unit: deoxyribose for DNA, ribose for RNA. DNA replication and RNA synthesis from DNA is facilitated by the complementary character of the base pairs A–T, G–C, and A–U. The double helix partly unwinds and functions as a template for replication.

26-10 Protein Synthesis Through RNA

The mechanism of duplicating the entire nucleotide sequence in DNA replication is used by nature and by chemists to obtain partial copies of the genetic code for various purposes. In nature, the most important application is the assembly of RNA, called transcription, which transcribes the parts of the DNA that contain the information (the genes) necessary to synthesize proteins in the cell. The process by which this transcribed information is decoded and used to construct proteins is called translation. The three key players in protein synthesis are the “DNA transcript” messenger RNA (mRNA), the “delivery unit” for the specific amino acids to be connected by peptide bonds, transfer RNA (tRNA), and the catalyst that enables amide bond formation—the ribosome.

Protein synthesis starts with mRNA, a transcript of a piece of a single strand of partly unwind DNA (Figure 26-14). Its chain is much shorter than that of DNA, and it does not stay bound to the DNA but breaks away as its synthesis is finished. The mRNA is the template responsible for the correct sequencing of the amino acid units in proteins. How does mRNA do that? Each sequence of three bases, called a codon, specifies a particular amino acid (Table 26-3). Simple permutation of this three-base code with a total of four
bases gives $4^3 = 64$ possible distinct sequences. That number is more than enough, because only 20 different amino acids are needed for protein synthesis. This might seem like overkill, but consider that the next lower alternative—namely, a two-base code—would give only $4^2 = 16$ combinations, too few for the number of different amino acids found in natural proteins.

Codons do not overlap; in other words, the three bases specifying one amino acid are not part of another preceding or succeeding codon. Moreover, the “reading” of the base sequence is consecutive; each codon immediately follows the next, uninterrupted by genetic “commas” or “hyphens.” Nature also makes full use of all 64 codons by allowing for several of them to describe the same amino acid (Table 26-3). Only tryptophan and methionine are characterized by single three-base codes. Some codons act as signals to initiate or terminate production of a polypeptide chain. Note that the initiator codon (AUG) is also the codon for methionine. Thus, if the codon AUG appears after a chain has been initiated, methionine will be produced. The complete base sequence of the DNA in a cell defines its genetic code.

Mutations in the base sequence of DNA can be caused by physical (radiation) or chemical (carcinogens; see, e.g., Section 16-7) interference. Mutations can either replace one base with another or can add or delete one base or more. Here is some of the potential value of redundant codons. If, for example, the RNA sequence CCG (proline) were changed as a result of a DNA mutation to the RNA sequence CCC, proline would still be correctly synthesized.
Exercise 26-23
What is the sequence of an mRNA molecule produced from a DNA template strand with the following composition?

Exercise 26-24
(a) What amino acid sequence is encoded in the following mRNA base sequence (starting at the left end)?

(b) Identify the mutation that would have to occur for Trp to be present in the resulting peptide.

Figure 26-15 Representation of the biosynthesis of the tripeptide Gly-Ala-Asn. The tRNAs carrying their specific amino acids line up their anticodons along the codons of mRNA, before ribosomal enzymes accomplish amide linkage.

With a copy of the requisite codons in hand, proteins are then synthesized along the mRNA template with the help of a set of other important nucleic acids, the tRNAs. These molecules are relatively small, containing from 70 to about 90 nucleotides. Each tRNA is specifically designed to carry one of the 20 amino acids for delivery to the mRNA in the course of protein buildup. The amino acid sequence encoded in mRNA is read codon by codon by a complementary three-base sequence on tRNA, called an anticodon. In other words, the individual tRNAs, each carrying its specific amino acid, line up along the mRNA strand in the correct order. At this stage, catalytic ribosomes (very large enzymes) containing their own RNA facilitate peptide-bond formation (Figure 26-15). As the polypeptide chain grows longer, it begins to develop its characteristic secondary and tertiary structure (α helix, pleated sheets, etc.), helped by enzymes that form the necessary disulfide bridges. All of this happens with remarkable speed. It is estimated that a protein made up of approximately 150 amino acid residues can be biosynthesized in less than 1 minute, and that without protecting groups (Section 26-6)! Clearly, nature still has the edge over the synthetic organic chemist, at least in this domain.

In Summary RNA is responsible for protein biosynthesis; each three-base sequence, or codon, specifies a particular amino acid. Codons do not overlap, and more than one codon can specify the same amino acid.

26-11 DNA Sequencing and Synthesis: Cornerstones of Gene Technology

Molecular biology is undergoing a revolution because of our capability to decipher, reproduce, and alter the genetic code of organisms. Individual genes or other DNA sequences from a genome can be copied (cloned), often on a large scale. Genes of higher organisms
can be expressed (i.e., they can be made to start protein synthesis) in lower organisms, or they can be modified to produce “unnatural” proteins. Modified genes have been reintroduced successfully into the organism of their origin, causing changes in the physiology and biochemistry of the “starting” host. Much of this development is due to biochemical advances such as the discovery of enzymes that can selectively cut, join, or replicate DNA and RNA. For example, restriction enzymes cut long molecules into small defined fragments that can be joined by DNA ligases to other DNAs (recombinant DNA technology). Polymerases catalyze DNA replication, and selected DNA sequences are made on a large scale by the polymerase chain reaction (described later in this section). The list goes on and on, and its contents are beyond the scope of this text.

The essential foundation for these discoveries has been the knowledge of the primary structure of nucleic acids and the development of methods for their synthesis.

**Rapid DNA sequencing has deciphered the human genome**

The sequencing of DNA can be accomplished by using both chemical (introduced by Gilbert* with his student Maxam) and enzymatic methods, especially the Sanger† dideoxynucleotide protocol. In both approaches, and in analogy to protein analysis (Section 26-5), the unwieldy DNA chain is first cleaved at specific points by enzymes called restriction endonucleases.

There are more than 200 such enzymes, providing access to a multitude of overlapping sequences. In the Maxam–Gilbert procedure, described here in a simplified manner, the pieces of DNA obtained are then tagged at their 5′-phosphate ends (the starting end) with a radioactive phosphorus (³²P) label for analytical detection in the next step (oligonucleotides are colorless and cannot be identified visually). This step consists of subjecting multiple copies of the pure, labeled fragments in four separate experiments to chemicals that cleave only next to specific bases (i.e., only at A, G, T, and C, respectively). The conditions of cleavage are controlled so that cleavage occurs essentially only once on each copy, but, overall, at all possible places at which the particular base occurs. The products of the individual experiments are mixtures of oligonucleotides whose ends are known: Half of them contain the radioactive label at the beginning end, while the other half do not have any label and are ignored. The position of this end nucleotide in the original DNA is deduced from the length of the radioactive fragment, a measurement accomplished by electrophoresis (Section 26-5), which separates mixtures of oligonucleotides by size. The patterns of products that are made and identified in this way reveal the base sequence.

For a simple analogy, picture a measuring tape that has been marked randomly by spots of four different colorless labels. You can make multiple copies of this tape, and you have four special automatic scissors that cut the tape at only one specific label. You divide your collection of tapes into four batches and let each type of scissors do its work. The result from each experiment will be a collection of tapes of different lengths indicating where on the original a specific label occurs.

In the Sanger method, the piece of DNA to be sequenced, the template strand, is subjected to an enzyme, DNA polymerase, that replicates it many times (as the complementary strand, Section 26-9), starting from one end (the 3′ end). Replication requires addition of the four ingredient nucleotides (abbreviated as N below) A, G, T, and C [in the form of their reactive triphosphates (TP)], respectively, for chain buildup. The trick is to add very small amounts of a modified nucleotide to the mixture, which causes termination of chain growth at the very spot at which the normal nucleotide would have been incorporated. The modification is simple: Instead of the usual 2′-deoxyribose (d), we use 2′,3′-dideoxyribose (dd). Moreover, to visualize the end result, the base attached to the dideoxyribose is labeled with a fluorescent dye molecule that can be detected by exposure to light of the appropriate wavelength.

---

*Professor Walter Gilbert (b. 1932), Harvard University, Nobel Prize 1980 (chemistry).
†Professor Frederick Sanger (b. 1918), Cambridge University, England, Nobel Prizes 1958 (chemistry; for the structure of insulin) and 1980 (chemistry; for nucleotide sequencing).
The stepwise procedure is as follows (Figure 26-16). In the first step, multiple copies of the template strand are made by a procedure that also adds a short known nucleotide sequence to its 3'-end. This auxiliary is necessary to bind to a complementary section of the template, making a short double strand that serves as a primer for DNA polymerase; in other words, it tells the enzyme where to start replicating (namely, where the known double strand ends and the unknown single strand starts). We then divide our supply of template strands to be sequenced into four portions and carry out polymerase reactions on each of them separately. In the first, we use dATP, dTTP, dGTP, and dCTP, in addition to 1% of ddATP, and let the reaction run its course. The polymerase will begin to synthesize a complementary strand to the template; that is, when it encounters a T, it will add an A; when it encounters a C, it will add a G, and vice versa. The key is that 1% of the time, when it finds a T, it will add...
a defunct ddA, lacking the OH group necessary for further chain lengthening. Replication will stop and the incomplete strand will fall off the template.

Note that, since 99% of the time T will be matched by dA and therefore replication will continue uninterrupted, all Ts along the sequence have essentially the same chance of being “hit” by ddA. In this way, all Ts are tagged and a collection of oligonucleotides of different lengths is assembled, all of which end with ddA. In step 2, this mixture is then separated by electrophoresis and the position of the bands visualized by fluorescent light emission of the dye that is part of ddA. The position of the bands gives the length of the fragment strand and therefore the positions of the nucleotide A in the replicate strand and T in the template strand.

Having established the location of all the Ts in the template strand, the same experiment is carried out three additional times, with ddT, ddG, and ddC, respectively, as the chain-stopping additives, thus giving away the position of the other three nucleotides in the sequence.

The Sanger method has been automated such that oligonucleotides with 3 million bases can be reliably sequenced in a day or less. The keys to automation have been the attachment of dyes of differing color to the ddNTP building blocks, for example, red for T, green for A, yellow for G, and blue for C; the use of laser detection; parallel analysis; and the ever-increasing power of computers. The sequencing machine produces chromatographic printouts providing the sequence under investigation on simple sheets of paper (Figure 26-17). The technique has become so convenient that DNA sequencing, rather than peptide sequencing, has become the method of choice for structural elucidation of the encoded proteins (see Sections 26-5 and 26-10). Moreover, it has allowed the determination of the sequence of entire genomes with billions of bases, including our own.

The first genome of a live organism to be sequenced (in 1995) was that of the bacterium Haemophilus influenzae Rd. (which causes ear infections, such as meningitis), with 1.8 million base pairs (Mb). After this milestone, larger genomes were tackled, including those of yeast (12 Mb; 1996), the worm Caenorhabditis elegans (97 Mb; 1998), and the fruit fly (160 Mb; 1999), as a preamble for the “real thing,” our own blueprint of hereditary information.

In 1990, the Human Genome Project was begun—an international effort aimed at establishing the sequence of the 2.9 billion bases in human DNA and hence identifying the associated genes. The project was originally expected to take about 15 years, but thanks to the above advances in nucleotide sequencing, it was finished in April 2003. Only about 1% of the sequence codes for proteins (Section 26-10), which are responsible for what we are and how we function. Most of our genome (about 95%) consists of long chains of often-repeating segments that do not code for amino acids and that seem to be active in regulating gene expression, affecting cellular machinery in the reading of nearby genes and protein synthesis, and functioning as the “glue” of chromosomal structure. A big surprise is that we have only about 27,000 genes, many fewer than the expected 100,000, and a rather sobering number, considering that it is in the ballpark of that of the worm Caenorhabditis elegans (19,500 genes) or of the first two other mammalian genomes to be unraveled, those of the mouse (2002) and rat (2004), both with about 29,000 genes. It now appears that the

Figure 26-17 The color of the peaks in a printout from an automated DNA sequencer tells us the sequence of an oligonucleotide.
quality of genes is as important as their quantity: Human complexity may arise from the fact that our genes can produce not only more, but also more sophisticated proteins, capable of fulfilling more than one function. Moreover, complexity is also dependent on the interplay of proteins, evidently more varied in humans.

The development of automated DNA sequencing in conjunction with several ingenious time-saving strategies, including sophisticated computer analyses, has dramatically shortened the time required to decipher genomes. In 2008, the sequencing of the genes of the first (two) females was reported, accomplished in only a few months in each case. One of the donors was afflicted with cancer, and the study allowed the detection of all the mutations that might have been responsible for the onset of the disease. Such information might lead to new therapies and help doctors in their choices among existing treatments.

The deciphering of the human genome has sparked the development of several new research areas attempting to grapple with the enormous quantity of data becoming available on a daily basis. For example, functional genomics aims to find out what genes do, especially as it pertains to human health. Comparative genomics is establishing similarities in the genomes of a variety of species, from pigs to Japanese puffer fish.

Equally or arguably even more important is proteomics, the identification and functional study of the abundant new proteins that are being discovered as a consequence of the knowledge of the encoding gene. Compared to the genome, the corresponding proteome may be much more complex because proteins exist in a multitude of substitutionally “decorated” forms, such as phosphorylated, glycosylated, sulfated, and other variants. Some estimates place their number at 1 million. The Protein Structure Initiative is a U.S. national program devoted to determining the three-dimensional shapes of these molecules. Started in the year 2000 and greatly aided by robotic technology, it had determined over 3200 structures of proteins derived from plants, mice, yeast, and bacteria by mid-2008.

Finally, bioinformatics is the application of computer technology to the discovery of more deep-seated information in biological data. To use language as an analogy: The genome has provided words; now is the time to decipher sentences and meanings. Among the tasks that will occupy the attention of scientists for decades are the determination of the number of genes, their exact locations, and their regulation and function. Unraveling these aspects of genetics may help us understand an organism’s susceptibility to disease; the details of gene expression and protein synthesis; the cooperation between proteins to elicit complex function; the evolutionary relationship among the species on our planet; the relationship of single point mutations to disease; and the details of multiple gene expression for the development of complex traits.

Like sequencing, DNA synthesis is automated

You can order your custom-made oligonucleotide today and receive it tomorrow. The reason for this efficiency is the use of automated nucleotide coupling by so-called DNA synthesizers that operate on the same principle as that of the Merrifield polypeptide synthesis (Section 26-7): solid-phase attachment of the growing chain and the employment of protected nucleotide building blocks. Protection of the bases cytosine, adenine, and guanine is required at their amino functions (absent in thymine, which needs no protection), in the form of their amides.
The sugar moiety is blocked at C5’ as a dimethoxytrityl [di(4-methoxyphenyl)phenylmethyl, DMT] ether, readily cleaved by mild acid through an SN1 mechanism (Section 22-1 and Problem 40 in Chapter 22), much like 1,1-dimethylethyl (tert-butyl) ethers (Section 9-8, Chemical Highlight 9-2). To anchor the first protected nucleoside on the solid support, the C3’-OH is attached to an activated linker, a diester. Unlike the Merrifield medium of polystyrene, the solid used in oligonucleotide synthesis is surface-functionalized silica (SiO₂) bearing an amino substituent as a “hook.” Coupling to the anchor nucleoside is by amide formation.

**Anchoring the Protected Nucleoside on SiO₂**

With the first nucleoside in place, we are ready to attach to it the second. For this purpose, the point of attachment, the 5’-OH, is deprotected with acid. Subsequent addition of a 3’-OH activated nucleoside effects coupling. The activating group is an unusual phosphoramidite [containing P(III)], which, as we shall see shortly, also serves as a masked phosphate [P(V)] for the final dinucleotide and is subject to nucleophilic substitution, not unlike PBr₃ (recall Sections 9-4 and 19-8). The displacement reaction is catalyzed and furnishes a phosphite derivative; the catalyst is the, again unusual, aromatic heterocycle tetrazole, a tetracyclopentadiene related to pyrrole (Section 25-3) and imidazole (Section 26-1). Finally, the phosphorus is oxidized with iodine to the phosphate oxidation state.

**Dinucleotide Synthesis: Deprotection, Coupling, and Oxidation**
The sequence (1) DMT hydrolysis, (2) coupling, and (3) oxidation can be repeated multiple times in the synthesizer machine until the desired oligonucleotide is assembled in its protected and immobilized form. The final task is to remove the product from the silica and deprotect the DMT-bearing terminal sugar, all the bases, and the phosphate group, without cleaving any of the other bonds. Remarkably, this task can be done in just two steps, first treatment with acid and then with aqueous ammonia, as shown here for the dinucleotide made in the preceding scheme.

**Liberation of the Solid-Phase-Supported and Protected Dinucleotide**

**Exercise 26-25**

**Working with the Concepts: Exploring Mechanistic Features of Solid-Phase Dinucleotide Synthesis**

As shown in this section, oligonucleotide synthesis features as the key step a tetrazole-catalyzed coupling of an alcohol (the first nucleotide) with a phosphoramidite (the second nucleotide). On first sight (focusing on all the nitrogen lone pairs), the function of tetrazole appears to be that of a base (to deprotonate the alcohol), but this heterocycle is actually quite acidic ($pK_a = 4.8$), about as much as acetic acid (Section 19-4). Moreover, kinetic experiments indicate a rate-determining step involving both the tetrazole and phosphoramidite. Explain these observations and suggest a plausible mechanism for the coupling process. (**Hint:** Review pyrrole in Sections 25-3 and 25-4.)
**Strategy**

We follow the hint and try to extrapolate the chemistry of pyrrole to that of tetrazole, in particular its acidity and, considering the kinetic evidence that points to attack of phosphoramidite on the heterocycle, its most nucleophilic site.

**Solution**

• Why is tetrazole so acidic? This molecule is obviously no ordinary amine, which would exhibit a \( pK_a \) of about 35 (Section 21-4). A clue is provided by the observation of similar relatively high acidity in pyrrole, with a \( pK_a \) of 16.5 (Section 25-4). The explanation was delocalization of the charge in the anion and the \( sp^2 \) hybridization of the substituent carbons. The same reasoning holds here, accentuated by the presence of the additional three electron-withdrawing nitrogen atoms on the ring.

• Turning to the mechanism of the coupling reaction and considering the acidity of tetrazole, it is reasonable to assume that the most basic amine nitrogen on the phosphoramidite is protonated rapidly (reversibly), changing the substituent into an excellent leaving group (the first step in the scheme below).

• Formulation of this protonated species suggests the nature of the rate-determining second step: nucleophilic displacement of the protonated amine from the phosphorus.

• Which nitrogen of tetrazole will attack? Recalling the electrophilic aromatic substitution chemistry of pyrrole (Section 25-4), we note that optimal resonance stabilization of the resulting cation is attained by involving the position at the terminus of the diene portion, in the present case N2.

• Rapid proton loss (step 3) then furnishes a new intermediate, in which the amino substituent on the original phosphorus reagent has been replaced by tetrazolyl.

• Tetrazolyl anion is a much better leaving group than the original amide, because it is a much weaker base. Thus, the actual coupling with the alcohol takes place through this intermediate by nucleophilic displacement, as shown next.

---

**Exercise 26-26**

**Try It Yourself**

Formulate mechanisms for all the hydrolysis reactions that effect deprotection of the solid-phase supported dinucleotide in the scheme on page 1254. **Caution:** The cyanoethyl protecting group is not removed by nucleophilic hydrolysis of the phosphate ester, because such a process would cleave all P–O bonds indiscriminately. Can you imagine another way? **Hint:** Like other carboxylic acid derivatives (Section 20-1), the α hydrogen in nitriles is acidic.]
CHEMICAL HIGHLIGHT 26-4

DNA Fingerprinting

The human genome is unique and unalterable for each individual and is the same for every cell in his or her body. Therefore, in principle, it should be usable to establish identity unambiguously, much like conventional fingerprinting. However, sequencing 3 billion base pairs per person is still too time consuming and costly to be practicable. Instead, DNA fingerprinting applies abbreviated and much faster techniques.

An older but instructive approach, called Southern blotting (after its inventor, E. M. Southern), is probably best known from its application in crime laboratories and in paternity cases in the late 1980s and early 1990s. It is based on the finding that those pieces of DNA that seemingly have no coding function contain repeating sequences (from 20 to 100 base pairs) called variable-number tandem repeats or VNTR. The key is that the number of repeats, from 1 to 30 in a row, at certain places (also called loci) differs among individuals. The size of the corresponding DNA section will differ accordingly. The DNA fingerprint then is the visualization of the number of VNTR at a number of loci.

In practice, the sample of DNA (for example, from the blood at the scene of a crime or from the suspected father of a child) was cut into smaller pieces by restriction enzymes and the smaller fragments sorted by size using electrophoresis through a slab of agarose gel. To save the electrophoresis pattern on a more stable surface, it was literally “blotted” onto a nylon membrane (hence the “Southern blot”). To locate a specific VNTR sequence on one of the DNA fragments, a DNA sequence complementary to that of a VNTR locus was generated, bearing a radioactive or chemiluminescent label. This probe was then allowed to bind to complementary DNA sequences on the membrane and the pattern visualized on a photographic film (see photo). Standard forensic analysis used between 3 and 5 loci, and analysis of the combined data placed the odds of finding two individuals with the same observed pattern at 1 to about 10–100 million, unless they were biologically related.

A similar procedure can be followed to establish genealogy, even over several generations. Thus, your VNTR could be derived from the DNA of either or both of your parents, but you can’t have any VNTR that are not present in your mother or father. A hypothetical case is shown in the simplified Southern blot patterns on the facing page. You can see that the parents’ sequences (and no others) show up in part in their joint biological offspring (red and blue). However, the son from another marriage exhibits none of the current father’s traits (no blue), but those of his biological father (green). Even more strikingly, the adopted daughter has a completely incongruent pattern (orange). In paternity disputes, the identity of the father can be ascertained with a probability of up to 100,000 to 1.

Currently, forensic DNA analysis uses the polymerase chain reaction to amplify 13 specific DNA loci. The VNTR at these loci are only four base pairs, called short tandem repeats (STR). The amplification primers are chemically labeled with differently colored fluorescent dyes so that the PCR products can be subjected to electrophoresis into the path of a camera, through a capillary or a thin slab of polyacrylamide gel, and detected by their fluorescence. Elapsed electrophoresis time to detection enables measurement of the molecular weight of the PCR products, from which the number of STR at any of the loci can be determined. The odds of obtaining a “false positive” with this method can be as low as 1 in 100 billion.

A case of an application of DNA fingerprinting that had historical impact is the identification of the remains of Tsar Nicholas II of Russia and some of his family members. It had been believed that the Tsar’s entire family, along with the Royal Physician and three servants, had been executed by the Bolshevik revolutionaries during the night of July 16, 1918, and their remains hastily buried in a makeshift grave. This story could not be confirmed until
the grave was found in 1991 and nine bodies exhumed. Mitochondrial DNA (mtDNA) sequencing using bone samples enabled identification of the Tsar, his wife (the Tsarina), their three daughters, and the other four skeletons belonging to the non-family members. Each of the three purported daughters revealed an mtDNA sequence consistent with the purported parents, confirming their family relationship. Moreover, the sequences relating the three daughters to the Tsarina were also found in Prince Philip, the Duke of Edinburgh, who is a distant relative of the late Tsarina through a maternal line. The Tsar’s remains were similarly analyzed by comparison to the DNA fingerprints of two living relatives of the Tsar. The fate of the youngest, fourth daughter and the hemophiliac son (and Crown Prince) of the Tsar remained unknown until 2008, when their burned and shattered skeletons were found in a forest near the grave of the other members of the family. Despite the poor condition of the bone fragments recovered, sufficient amounts of DNA could be extracted to confirm their identity.

Tsar Nicholas II of Russia and his family were executed in 1918 during the Russian revolution, as was verified in 1991 and 2008 by DNA fingerprinting.
The polymerase chain reaction (PCR) makes multiple copies of DNA

DNA cloning—the preparation of large numbers of identical DNA molecules for the study of their sequence, expression, and regulation—revolutionized molecular biology in the mid-1970s. Cloning needs living cells to amplify inserted DNA. Therefore, the discovery of a procedure by Mullis* in 1984 that reproduces DNA segments in vitro by the millions, without the necessity of living cells, marked a stunning advance: the polymerase chain reaction (PCR).

The key to this reaction is the ability of some DNA-copying enzymes to remain stable at temperatures as high as 95°C. The original enzyme used in PCR is Taq DNA polymerase, found in a bacterium, Thermus aquaticus, in a hot spring in Yellowstone National Park (now other improved enzymes have become available). As described earlier in the Sanger dideoxyribose method of DNA sequencing, polymerases need a supply of the four nucleotides and a short primer to start their job. In nature, a primase enzyme takes care of the priming and the entire DNA sequence behind the primer is reproduced. In PCR, the primer consists of a short (20 bases) oligonucleotide strand that is complementary to a short piece of the DNA to be copied.

In practice, the PCR is carried out as shown schematically in Figure 26-18. The reaction flask is charged with the (double-stranded) DNA to be copied, the four nucleotides, the primer, and Taq polymerase. In the first step, the mixture is heated to 90–95°C to induce the DNA to separate into two strands. Cooling to 54°C allows the primers to attach themselves to the individual DNA molecules. Raising the temperature to 72°C provides optimum (in fact, “native”) conditions for Taq polymerase to add nucleotides to the primer along the attached DNA strand until the end, resulting in a complementary copy of the template. All of this takes only a few minutes and can be repeated in automated temperature-regulated vessels multiple times. Because the products of each cycle are again separated into their component strands to function as additional templates in the subsequent cycle, the amount of DNA produced with time increases exponentially: After \( n \) cycles, the quantity of DNA is \( 2^n \). For example, after 20 cycles (less than 3 h), it can be about 1 million; after 32 cycles, 1 billion.

There are many practical applications of this technique. In medical diagnostics, bacteria and viruses (including HIV) are readily detected through the use of specific primers. Early cancer detection is made possible by identifying mutations in growth-control genes. Inherited disorders can be pinpointed, starting from unborn babies to dead bodies. For example, blood stains on the clothing of Abraham Lincoln have been analyzed to show that he had a genetic disorder called Marfan’s syndrome, which affects the structure of the connective tissue. In forensics and legal medicine, PCR has been used to identify the origin of blood, saliva, and other biological clues left by the perpetrator of a crime. Paternity and genealogy can be proved fairly conclusively (Chemical Highlight 26-4). In molecular evolution, ancient DNA can be multiplied or even reconstructed by amplification of isolated fragments. In this way, the agent of the bubonic plague was successfully identified to be the bacterium Yersinia pestis, isolated from the teeth of victims buried in French mass graves dating from 1590 to 1722. Similarly, some of the genes of a 2400-year-old Egyptian mummy have been deciphered, leading to a broad effort to use this technology to help identify the genealogy of other mummies found in ancient Egyptian graves. For example, the purported identity of a mummy excavated from a tomb found in Egypt’s Valley of the Kings as that of the female ruler Hatshepsut in 2007 is being confirmed by DNA analysis. Similarly, the possibility that two embalmed fetuses found in King Tutankhamun’s tomb are his daughters is being established. What will be next?

*Dr. Kary B. Mullis (b. 1945), La Jolla, California, Nobel Prize 1993 (chemistry).
This concluding chapter drives home the message we have expressed in many places: Life is based on organic molecules. From a chemical standpoint, life at the level of amino acids and nucleic acids is astonishingly simple. It is the structures and properties of the polymeric arrays that add the more complex dimensions and functions typical of living organisms. To use an analogy, think of a modern desktop computer. At the level of individual chips, the interactions are well defined and understood, and can be analyzed in terms of on and off pulses of current. However, when we add some controlling software, guiding the microcircuits to act in unison, we achieve the complex problem-solving ability we desire from a computer. Similarly, at the molecular level of biology, all molecules, no matter how complicated, react according to the same chemical principles we have studied in this book. However, when the molecules and cells act in unison, the unpredictable behavior of life occurs.

For those of you who will go on to specialize in the life sciences, as biochemists, molecular cell biologists, doctors, and so on, this chapter will have whetted your appetite for more and will also have laid a molecular foundation for your future studies. For others, it will have provided a glimpse of the molecular basis for all life-related biochemical processes, including protein synthesis, function, and biological origin in the nucleic acids. In today’s society, as we grapple with issues involving genetic engineering, development of drugs to fight disease, environmental dangers, energy resources—an entire range of issues involving science and technology—it is useful to understand the chemical principles that underlie these developments and make them possible for good and for ill.
CHAPTER INTEGRATION PROBLEMS

26-28. Aspartame (NutraSweet), Asp-Phe-OCH₃, appears to be a simple target of synthesis. That this is not so becomes apparent when you try to devise routes to it, starting simply from aspartic acid (Asp) and phenylalanine (Phe). Analyze the problem and formulate various approaches to the synthesis of this compound.

\[\text{Aspartame} \]

\[\text{HO} \quad \text{N} \quad \text{CH}_2\text{C}_6\text{H}_5 \quad \text{OCH}_3\]

**SOLUTION**

Simple retrosynthetic analysis dissects the molecule into its two amino acid components, Asp and Phe-OCH₃ (made by methyl esterification of Phe), which might be envisaged to be coupled with DCC (Section 26-6). There is a problem, however: Asp has an additional \(\beta\)-carboxy group, bound to interfere. We are therefore facing the task of preparing a selectively carboxy-protected Asp. We can think about accomplishing it by two strategies: (A) the direct protection of the Asp nucleus or, if strategy A is not successful, (B) a total synthesis of an appropriately derivatized Asp from simpler starting materials that avoids Asp altogether. The following strategies focus on practical solutions to our problem found in the literature, although you may come up with alternatives that might be even better.

**A. Selective Protection of the Asp Nucleus**

Are the two carboxy groups chemically sufficiently different to warrant the investigation of selective monoprotection of one of the carboxy groups in Asp? The answer is yes, perhaps. Thus, we have learned that an \(\alpha\)-amino group causes an increase in the acidity of a carboxylic acid by about 2 \(pK_a\) units (Section 26-1). For Asp, \(pK_a(\alpha\text{-COOH}) = 1.9\), whereas \(pK_a(\beta\text{-COOH}) = 3.7\) (Table 26-1). One might therefore be tempted to try a selective ammonium salt formation with the \(\alpha\)-carboxylate function at carefully controlled \(pH\), followed by thermolysis (Section 19-10). The problem is that, under the thermal conditions of the relatively slow amide formation, fast proton exchange takes place. It is better to hope for differing reactivity of the two carbonyl groups in addition – elimination reactions of an appropriate derivative. The electron-withdrawing effect of the \(\alpha\)-amino group should manifest itself here in increased electrophilicity of the adjacent carbonyl carbon (Sections 17-6, 19-4, and 20-1), rendering the corresponding ester function more susceptible to basic hydrolysis. Indeed, this approach has been realized successfully with the \(N\)-Cbz-protected (phenylmethyl) diester of Asp (prepared by standard procedures, see Section 26-6), as shown below.

\[\text{Cbz-Asp-(OCH}_2\text{C}_6\text{H}_5)_2\]  

\[\text{H}_2\text{C}_6\text{O} \quad \text{H} \quad \text{NH} \quad \text{Cbz} \quad \text{C}_6\text{H}_5\text{O} \quad \text{C}_6\text{H}_5 \quad \text{O} \quad \text{H} \quad \text{NC} \]  

\[\text{H}_2\text{C}_6\text{O} \quad \text{H} \quad \text{NH} \quad \text{Cbz} \quad \text{C}_6\text{H}_5\text{O} \quad \text{C}_6\text{H}_5 \quad \text{O} \quad \text{H} \quad \text{NC} \]  

\[67\%\]

The product was coupled with Phe-OCH₃ and DCC, and then deprotected by catalytic hydrogenolysis (Section 26-6) to give aspartame.

A simplified synthesis relies on the potential to protect difunctional compounds as cyclic derivatives. For example, 1,2-diols are “masked” as cyclic acetals (Section 24-8), hydroxy acids as lactones (Section 19-9), amino acids as lactams (Section 19-10), and dicarboxylic acids as anhydrides (Section 19-8). The last two possibilities merit consideration as applied to Asp. However, direct lactam formation can be quickly ruled out because of the complications of ring strain (although \(\beta\)-lactams have been used in the preparation of aspartame). This problem is absent with respect to dehydration to the five-membered ring anhydride. Because anhydrides are activated carboxylic acid derivatives (Section 20-3), the Asp anhydride can be coupled directly with Phe-OCH₃ without the help of added DCC. Nucleophilic attack of the amino end of Phe-OCH₃ occurs preferentially at the desired position, albeit not completely so; 19% of the product derives from peptide-bond formation at the \(\beta\)-carboxy group of Asp.
Chapter Integration Problems

B. Total Syntheses of Carboxy-Differentiated Asp Derivatives

The alternative to approach A is to start from scratch and build up the Asp framework by using the methods of Section 26-2 in such a way as to provide as a final product a selectively monoprotected carboxy derivative. There are many possible strategies for the solution of this problem, but, as you contemplate them, you will discover that finding an appropriate masked \(\beta\)-carboxy group that is not unmasked during the manipulations of the \(\alpha\)-amino acid part is not easy. In the following Gabriel synthesis, recourse was made to the relatively innocuous 2-propenyl substituent, which is eventually elaborated by oxidative cleavage (Sections 12-12 and 24-5) to the free \(\beta\)-carboxy moiety.

\[
\begin{align*}
\text{N} \quad \text{C} & \quad \text{H} \quad \text{(CO}_2\text{CH}_2\text{CH}_3)\text{_2} \\
\text{O} & \\
\text{O} & \\
\end{align*}
\]

1. \(\text{CH}_3\text{CH}_2\text{OH}, \text{H}_2\text{O}, \text{H}_2\text{O} \rightarrow \text{aspartame}

\[
\begin{align*}
\text{N} \quad \text{C} & \quad \text{H} \quad \text{(CO}_2\text{CH}_2\text{CH}_3)\text{_2} \\
\text{O} & \\
\text{O} & \\
\end{align*}
\]

2. \(\text{Br} \rightarrow \text{Phe-OCH}_3, \text{DCC} \rightarrow \text{aspartame}

3. Oxidative cleavage

26-29. The amino acid analyzer (Section 26-5) “detects” the elution of any amino acid by the presence of an indicator that turns a deep violet color. This indicator is ninhydrin A, which reacts with amino acids to the purple compound B (“Ruhemann’s purple”), generating as by-products an aldehyde and \(\text{CO}_2\).

\[
\begin{align*}
\text{N} & \quad \text{H}_2\text{NCHCOOH} \\
\text{O} & \quad \text{R} \\
\end{align*}
\]

Write a reasonable mechanism for this process.

SOLUTION

Let’s take an inventory: (1) Ninhydrin is a carbonyl hydrate (Section 17-6) of the corresponding trione, whose central carbonyl group is activated by its two neighbors. (2) Two molecules of the indicator disassemble one molecule of the amino acid into B (containing the amino nitrogen), an aldehyde (accounting for the RCH part), and \(\text{CO}_2\) (derived from the carboxy function). (3) Decarboxylations of carboxylic acids occur readily in the presence of 3-oxo (or similar) functions (Section 23-2). (4) The highly delocalized (hence colored; Section 14-11) B is the enolate (Section 18-1) of an imine (Section 17-9).

The recognition of the last point allows us to simplify the problem somewhat, as B must be derived by a condensation of the dehydrated A with the corresponding amine C.

Simplifying B

\[
\begin{align*}
\text{B} & \quad \text{N} \quad \text{H}_2\text{NCHCOOH} \\
\text{O} & \quad \text{R} \\
\end{align*}
\]
Coupling this realization with point 1 suggests that the first step of the mechanism is a base-catalyzed dehydration (Section 17-6) to the trione form of ninhydrin, which condenses with the amino acid to the corresponding imine D.

**Steps 1 and 2**

![Chemical structure](image)

Point 3 encourages us to look for a 3-oxocarboxylic acid-type intermediate that would spontaneously lose CO₂ via an aromatic transition state (Section 23-2). Indeed, D fits the bill: It is an imine derivative of such a species, electronically quite equivalent, and smoothly rendering E.

**Step 3**

![Chemical structure](image)

Now we can see the step that provides a connection to C and also the aldehyde product: simple hydrolysis of E.

**Step 4**

![Chemical structure](image)

As already discussed, C then condenses with ninhydrin under the basic conditions to generate the salt B.

**New Reactions**

1. **Acidity of Amino Acids (Section 26-1)**

   ![Chemical structure](image)

   \[ \text{pK}_a = 2-3 \quad \text{and} \quad \text{pK}_a = 9-10 \]

   Isoelectric point \( pI = \frac{\text{pK}_a + \text{pK}_b}{2} \)

2. **Strongly Basic Guanidino Group in Arginine (Section 26-1)**

   ![Chemical structure](image)

   \[ \text{pK}_a = 13 \]

3. **Basicity of Imidazole in Histidine (Section 26-1)**

   ![Chemical structure](image)

   \[ \text{pK}_a = 7.0 \]
Preparation of Amino Acids

4. Hell-Volhard-Zelinsky Bromination Followed by Amination (Section 26-2)

\[
\text{RCH}_2\text{COOH} \xrightarrow{1. \text{ Br}_2, \text{ trace PBr}_3, \text{ 2. NH}_3, \text{ H}_2\text{O}} \text{RCHCOO}^- + \text{NH}_3
\]

5. Gabriel Synthesis (Section 26-2)

\[
\text{BrCH(CO}_2\text{CH}_3)_2 \xrightarrow{1. \text{ RO}^-\text{Na}^+, \text{ 2. R'X, } \text{ 3. H}^+, \text{ H}_2\text{O, } \Delta} \text{R'CHCOO}^-
\]

6. Strecker Synthesis (Section 26-2)

\[
\text{O} \xrightarrow{\text{HCN, NH}_3} \text{NH}_2 \xrightarrow{\text{H}^+, \text{ H}_2\text{O, } \Delta} \text{RCHCN} \xrightarrow{\text{H}_2\text{O}} \text{RCHCOO}^-
\]

Polypeptide Sequencing

7. Hydrolysis (Section 26-5)

\[
\text{Peptide} \xrightarrow{6 \text{ N HCl, 110°C, 24 h}} \text{ amino acids}
\]

8. Edman Degradation (Section 26-5)

\[
\text{N=C=S} \xrightarrow{\text{H}_2\text{O, } \text{H}^+, \text{ H}_2\text{O}} \text{Phenylthiohydantoin} \xrightarrow{\text{H}_2\text{N}} \text{Lower polypeptide}
\]

Preparation of Polypeptides

9. Protecting Groups (Section 26-6)

\[
\text{NH}_3^+ \xrightarrow{\text{RCHCOO}^-} \xrightarrow{\text{C}_6\text{H}_5\text{CH}_2\text{OCOCl}} \xrightarrow{\text{NaOH, } \text{NaCl}} \xrightarrow{\text{C}_6\text{H}_5\text{CH}_2\text{OCNHCHCOOH}} \xrightarrow{\text{H}_2, \text{ Pd–C, Deprotection}} \text{RCHCOO}^-
\]

\[
\text{NH}_3^+ \xrightarrow{\text{RCHCOO}^-} \xrightarrow{\text{(CH}_3\text{)}_2\text{COOCOCOC(CH}_3\text{)}_3} \xrightarrow{\text{(CH}_3\text{)}_2\text{H}_3\text{N}} \xrightarrow{\text{(CH}_3\text{)}_2\text{COOCNHCHCOOH}} \xrightarrow{\text{H}^+, \text{ H}_2\text{O, Deprotection}} \text{RCHCOO}^-
\]

10. Peptide-Bond Formation with Dicyclohexylcarbodiimide (DCC; Section 26-6)

\[
\text{Cbz-Gly} + \text{Ala-OCH}_2\text{C}_6\text{H}_5 + \text{C}_6\text{H}_{11}\text{N=NC}=\text{NC}_6\text{H}_{11} \rightarrow \text{DCC} \rightarrow \text{Cbz-Gly-Ala-OCH}_2\text{C}_6\text{H}_5 + \text{C}_6\text{H}_{11}\text{NHCNHC}_6\text{H}_{11}
\]
11. Merrifield Solid-Phase Synthesis (Section 26-7)

Important Concepts

1. **Polypeptides** are poly(amino acids) linked by amide bonds. Most natural polypeptides are made from only 19 different l-amino acids and glycine, all of which have common names and three- and one-letter abbreviations.

2. Amino acids are amphoterically charged; they can be protonated and deprotonated.

3. Enantiomerically pure amino acids can be made by classical fractional crystallization of diastereomeric derivatives or by enantioselective reactions of appropriate achiral precursors.

4. The structures of polypeptides are varied; they can be linear, cyclic, disulfide bridged, pleated sheet, α-helical or superhelical, or disordered, depending on size, composition, hydrogen bonding, and electrostatic and London forces.

5. Amino and nucleic acids are separated mainly by virtue of their size- or charge-based differences in ability to bind to solid supports.

6. Polypeptide sequencing entails a combination of selective chain cleavage and amino acid analysis of the resulting shorter polypeptide fragments.

7. Polypeptide synthesis requires end-protected amino acids that are coupled by dicyclohexylcarbodiimide. The product can be selectively deprotected at either end to allow for further extension of the chain. The use of solid supports, as in the Merrifield synthesis, can be automated.

8. The proteins myoglobin and hemoglobin are polypeptides in which the amino acid chain envelops the active site, heme. The heme contains an iron atom that reversibly binds oxygen, allowing for oxygen uptake, transport, and delivery.

9. The nucleic acids are biological polymers made of phosphate-linked base-bearing sugars. Only four different bases and one sugar are used for DNA and RNA, respectively. Because the base pairs adenine–thymine (uracil for RNA) and guanine–cytosine are held by particularly favorable hydrogen bonding, a nucleic acid can adopt a dimeric helical structure containing complementary base sequences. In DNA, this arrangement unwinds and functions as a template during DNA replication and RNA synthesis. In protein synthesis, each amino acid is specified by a set of three consecutive RNA bases, called a codon. Thus, the base sequence (genetic code) in a strand of RNA translates into a specific amino acid sequence in a protein.

10. DNA sequencing relies on restriction enzymes, radioactive labeling, and specific chemical cleavage reactions to small fragments, analyzed by electrophoresis.

11. DNA synthesis employs silica as a support on which the growing oligonucleotide sequence is built up with the help of base, alcohol, and phosphite–phosphate protecting groups.

12. The polymerase chain reaction (PCR) makes multiple copies of DNA.

Problems

30. Draw stereochemically correct structural formulas for isoleucine and threonine (Table 26-1). What is a systematic name for threonine?

31. The abbreviation allo means diastereomer in amino acid terms. Draw allo-l-isoleucine, and give it a systematic name.

32. Draw the structure that each of the following amino acids would have in aqueous solution at the indicated pH values. (a) Alanine at pH = 1, 7, and 12; (b) serine at pH = 1, 7, and 12; (c) lysine
at pH = 1, 7, 9.5, and 12; (d) histidine at pH = 1, 5, 7, and 12; (e) cysteine at pH = 1, 7, 9, and 12; (f) aspartic acid at pH = 1, 3, 7, and 12; (g) arginine at pH = 1, 7, 12, and 14; (h) tyrosine at pH = 1, 7, 9.5, and 12.

33. Group the amino acids in Problem 32 according to whether they are (a) positively charged, (b) neutral, or (c) negatively charged at pH = 7.

34. Show how the pI values for the amino acids in Problem 32 (see Table 26-1) are derived. For each amino acid that possesses more than two pK_a values, give the reason for your choice when calculating pI.

35. Show how Hell-Volhard-Zelinsky bromination followed by amination can be used to synthesize each of the following amino acids in racemic form: (a) Gly; (b) Phe; (c) Ala.

36. Show how the use of a Strecker synthesis can give each of the following amino acids in racemic form: (a) Gly; (b) Ile; (c) Ala.

37. What amino acid would result from carrying out the following synthetic sequence on

\[
\text{\begin{align*}
\text{O} & \quad \text{N} \quad \text{CH}(\text{CO}_2\text{CH}_2\text{CH}_3)_2 \quad ? \\
1. \text{CH}_3\text{CH}_2\text{O}^-\text{Na}^+ \quad \text{CH}_3\text{CH}_2\text{OH}; \\
2. \text{Br(CH}_2)_3\text{NHC(OH)}_2; \\
3. \text{H}^+ \quad \text{H}_2\text{O}, \Delta.
\end{align*}}
\]

38. Using either one of the methods in Section 26-2 or a route of your own devising, propose a reasonable synthesis of each of the following amino acids in racemic form. (a) Val; (b) Leu; (c) Pro; (d) Thr; (e) Lys.

39. (a) Illustrate the Strecker synthesis of phenylalanine. Is the product chiral? Does it exhibit optical activity? (b) It has been found that replacement of NH_3 by an optically active amine in the Strecker synthesis of phenylalanine leads to an excess of one enantiomer of the product. Assign the R or S configuration to each stereocenter in the following structures, and explain why the use of a chiral amine causes preferential formation of one stereoisomer of the final product.

40. The antibacterial agent in garlic, allicin (Chemical Highlight 9-4, Problem 73 in Chapter 9), is synthesized from the unusual amino acid alliin by the action of the enzyme allinase. Because allinase is an extracellular enzyme, this process takes place only when garlic cells are crushed. Propose a reasonable synthesis for the amino acid alliin. (Hint: Begin by designing a synthesis of an amino acid from Table 26-1 that is structurally related to alliin.)

\[
\text{\begin{align*}
\text{O} & \quad \text{NH}_3 \\
\text{H}_2\text{C} & \equiv \text{CHCH}_2\text{SCH}_2\text{CHCOO}^- \\
\text{Alliin}
\end{align*}}
\]

41. Devise a procedure for separating a mixture of the four stereoisomers of isoleucine into its four components: (+)-isoleucine, (-)-isoleucine, (+)-alloisoleucine, and (-)-alloisoleucine (Problem 31). (Note: Alloisoleucine is much more soluble in 80% ethanol at all temperatures than is isoleucine.)
42. Identify each of the following structures as a dipeptide, tripeptide, and so forth, and point out all the peptide bonds.

(a) \( \text{H}_3\text{N} - \text{CH} - \text{C} - \text{NH} - \text{CH} - \text{CH} - \text{COO}^- \)

(b) \( \text{H}_3\text{N} - \text{CH} - \text{C} - \text{NH} - \text{CH} - \text{COO}^- \)

(c) \( \text{H}_3\text{N} - \text{CH} - \text{C} - \text{NH} - \text{CH} - \text{NH} - \text{CH} - \text{COO}^- \)

(d) \( \text{H}_3\text{N} - \text{CH} - \text{C} - \text{NH} - \text{CH} - \text{CH} - \text{CH} - \text{NH} - \text{CH} - \text{COO}^- \)

43. Using the three-letter abbreviations for amino acids, write the peptide structures in Problem 42 in short notation.

44. Indicate which of the amino acids in Problem 32 and the peptides in Problem 42 would migrate in an electrophoresis apparatus at \( \text{pH} = 7 \) (a) toward the anode or (b) toward the cathode.

45. Silk is composed of \( \beta \) sheets whose polypeptide chains consist of the repeating sequence Gly-Ser-Gly-Ala-Gly-Ala. What characteristics of amino acid side chains appear to favor the \( \beta \)-sheet configuration? Do the illustrations of \( \beta \)-sheet structures (Figure 26-3) suggest an explanation for this preference?

46. Identify as many stretches of \( \alpha \) helix as you can in the structure of myoglobin (Figure 26-8C). Prolines are located in myoglobin at positions 37, 88, 100, and 120. How does each of these prolines affect the tertiary structure of the molecule?

47. Of the 153 amino acids in myoglobin, 78 contain polar side chains (i.e., Arg, Asn, Asp, Gln, Glu, His, Lys, Ser, Thr, Trp, and Tyr). When myoglobin adopts its natural folded conformation, 76 of these 78 polar side chains (all but those of two histidines) project outward from its surface. Meanwhile, in addition to the two histidines, the interior of myoglobin contains only Gly, Val, Leu, Ala, Ile, Phe, Pro, and Met. Explain.

48. Explain the following three observations. (a) Silk, like most polypeptides with sheet structures, is water insoluble. (b) Globular proteins such as myoglobin generally dissolve readily in water. (c) Disruption of the tertiary structure of a globular protein (denaturation) leads to precipitation from aqueous solution.

49. In your own words, outline the procedure that might have been followed by the researchers who determined which amino acids were present in vasopressin (Exercise 26-10).

50. Write the products of a single Edman degradation of the peptides in Problem 42.

51. What would be the outcome of reaction of gramicidin S with phenyl isothiocyanate (Edman degradation)? (Hint: With which functional group does this substance react?)

52. The polypeptide bradykinin is a tissue hormone that can function as a potent pain-producing agent. By means of a single treatment with the Edman reagent, the \( N \)-terminal amino acid in bradykinin is identified as Arg. Incomplete acid hydrolysis of the intact polypeptide causes random cleavage of many bradykinin molecules into an assortment of peptide fragments that includes Arg-Pro-Pro-Gly, Phe-Arg, Ser-Pro-Phe, and Gly-Phe-Ser. Complete hydrolysis followed by amino acid analysis indicates a ratio of 3 Pro, 2 Phe, 2 Arg, and one each of Gly and Ser. Deduce the amino acid sequence of bradykinin.

53. The amino acid sequence of met-enkephalin, a brain peptide with powerful opiate-like biological activity, is Tyr-Gly-Gly-Phe-Met. What would be the products of step-by-step Edman degradation of met-enkephalin?
Chapter 26

The peptide shown in Problem 42(d) is leu-enkephalin, a relative of met-enkephalin with similar properties. How would the results of Edman degradation of leu-enkephalin differ from those of met-enkephalin?

55. Propose a synthesis of leu-enkephalin [see Problem 42(d)] from the component amino acids.

56. The following molecule is thyrotropin-releasing hormone (TRH). It is secreted by the hypothalamus, causing the release of thyrotropin from the pituitary gland, which, in turn, stimulates the thyroid gland. The thyroid produces hormones, such as thyroxine, that control metabolism in general.

![TRH molecule diagram]

The initial isolation of TRH required the processing of 4 tons of hypothalamic tissue, from which 1 mg of the hormone was obtained. Needless to say, it is a bit more convenient to synthesize TRH in the laboratory than to extract it from natural sources. Devise a synthesis of TRH from Glu, His, and Pro. Note that pyroglutamic acid is the lactam of Glu and may be readily obtained by heating Glu to 140°C.

57. (a) The structures illustrated for the four DNA bases (Section 26-9) represent only the most stable tautomers. Draw one or more alternative tautomers for each of these heterocycles (review tautomerism, Sections 13-7 and 18-2). (b) In certain cases, the presence of a small amount of one of these less stable tautomers can lead to an error in DNA replication or mRNA synthesis due to faulty base pairing. One example is the imine tautomer of adenine, which pairs with cytosine instead of thymine. Draw a possible structure for this hydrogen-bonded base pair (see Figure 26-11). (c) Using Table 26-3, derive a possible nucleic acid sequence for an mRNA that would code for the five amino acids in met-enkephalin (see Problem 53). If the mispairing described in (b) were at the first possible position in the synthesis of this mRNA sequence, what would be the consequence in the amino acid sequence of the peptide? (Ignore the initiation codon.)

58. Factor VIII is one of the proteins participating in the formation of blood clots. A defect in the gene whose DNA sequence codes for Factor VIII is responsible for classic hemophilia. Factor VIII contains 2332 amino acids. How many nucleotides are needed to code for its synthesis?

59. In addition to the conventional 20 amino acids in Tables 26-1 and 26-3, two others, selenocysteine (Sec) and pyrrolysine (Pyl), are incorporated into proteins using the nucleic acid–based cell machinery described in Section 26-10. The three-base codes for Sec and Pyl are UGA and UAG, respectively. These codes normally serve to terminate protein synthesis. However, if they are preceded by certain specific base sequences, they instead cause incorporation of these unusual amino acids and continued growth of the peptide chain.

Pyl is rare, occurring only in some ancient bacteria. Sec, containing the side chain CH₂-SeH, is widespread; in fact, it occurs in at least two dozen human proteins that rely on the reactivity of the essential trace element selenium for their function. The pKₐ for the SeH group in Sec is 5.2. (For comparison, the pKₐ for the SH in Cys is 8.2.) (a) Draw the structure of Sec at pH 7; compare it with that of Cys at the same pH. (b) Determine pf for Sec. (c) Given the relationship between sulfur and selenium in the periodic table, and the pKₐ differences between SH and SeH, how do you expect the chemical reactivities of Sec and Cys to compare?

60. Hdroxyproline (Hyp), like many other amino acids that are not “officially” classified as essential, is nonetheless a very necessary biological substance. It constitutes about 14% of the amino acid content of the protein collagen. Collagen is the main constituent of skin and connective tissue. It is also present, together with inorganic substances, in nails, bones, and teeth. (a) The systematic name for hydroxyproline is (2S,4R)-4-hydroxyazacyclopentane-2-carboxylic
acid. Draw a stereochemically correct structural formula for this amino acid. (b) Hyp is synthesized in the body in peptide-bound form from peptide-bound proline and O$_2$, in an enzyme-catalyzed process that requires vitamin C. In the absence of vitamin C, only a defective, Hyp-deficient collagen can be produced. Vitamin C deficiency causes scurvy, a condition characterized by bleeding of the skin and swollen, bleeding gums.

In the following reaction sequence, an efficient laboratory synthesis of hydroxyproline, fill in the necessary reagents (i) and (ii), and formulate detailed mechanisms for the steps marked with an asterisk.

(c) Gelatin, which is partly hydrolyzed collagen, is rich in hydroxyproline and, as a result, is often touted as a remedy for split or brittle nails. Like most proteins, however, gelatin is almost completely broken down into individual amino acids in the stomach and small intestine before absorption. Is the free hydroxyproline thus introduced into the bloodstream of any use to the body in the synthesis of collagen? (Hint: Does Table 26-3 list a three-base code for hydroxyproline?)

61. **Challenge** The biosynthesis of oligosaccharides (Chapter 24) employs the chemical constituents of proteins and nucleic acids as well as carbohydrates. In the example shown, a disaccharide linkage is created between a molecule of galactose and a molecule of N-acetylgalactosamine. The galactose (the “donor” sugar) is carried into the process as a uridine diphosphate ester, and the “acceptor” galactosamine is held in place by a glycoside linkage to the hydroxyl group of a serine residue in a protein. The enzyme galactosyl transferase specifically forms a disaccharide linkage between C1 of the donor and C3 of the acceptor:

![Disaccharide linkage](image)
What type of basic mechanistic process does this reaction resemble? Discuss the roles played by the various participants of the reaction.

**62. CHALLENGE**

Sickle-cell anemia is an often fatal genetic condition caused by a single error in the DNA gene that codes for the β chain of hemoglobin. The correct nucleic acid sequence (read from the mRNA template) begins with AUGGUGCACCUGACCCUGAGAGAAG . . . , and so forth. (a) Translate this into the corresponding amino acid sequence of the protein. (b) The mutation that gives rise to the sickle-cell condition is replacement of the boldface A in the preceding sequence by U. What is the consequence of this error in the corresponding amino acid sequence? (c) This amino acid substitution alters the properties of the hemoglobin molecule—in particular, its polarity and its shape. Suggest reasons for both these effects. (Refer to Table 26-1 for amino acid structures and to Figure 26-8C for the structure of myoglobin, which is similar to that of hemoglobin. Note the location of the amino acid substitution in the tertiary structure of the protein.)

**Team Problem**

63. Amino acids can be used as enantiomerically pure starting materials in organic synthesis. Scheme I depicts the first steps in the synthesis of a reagent employed in the preparation of enantiomerically pure β-amino acids, such as that occurring in the side chain of taxol (Section 4-7). Scheme II features an ester of the same amino acid for the preparation of an unusual heterocyclic dipeptide used in the study of polypeptide conformations.

**Scheme I: Synthesis of an enantiomerically pure reagent**

Consider the following questions:

1. There are two diastereomers of A formed in a 90:10 ratio. The major isomer is the one that can attain the most stable chair conformation. Are the two substituents on the ring cis or trans to each other? Label their positions as equatorial or axial.
2. Which nitrogen is nucleophilic and yields the carbamic ester (Section 20-6) B?

**Scheme II: Synthesis of an unusual heterocyclic dipeptide**

Consider the following questions:

1. What functional group is generated in C?
2. Where is the peptide bond in D? Circle it.

Reconvene to discuss the answers to the questions posed in each scheme and the structures you proposed for A–D.
Preprofessional Problems

64. Structure A (shown in the margin) is that of a naturally occurring $\alpha$-amino acid. Select its name from the following list. (a) Glycine; (b) alanine; (c) tyrosine; (d) cysteine.

65. The primary structure of a protein refers to: (a) cross-links with disulfide bonds; (b) presence of an $\alpha$ helix; (c) the $\alpha$-amino acid sequence in the polypeptide chain; (d) the orientation of the side chains in three-dimensional space.

66. Which one of the following five structures is a zwitterion?

(a) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(b) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(c) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(d) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(e) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$

67. When an $\alpha$-amino acid is dissolved in water and the pH of the solution adjusted to 12, which of the following species is predominant?

(a) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(b) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(c) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$
(d) $\text{O} \quad \text{O} \quad \text{O} \quad \text{O}$

68. How many stereocenters are present in the small, naturally occurring protein glycylalanylalanine? (a) Zero; (b) one; (c) two; (d) three.
The section that follows includes material from previously administered MCAT® items and is reprinted with permission of the Association of American Medical Colleges (AAMC).

Passage Number I

The addition of hydrogen halides to double or triple carbon-carbon bonds can result in more than 1 product, as illustrated in Reactions 1 and 2.

\[
\text{Product A} \quad \text{Product B} \\
\text{Reaction 1}
\]

\[
\text{Product C} \quad \text{Product D} \\
\text{Reaction 2}
\]

A chemist postulated that the formation of Products A and C involves a carbocation intermediate, whereas Products B and D result from a competing radical-chain addition.

It was discovered that the results of these additions were strongly affected by the reaction conditions. For example, when Reactions 1 and 2 were carried out in the presence of silica gel (SiO₂) or alumina (Al₂O₃) surfaces, the yields and product distributions were dramatically altered. Tables 1 and 2 summarize the effects of the reaction conditions on the results of Reactions 1 and 2.

1. From Tables 1 and 2 it can be concluded that the reaction of HCl with 1-octene or 1-phenylpropyne in the absence of silica or alumina:
   (a) results in a mixture of products.
   (b) results in a 100% yield of the products.
   (c) requires 3 hr of reaction time.
   (d) does not occur within 1 hr.

2. Which of the following is most likely the predominant competing reaction in Reaction 2?
   (a) Rearrangement of carbocationic intermediates
   (b) Migration of the double bond in the product alkenes

3. Which of the following is the structure of the carbocation intermediate that will result in the formation of Product C?
(a) \( \text{C}_6\text{H}_5\text{C}≡\text{C}≡\text{C}–\text{CH}_3 \)
(b) \( \text{C}_6\text{H}_5\text{C}≡\text{CH}–\text{C}≡\text{C}–\text{CH}_3 \)
(c) \( \text{C}_6\text{H}_5\text{C}≡\text{C}≡\text{C}–\text{CH}_3 \)
(d) \( \text{C}_6\text{H}_5\text{C}≡\text{C}≡\text{C}–\text{CH}_3 \)

4. The transformation of 1-octene to Product A involves the conversion of:
(a) \( sp^3 \) hybrid orbitals to \( sp \) hybrid orbitals.
(b) \( sp^3 \) hybrid orbitals to \( sp^2 \) hybrid orbitals.
(c) \( sp \) hybrid orbitals to \( sp^2 \) hybrid orbitals.
(d) \( sp \) hybrid orbitals to \( sp^3 \) hybrid orbitals.

5. According to the results of Table 1, which of the following should be the major product of the reaction of 1-butene with HBr/SiO\(_2\) after 0.7 hr?
(a) 1-Bromo-1-butene
(b) 2-Bromo-2-butene
(c) 2-Bromobutane
(d) 1-Bromobutane

For further information, see Chapters 12 and 13.

**Passage Number II**

A variety of highly functionalized compounds (Compounds 1–4) were recently isolated from marine sources in British Columbia.

![Compounds 1-4](Images)
The marine material was extracted with methanol, and the methanol was removed from the resulting organic material by evaporation. The residue was subsequently extracted from a saturated NaCl solution with ethyl acetate. The ethyl acetate fractions were combined, and the ethyl acetate was removed by evaporation. The remaining material contained Compounds 1–4, which were separated and purified by chromatography.

The structures of the four compounds were determined by NMR and IR spectroscopy. Furthermore, the structure of Compound 3 was confirmed by treatment with acetic anhydride to give a previously known ester, Compound 5 (Reaction 1).

\[ \text{Compound 3} \xrightarrow{(CH_3C)_2O} \text{Compound 5} \]

**Acetic anhydride**

**Reaction 1**

1. Compounds 1 and 3 can be distinguished from each other by their IR spectra because the spectrum of:
   (a) Compound 1 will exhibit a C–O stretch, and that of Compound 3 will not.
   (b) Compound 1 will exhibit an O–O stretch, and that of Compound 3 will not.
   (c) Compound 3 will exhibit a C–H stretch, and that of Compound 1 will not.
   (d) Compound 3 will exhibit an O–H stretch, and that of Compound 1 will not.

2. Conjugated double bonds can be found in which of the compounds described in the passage?
   (a) Compounds 1 and 2 only
   (b) Compound 4 only
   (c) Compounds 1, 2, and 3 only
   (d) Compounds 1, 2, 3, and 4

3. Compound 6 is shown below. What is the stereochemical relationship between Compound 6 and Compound 3?

   ![Diagram of Compound 6]

   (a) They are identical.
   (b) They are structural isomers.
   (c) They are nonsuperimposable and are mirror images of each other.
   (d) They are nonsuperimposable and are not mirror images of each other.

4. Which of the following reaction conditions can be used to convert Compound 2 into Compound 4?
   (a) $\text{H}_2\text{SO}_4/\text{H}_2\text{O}$
   (b) $\text{NaOH}/\text{CH}_3\text{CH}_2\text{OH}$
   (c) $\text{H}_2/\text{Pd/C}$
   (d) $\text{Cr}_2\text{O}_7^{2-}/\text{H}^+$

For further information, see Chapter 11.

**Passage Number III**

A forensic chemist was given a liquid sample and was asked to identify its components. A small portion of the liquid was subjected to gas chromatographic (GC) analysis, and it was observed that the sample contained two volatile compounds, one of which was diethylamine.
The sample was dissolved in methylene chloride (CH₂Cl₂), and the diethylamine was removed by extraction. The methylene chloride was subsequently removed by evaporation, leaving the other volatile component, Compound A.

Compound A was neutral to litmus but dissolved in refluxing sulfuric acid. Workup of the sulfuric acid solution yielded a solid, Compound B (melting point [MP] = 133°C), and a liquid, Compound C. Possible structures for Compound B are listed in Table 1. The identity of Compound B was then determined from its neutralization equivalent, which is equal to the molecular weight of the acid divided by the number of carboxy groups in the molecule.

The IR spectrum of Compound C indicated that it was an alcohol, and the proton NMR data allowed the chemist to assign its structure.

Ultimately, the structure of Compound A was deduced from the identities of Compounds B and C. The structure of Compound A was confirmed by comparison with an authentic reference sample.

1. Which of the following solutions would be suitable for the extraction of diethylamine from the methylene chloride solution?
   (a) Benzene
   (b) Ethyl alcohol
   (c) 10% aqueous HCl
   (d) 10% aqueous NaHCO₃

2. Based on the observation that Compound A was determined to be a neutral substance, which of the following types of compounds should have been considered as possible structures?
   (a) RC(O)H and RC(O)OH
   (b) RC(O)OR and R—O—R
   (c) R—NH₂ and RC(O)OR
   (d) RC(O)OH and R—O—R

3. Which absorption band from the IR spectrum of Compound C is most characteristic of an alcohol?
   (a) A broad absorption band at approximately 3,300 cm⁻¹
   (b) A broad absorption band at approximately 2,000 cm⁻¹
   (c) A strong, sharp absorption band at approximately 1,600 cm⁻¹
   (d) A strong, sharp absorption band at approximately 800 cm⁻¹

4. Under the proper conditions, any of the compounds in Table 1 could react with diethylamine to form the corresponding:
   (a) nitrile
   (b) amine
   (c) imine
   (d) amide

For further information, see Chapter 19.
Passage Number IV

Two chemists proposed methods to synthesize esters.

CHEMIST A Chemist A suggested that the best method for preparing an ester involves the reaction of a carboxylic acid with an alcohol, as shown in Reaction A.

\[
\text{CH}_3\text{COH} + \text{HOCH}_2\text{CH}_3 \xrightleftharpoons{\text{H}_2\text{SO}_4} \text{CH}_3\text{COCH}_2\text{CH}_3 + \text{H}_2\text{O}
\]

Reaction A

Chemist A proposed the following mechanism for Reaction A.

\[
\begin{align*}
\text{CH}_3\text{COH} \xrightarrow{\text{H}^+} & \text{CH}_3\text{COH} \xrightarrow{\text{CH}_3\text{CH}_2\text{OH}} \text{CH}_3\text{COH} \\
& \quad \uparrow \text{HOCH}_2\text{CH}_3 \\
\text{H}_2\text{O} + \text{CH}_3\text{COCH}_2\text{CH}_3 \xrightarrow{\text{OH}^+} & \text{CH}_3\text{COH} \quad \uparrow \text{H}_2\text{O} \\
& \quad \downarrow \text{OCH}_2\text{CH}_3 \\
\text{CH}_3\text{COCH}_2\text{CH}_3 + \text{H}^+ & 
\end{align*}
\]

CHEMIST B Chemist B pointed out that Reaction A often gives low yields because the equilibrium constant is relatively low. As an alternative, Chemist B suggested that a higher yielding method to synthesize esters involves the reaction of an acid chloride (such as acetyl chloride) with an alcohol, as shown in Reaction B.

\[
\text{CH}_3\text{COH} \xrightarrow{\text{SOCl}_2} \text{CH}_3\text{CCl} \xrightarrow{\text{Et}_3\text{N}} \text{CH}_3\text{COCH}_2\text{CH}_3 + \text{HCl}
\]

Reaction B

1. According to Chemist A, the role of the sulfuric acid in Reaction A is to:
   (a) provide energy for the nucleophilic attack of the alcohol.
   (b) act as a solvating medium.
   (c) make the hydroxy group of the alcohol more nucleophilic.
   (d) make the carbonyl group of the carboxylic acid more electrophilic.

2. Chemist A separated the three organic compounds in Reaction A on a thin-layer chromatography plate that separated the compounds according to polarity. If the least polar compound traveled the farthest up the plate, what was the order of the distances traveled by the three compounds?
   (a) Carboxylic acid < alcohol < ester
   (b) Ester < alcohol < carboxylic acid
   (c) Alcohol < carboxylic acid < ester
   (d) Ester < carboxylic acid < alcohol
3. Which of the following is most likely a role of the weak base Et₃N in Reaction B?
   (a) It neutralizes the acetic acid.
   (b) It neutralizes the HCl by-product.
   (c) It protonates the acid chloride.
   (d) It protonates the ethanol.

4. If \((R)\)-2-phenylpropanoic acid is substituted for acetic acid in Reaction A, what will
   Chemist A predict about the stereochemistry of the product ester?
   (a) The ester will have an \(R\) configuration.
   (b) The ester will have an \(S\) configuration.
   (c) The product will be a mixture of the \(R\) and \(S\) esters.
   (d) The product will not contain a chiral center.

For further information, see Chapter 20.

Passage Number V

The preparation, isolation, and characterization of highly unstable compounds remain a challenge for synthetic organic chemists. To circumvent these problems, chemists have developed the method of matrix isolation, which typically involves trapping an unstable compound by freezing it in a solid matrix. Two high-energy compounds that have been successfully isolated by this technique are benzyne and a propellane.

Benzyne

Benzyne is a highly unstable intermediate that is thought to be formed from the base-promoted elimination of a halide and a hydrogen from adjacent carbon atoms in an aryl halide. It has been proposed that the structure of benzyne is highly strained and contains a very reactive triple bond. Although benzyne cannot be routinely isolated, evidence for the existence of this intermediate has been provided by the isolation of its decomposition by-product, triphenylene, which is presumably formed from a reaction between three molecules of benzyne. In addition, benzyne can now be trapped (and detected spectroscopically) by the photochemical decomposition of a high-energy reactant in a frozen argon matrix (see Reaction 1).

\[ \text{O} \text{O} \text{O} \]
\[ \text{O} \text{O} \text{O} \]
\[ \text{hν} \]
\[ \text{Ar, 8 K} \]

\[ \text{O} \text{O} \text{O} \]
\[ \text{O} \text{O} \text{O} \]
\[ \text{hv} \]
\[ \text{Ar, 8 K} \]

\[ \text{Benzyne} \]

Reaction 1

Propellanes

Propellanes are extremely reactive compounds in which two carbons that are directly connected are also connected by three other bridges. The propellane shown in Reaction 2 readily reacts with itself to form the corresponding dimer.

\[ \text{2} \]
\[ \text{Propellane} \]

Reaction 2
Under controlled reaction conditions, however, this propellane can be isolated. As shown in Reaction 3, when the diiodo compound is treated with potassium at relatively high temperatures, the resulting propellane may be trapped by rapidly freezing the vapor into a nitrogen matrix.

\[ \text{I} \quad \text{K} \quad 395 \text{K} \quad \text{N}_2 \quad 29 \text{K} \]

**Reaction 3**

1. The high reactivity of the propellane described in the passage is most likely a result of:
   (a) its bent shape.  
   (b) forced planarity.  
   (c) ring strain.  
   (d) steric repulsion between substituents.

2. Which of the following represents a resonance structure of benzyne?
   (a) ![Resonance Structure A]
   (b) ![Resonance Structure B]
   (c) ![Resonance Structure C]
   (d) ![Resonance Structure D]

3. On the basis of the information in the passage, what is the temperature at which the product of Reaction 3 is frozen in a matrix?
   (a) −273°C  
   (b) −244°C  
   (c) 120°C  
   (d) 151°C

4. According to the passage, the solid matrix in which an unstable compound is to be trapped should:
   (a) be composed of a substance with a high freezing point.
   (b) be composed of a substance with a low freezing point.
   (c) react with the starting material to give the unstable product.
   (d) react with the unstable product to give a new, stable product.

5. In addition to benzyne, which of the following compounds will most likely be formed in Reaction 1?
   (a) 4 O_2  
   (b) 2 CO  
   (c) 2 CO_2  
   (d) H_2CO_3

For further information, see Chapter 22.

**Passage Number VI**

Recently, it has been reported that the mushroom tyrosinase enzyme catalyzes an oxidative coupling reaction of 2,6-disubstituted phenols (Compounds 1a–f) to the corresponding diphenoquinones (Compounds 2a–f) and bisphenols (Compounds 3a–f), as shown below.

It was discovered that the outcome of the reaction was affected by the presence of acetonitrile, as well as the substituents on the phenol starting materials (see Table 1). It was also observed that the reaction did not proceed under an argon atmosphere.
1. The reaction of Compound 1f is most likely unsuccessful because the chloride substituent:
   (a) is too sterically bulky.
   (b) contains lone electron pairs.
   (c) is electron donating.
   (d) is electron withdrawing.

2. From the data in Table 1, what can be determined about the effect of reaction time on the product distribution?
   (a) Longer reaction times result in lower yields.
   (b) Longer reaction times result in higher yields.
   (c) Longer reaction times result in increased bisphenol formation.
   (d) Nothing can be determined without further data.

3. Which of the following compounds from the passage can be most obviously distinguished from each other by their IR spectra?
   (a) Compounds 1a and 1d  (b) Compounds 2d and 2e
   (c) Compounds 3b and 3e  (d) Compounds 3d and 3e

4. Which of the phenols in Table 1 has the most acidic hydrogen?
   (a) Compound 1a  (b) Compound 1b
   (c) Compound 1e  (d) Compound 1f

For further information, see Chapter 22.

*Reaction carried out in acetonitrile solvent.
Passage Number VII

Six unlabeled vials were discovered in a laboratory and were each thought to contain one of the following sweeteners.

A chemist performed a variety of experiments in order to determine the identity of the unknown compounds.

1. HNO₃ oxidizes primary alcohols and aldehydes to the corresponding carboxylic acid. One of the sweeteners was found to be optically active; however, its optical activity vanished upon treatment with HNO₃. Which of the following compounds could it be?
   (a) Compound B
   (b) Compound C
   (c) Compound E
   (d) Compound F

2. Phenylketonuria (PKU) is a genetic disease, the victims of which are unable to metabolize phenylalanine \([\text{C}_6\text{H}_5\text{CH}_2\text{CH}(\text{CO}_2^-)(\text{NH}_3^+)])\). Which of the sweeteners in the passage should someone with PKU avoid ingesting?
   (a) Compound A
   (b) Compound B
   (c) Compound C
   (d) Compound D

3. The trade name of one stereoisomer of Compound B is Aspartame. How many total stereoisomers of Compound B exist?
   (a) 2
   (b) 4
   (c) 6
   (d) 8
4. Which of the following observations best supports the argument that the physiological sensation of taste involves a receptor site that is chiral?
(a) Compound A is 2 times as sweet as Compound B.
(b) Compound A is 1/10 as sweet as Compound C.
(c) Two stereoisomers of Compound E are sweet.
(d) One stereoisomer of Compound C is sweet and another is tasteless.

For further information, see Chapter 24.

Passage Number VIII

A chemist tested the proteins in a snake venom for hemorrhagic activity (the ability to cause bleeding). To separate the proteins, the chemist used two methods. The first method was gel-filtration chromatography, which separates proteins according to size. In this technique, a column is filled with porous beads, and a mixture of proteins is allowed to pass through the beads. Proteins that are too large to enter the beads pass through the column at a faster rate than do smaller proteins; therefore, the larger proteins emerge from the column earlier.

In the second method, ion-exchange chromatography, proteins are separated on the basis of their net charge. If a column is loaded with positively charged beads, negatively charged proteins bind to the beads, and positively charged proteins pass through the column. The negatively charged proteins are subsequently released from the beads after the addition of a sodium chloride solution.

**EXPERIMENT 1** The snake venom was subjected to gel-filtration chromatography, and Fractions 1, 2, 3, and 4 were collected in order as they passed out of the column (each fraction contains either a single protein or a group of proteins). The chemist discovered that only the material in the last fraction (Fraction 4) showed hemorrhagic activity.

**EXPERIMENT 2** When the material in Fraction 4 was subjected to ion-exchange chromatography, Fraction A passed out of the column. Addition of a sodium chloride solution resulted in the elution of Fractions B and C. None of the three materials exhibited hemorrhagic activity; however, activity was restored when Fractions A, B, and C were recombined.

**EXPERIMENT 3** The chemist subsequently determined that Fractions B and C each contained a single, pure protein (Proteins B and C, respectively), whereas Fraction A contained two different proteins (Proteins A1 and A2).

1. Which of the following modifications to Experiment 1 might result in a better separation of only the materials found in Fraction 4?
   (a) Using beads with smaller pores
   (b) Using beads with larger pores
   (c) Using a shorter column
   (d) Filling the column with fewer beads

2. In Experiment 2, which of the following is the most reasonable explanation for the effect of the sodium chloride solution?
   (a) Sodium and chloride ions increase the charge interactions between the proteins and the charged beads.
   (b) Sodium and chloride ions clean out the column by passing through the column immediately.
   (c) Sodium and chloride ions bind to the charged proteins, and the resulting complex is retained in the column.
   (d) Sodium and chloride ions competitively bind to the beads, and the charged proteins are released from the column.
3. The beads in a gel-filtration chromatography column should have which of the following characteristics?
   (a) Neutral and inert
   (b) Neutral and reactive
   (c) Charged and inert
   (d) Charged and reactive

4. Which of the following statements accurately describes the relative size and charge of Proteins A1 and A2?
   (a) They are approximately the same size and have the same charge.
   (b) They are approximately the same size and have opposite charges.
   (c) They are very different in size and have the same charges.
   (d) They are very different in size and have opposite charges.

For further information, see Chapter 26.

Passage Number IX

Cyclophosphamide (Compound 1) is an anticancer drug that is effective against a broad range of human tumors. The metabolic pathway of cyclophosphamide has been the subject of much research. The metabolism as it was understood in 1990 is shown in Scheme A.

Scheme A

Cyclophosphamide (Compound 1) is enzymatically oxidized in the liver to Compound 2 (Step 1). Oxidation of Compound 2 to an inactive carbonyl-containing metabolite can occur. This is also an enzyme-catalyzed reaction, but the enzyme is different from the enzyme causing the oxidation in Step 1. If this second oxidation does not occur, an equilibrium between Compound 2 and Compound 3 is established, favoring Compound 3.
At this point, the pathway splits into two irreversible reactions. In Step 4, oxidation by a third enzyme forms another inactive metabolite. Alternatively, a base can remove an α-proton from Compound 3. Loss of the leaving group followed by neutralization of all charges produces propenal or acrolein and phosphoramide mustard (Compound 4), the anticancer active metabolite.

1. Which of the following functional groups best describes the portion of cyclophosphamide shown below? (R represents an alkyl group.)

\[
\begin{align*}
\text{RO} & \quad \overset{\text{P}}{\longrightarrow} \quad \text{O} \\
\end{align*}
\]

(a) Carboxylic acid derivative  
(b) Phosphate ester  
(c) Phosphate ether  
(d) Alkyl phosphorylase

2. The aldehyde, (E)-2-butenal, is an analog of propenal, the by-product produced in Step 5.

\[
\begin{align*}
\text{O} & \quad \overset{\text{H}}{\longrightarrow} \\
\text{(E)-2-Butenal} \\
\end{align*}
\]

If (E)-2-butenal were treated with bromine in carbon tetrachloride, the dibromide product would be the result of:

(a) anti addition.  
(b) cis addition.  
(c) syn addition.  
(d) cycloaddition.

3. Enzymes are naturally occurring proteins which catalyze biological reactions. Because they are catalysts, enzymes:

(a) change the energy of the reactants.  
(b) change the energy of the products.  
(c) change the energy difference (\(\Delta H\)) between products and reactants.  
(d) change the reaction pathway.

4. What is the notation for the reaction mechanism for Step 5?

(a) E1  
(b) E2  
(c) S_N1  
(d) S_N2

5. Step 1 produces only one of the two possible isomeric secondary alcohols next to the N atom. The enzymatic reaction which produces the single isomer is called:

(a) regioselective.  
(b) regiospecific.  
(c) stereoselective.  
(d) stereospecific.

For further information, see Chapters 8, 12, and 20.

**Passage Number X**

Many organic compounds contain two functional groups, both of which may react with certain reagents. When attempting to react only one of the groups, it is often necessary to protect the other group by temporarily changing it into a functional group that is inert to the reagent to be used. This temporary group is known as a *protecting group* and it is removed at the end of the reaction.
**ALCOHOLS**  Alcohols can be protected by treatment with acetic anhydride, an enol ether, or an alkyl halide (see Reactions 1–3).

**Reaction 1**

\[
\begin{align*}
\text{HO-CH} &= \text{CH}_2\text{COCH}_3 \\
\text{Compound I} & \xrightarrow{\text{Pyridine}} \text{CH}_3\text{CO-CH} &= \text{CH}_2\text{COCH}_3 \\
\text{Compound II}
\end{align*}
\]

**Reaction 2**

\[
\begin{align*}
\text{Br} &= \text{CH}_2\text{OH} & + & \text{Br} &= \text{CH}_2\text{OH} \\
\text{Compound III} & \xrightarrow{\text{Compound IV}} \text{Br} &= \text{CH}_2\text{OCH}_2\text{CH}_2\text{Br} \\
\text{Compound IV} & \xrightarrow{\text{Compound V}} \text{Br} &= \text{CH}_2\text{COC} &= \text{BrCH}_2\text{CH}_2\text{OC} &= \text{CH}_2\text{Br} \\
\text{Compound V}
\end{align*}
\]

**Reaction 3**

\[
\begin{align*}
\text{CH} &= \text{CH}_2\text{OH} & + & \text{CH}_3 &= \text{CH}_2\text{OH} \\
\text{Compound VI} & \xrightarrow{\text{Base}} \text{CH} &= \text{CH}_2\text{OCH}_3 \\
\text{Compound VII}
\end{align*}
\]

**AMINES**  As with alcohols, amines can be protected with acetic anhydride (see Reaction 4).

**Reaction 4**

\[
\begin{align*}
\text{H}_3\text{C} &= \text{O} &= \text{NH}_2 & + & \text{H}_3\text{C} &= \text{O} &= \text{O} &= \text{CH}_3 \\
\text{H}_3\text{C} &= \text{NH}_2 & \xrightarrow{\text{Pyridine}} & \text{H}_3\text{C} &= \text{NHCOCH}_3 \\
\text{H}_3\text{C} &= \text{NH}_2
\end{align*}
\]

**ACIDS**  Carboxylic acids can be protected by treatment with thionyl chloride and potassium tert-butoxide, as illustrated in Reaction 5.

**Reaction 5**

\[
\begin{align*}
\text{BrCH}_2\text{CH}_2\text{COH} & \xrightarrow{1) \text{SOCl}_2} \text{BrCH}_2\text{CH}_2\text{CO} &= \text{BrCH}_2\text{CH}_2\text{CO} &= \text{CH}_3 \xrightarrow{2) \text{K}^+ \text{OCC(CH}_3)_3} \text{KCl} \\
\text{Compound VI} & \xrightarrow{\text{K}^+ \text{OC(C(CH}_3)_3} & \text{BrCH}_2\text{CH}_2\text{COC} &= \text{CH}_3 \\
\text{Compound VII}
\end{align*}
\]

1. Which of the following functional groups are present in the product shown for Reaction 4?
(a) Two ketones and an amide
(b) A ketone and an amide
(c) A ketone and an ester
(d) An ester and an amide
2. What is the product of the first step of Reaction 5?
   (a) \[
   \text{ClOSCH}_2\text{CH}_2\text{COH}
   \]
   (b) \[
   \text{ClCH}_2\text{CH}_2\text{COH}
   \]
   (c) \[
   \text{BrCH}_2\text{CH}_2\text{CCl}
   \]
   (d) \[
   \text{BrCH}_2\text{CH}_2\text{COSOCl}
   \]

3. If an ester, an ether, and an acid are contained in the same molecule, in what order will they react with aqueous base?
   (a) The ether, the acid, then the ester
   (b) The acid, the ester, then the ether
   (c) The acid, the ether, then the ester
   (d) The ester, the acid, then the ether

4. When Compound VII is subjected to acid hydrolysis, Compound VI is regenerated and 2-methylpropene is formed. Which of the following transformations accounts for the formation of 2-methylpropene?
   (a) Dehydration of an alcohol
   (b) Nucleophilic displacement of a halide
   (c) Cleavage of an ether
   (d) Oxidation of an acid

5. An important characteristic of a protecting group is that it must be:
   (a) small, to prevent steric hindrance of other reactions.
   (b) very reactive toward most reagents.
   (c) very inert to all reagents.
   (d) easy to remove at the end of a reaction.

For further information, see Chapters 9 and 20.

Passage Number XI

A chemist conducted a series of experiments in which styrene and para-substituted styrenes were allowed to react with anhydrous nitric acid in dichloromethane. Figure 1 shows the structures of some of the reactants the chemist used and the products obtained in the study.

\[\text{Figure 1} \quad \text{Reactants and products.}\]
Table 1 shows the results of five experiments in the study.

**TABLE 1 Experimental Results**

</tbody>
</table>

*Yes* in the last column of Table 1 means that minor products do form during the experiment, and *no* means that minor products do not form.

1. In Experiment 1, the major product results from what type of reaction?
   (a) An addition reaction
   (b) A substitution reaction
   (c) An elimination reaction
   (d) A cleavage reaction

2. The minor products of Experiment 1 result from mononitration of the aromatic ring. These by-products are related structurally in that they are
   (a) diastereomers.
   (b) resonance forms.
   (c) constitutional isomers.
   (d) enantiomers.

3. Is the hypothetical explanation that Compound 3 \( (R = -NO_2) \) arises from an \( S_N2 \) reaction between Compound 2 and HNO\(_3\) a plausible explanation?
   (a) Yes, because the nitro group bonds to a primary carbon atom, which favors an \( S_N2 \) reaction
   (b) Yes, because the \(-ONO_2\) group activates the site of substitution
   (c) No, because \( S_N2 \) reactions do not occur on aromatic substrates
   (d) No, because hydride ion cannot serve as a leaving group

4. Which of the following structures shows the major product of a reaction between 4-ethylstyrene and anhydrous nitric acid in dichloromethane?
   (a) [Structure not shown]
   (b) [Structure not shown]
5. A reaction between Compound 1, where R is an acetyl group (−COCH₃), and nitric acid would most closely mimic which experiment shown in Table 1?
(a) Experiment 1
(b) Experiment 2
(c) Experiment 3
(d) Experiment 5

For further information, see Chapters 5, 12, and 22.

Passage Number XII

Two chlorinated compounds, Compound 1 and Compound 2, have been isolated from a culture medium of the fungal strain *Bjerkandera fumosa*. The structures of these compounds (Figure 1) were proven by synthesis. The synthesis of Compound 1 is shown in Figure 2.

![Figure 1 Structures of Compounds 1 and 2.](image)

![Figure 2 Synthesis of Compound 1: key: (a) standard procedure; (b) PDC, CH₂Cl₂, rt.; (c) TMSCl, Et₃N, rt.; (d) cat. OsO₄, NMMO, acetone, 0°C; (e) Zn(BH₄)₂, ether, 0°C.](image)
A common procedure converted Compound 3 into Compound 4, which was allowed to react with PDC to produce Compound 5. The latter compound was converted into its trimethylsilyl enol ether and treated with OsO₄ in the presence of N-methylmorpholine N-oxide (NMMO) to produce Compound 6, an α-ketol. When treated with NaBH₄, Compound 6 gave a mixture of erythro and threo diols but yielded the desired erythro product exclusively on treatment with Zn(BH₄)₂.

The synthetic Compound 1 was shown to be identical to the natural compound by gas chromatography (GC) and mass spectroscopy (MS). Compound 2 was synthesized by a known procedure, starting with Compound 7. The structure of the synthetic Compound 2 was also shown to be identical to the natural compound by GC/MS.

![Compound 7](image)

1. If the chemists wished to cleave the methyl-oxygen bond of the methoxy ether in Compound 2, which of the following reagents would accomplish the task?
   (a) HI
   (b) I₂/NaOH
   (c) NaI
   (d) CH₃I

2. Step a of Figure 2 was accomplished by reacting Compound 3 with:
   (a) ethyl iodide in dry ether.
   (b) ethylmagnesium iodide in dry ether.
   (c) ethanol and a catalytic amount of HCl.
   (d) sodium borohydride in ethanol.

3. PDC functioned as what type of reagent in the synthetic scheme of Figure 2?
   (a) A reducing agent, because a carbonyl group was converted into a secondary alcohol
   (b) A reducing agent, because a secondary alcohol was converted into a ketone
   (c) An oxidizing agent, because a carbonyl group was converted into a secondary alcohol
   (d) An oxidizing agent, because a secondary alcohol was converted into a ketone

4. Compound 5 can be named as an aryl-substituted:
   (a) propan-1-one.
   (b) propan-1-ol.
   (c) propan-2-one.
   (d) propan-3-one.

5. What difference did the researchers use to distinguish the erythro and threo isomers by gas chromatography?
   (a) Retention times
   (b) Peak heights
   (c) Peak areas
   (d) Injection times

For further information, see Chapters 8 and 22.

Passage Number XIII

A research group conducted two experiments, summarized below, in which a substrate underwent elimination by an E2 mechanism. The factors that influence the orientation of the carbon-carbon double bond in the product were evaluated. The orientation was either Hofmann or Zaitsev, depending on the location of the double bond.
**EXPERIMENT 1** Several 2-halo hexanes were subjected to elimination. Either methoxide or tert-butoxide was the base and the corresponding alcohol was the solvent. The general reaction is shown in Equation 1, and the results are recorded in Table 1.

\[
\text{Base/Solvent} \quad \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \xrightarrow{\text{Base/Solvent}} \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH} = \text{CH}_2 \\
\text{Hofmann} \\
+ \\
(E)- \text{and } (Z)-\text{CH}_3\text{CH}_2\text{CH}_2\text{CH} = \text{CH}_3 \\
\text{Zaitsev}
\]

1. How does the nature of the leaving group correlate with the orientation of the product produced in Experiment 1?
(a) The poorer the leaving group, the higher the proportion of Hofmann orientation.
(b) The poorer the leaving group, the higher the proportion of Zaitsev orientation.
(c) The nature of the leaving group has little effect on orientation.
(d) The poorer the leaving group, the higher the proportion of (E)-2-hexene formed.
2. A by-product was observed in the reaction shown by Equation 1 when the base/solvent pair was CH₃O⁻/CH₃OH. What is the most likely byproduct?
   (a) CH₃CH₂CH₂CH₂CH₂CH₂OCH₃
   (b) CH₃CH₂CH₂CH₂CH(OCH₃)CH₃
   (c) CH₃CH₂CH₂CH₂CH(OH)CH₃
   (d) CH₃CH₂CH₂CH₂CH₂CH₂OH

3. If the leaving group in Experiment 1 were Br⁻, approximately what percentage of 1-hexene would be expected from the reaction when the base/solvent pair is CH₃O⁻/CH₃OH?
   (a) 15%
   (b) 25%
   (c) 50%
   (d) 70%

4. A student wished to prepare Compound 2.

Which of the following alkyl halides and base/solvent pairs would produce the highest yield of the desired product?
   (a) 2-Fluoro-1-methylcyclohexane and CH₃O⁻/CH₃OH
   (b) 2-Fluoro-1-methylcyclohexane and tert-BuO⁻/tert-BuOH
   (c) 1-Chloro-1-methylcyclohexane and CH₃O⁻/CH₃OH
   (d) 1-Fluoro-1-methylcyclohexane and tert-BuO⁻/tert-BuOH

For further information, see Chapters 6 and 7.

**Passage Number XIV**

The three-step reaction sequence shown in Figure 1 is a proven method for the synthesis of Compound 3, a very useful reagent for the asymmetric synthesis of medicinally important organic compounds.

**Step 1**

\[
\text{PhBr} \xrightarrow{\text{Mg}} \xrightarrow{\text{Solvent}} \text{PhMgBr}
\]

**Step 2**

\[
\text{H} \xrightarrow{\text{PhMgBr}} \xrightarrow{\text{H}_3\text{O}^+} \text{H}
\]

**Step 3**

\[
\text{H} \xrightarrow{\text{CH_3COCl}} \xrightarrow{\text{Pyridine \text{CH}_2\text{Cl}_2}} \text{O}
\]

**Figure 1** Synthesis of Compound 3 (Ph = phenyl, C₆H₅⁻).
The following facts relate to the first two steps shown in Figure 1.

Fact 1: The reaction shown in Step 1 does not occur if methanol is the solvent.

Fact 2: The transformation shown in Step 2 requires a minimum of three moles of phenylmagnesium bromide per mole of Compound 1 to effectively produce Compound 2.

Fact 3: If the reaction shown in Step 2a is conducted with one equivalent of PhMgBr and followed by a workup (Step 2b) in aqueous acid, there is no net consumption of Compound 1.

1. If only one equivalent of PhMgBr is added in Step 2a, the PhMgBr is converted into what organic product?
   (a) Phenol
   (b) Benzene
   (c) Bromobenzene
   (d) Benzoic acid

2. What is the function of pyridine in Step 3?
   (a) To serve as the principal solvent
   (b) To capture HCl as the hydrochloride
   (c) To remove a proton from CH₃COCl
   (d) To neutralize acetic acid as it forms

3. Which of the following compounds can replace PhMgBr in Step 2a?
   (a) PhOMgBr
   (b) PhI
   (c) Ph₂Cu
   (d) PhLi

4. What functional groups are present in Compound 3?
   (a) Ether and ester
   (b) Alcohol and ether
   (c) Alcohol and ester
   (d) Alcohol, ether, and ketone

5. What product is obtained from a reaction between methyl benzoate and an excess of PhMgBr?
   (a) Triphenylmethanol
   (b) Diphenylmethanol
   (c) Diphenyl ketone
   (d) Phenyl benzoate

For further information, see Chapters 8 and 20.

Passage Number XV

Scientists have proposed three different mechanisms for the Diels-Alder reaction between a diene and a dienophile. Mechanism 1 involves a cyclic 6-centered transition state in which no intermediate is formed. Mechanism 2 results in a dipolar intermediate from the stepwise attack of a pair of electrons from the diene on the dienophile. Mechanism 3 is a stepwise process in which the intermediate is a diradical.

Mechanism 1

Mechanism 2

Mechanism 3

Observations 1–6 have been compiled from experimental data.
OBSERVATIONS

1. The reaction is facilitated by electron-withdrawing groups on the dienophile.
2. If more than one product is possible, the substituents in the favored products are 1,2 or 1,4 to each other, rather than 1,3.
3. If two stereoisomers are possible, the addition is predominantly endo; that is, the larger substituents of the dienophile are under the ring.
4. Only the \textit{s-cis} conformation of the diene undergoes Diels-Alder reactions.
5. Both the diene and the dienophile retain their stereochemistry in the product.
6. The rates of reaction depend very little on the nature of the solvent.

1. Observation 6 supports Mechanism 1 over Mechanism 2 because if a charged intermediate were formed:
   (a) nonpolar solvents would increase the rate of reaction.
   (b) nonpolar solvents would not affect the rate of reaction.
   (c) polar solvents would increase the rate of reaction.
   (d) polar solvents would not affect the rate of reaction.

2. Which of the following dienophiles would best facilitate a Diels-Alder reaction?
   (a) \( \text{H} / \text{CH}_3 \)
   (b) \( \text{H} / \text{CH}_3 \)
   (c) \( \text{H} / \text{CH}_3 \)
   (d) \( \text{H} / \text{COOCH}_3 \)

3. The progress of the following Diels-Alder reaction was monitored by IR spectroscopy.

Which of the following spectroscopic features would be the most useful in determining when the reaction is complete?

(a) The appearance of the product \( C-C \) stretch
(b) The appearance of the product alkene \( C-H \) stretch
4. What is the name of the Diels-Alder product of the reaction shown below?

\[
\begin{array}{c}
\text{H}_3\text{C} \\
\text{H}_3\text{C} \\
\end{array} + \begin{array}{c}
\text{H} \\
\text{Cl} \\
\end{array} \rightarrow
\]

(a) 4-Chloro-1,2-dimethylcyclohexene
(b) 1-Chloro-3,4-dimethylcyclohexene
(c) 3-Chloro-1,6-dimethylcyclohexene
(d) 5-Chloro-1,2-dimethylcyclohexene

5. According to Observations 3 and 5, what should be the major product of the following reaction?

\[
\begin{array}{c}
\text{Cl} \\
\text{H} \\
\end{array} + \begin{array}{c}
\text{COOCH}_3 \\
\end{array} \rightarrow
\]

(a) 
(b) 
(c) 
(d) 

For further information, see Chapter 14.

Passage Number XVI

A research study of a soft coral of the genus *Lobophytum* collected in the Philippines revealed a new diterpene Compound 3 and two related but previously known compounds, Compounds 1 and 2.

The compounds (Figure 1) were isolated from a freeze-dried aqueous extract of the invertebrate by successive fractionations. Fractions that displayed HIV-inhibitory activity were purified by HPLC by elutions with increasing concentrations of acetonitrile in water to yield Compounds 1–3.

Compounds 1 and 2 were identified as the known cembranolides, lobohedleolide and its isomer (7E)-lobohedleolide, respectively. High-resolution FABMS of Compound 3 gave a (MH)

\[1\] at m/z 376.2496 (C\(_{22}\)H\(_{33}\)NO\(_4\)). The IR spectrum of Compound 3 displayed significant bands at 3400–3100, 1760, and 1674 cm\(^{-1}\). The \(^1\)H and \(^13\)C NMR spectra of Compound 3 were similar to those of Compound 1 except that the resonances due to the \textit{exo}-methylene group at C-17 in Compound 1 were replaced by dimethylaminomethyl (\(-\text{CH}_2\text{NMe}_2\)) resonances. The methylene protons of the dimethylaminomethyl group gave \(^1\)H NMR signals at 3.36 and 3.45 ppm. These signals were coupled to each other and to that of the proton at C-15.

Compound 3 was isolated as a white gum with a specific rotation of \(13.1^\circ\) when measured in chloroform at a concentration of 0.25 g/100 mL. The UV spectrum of Compound 3 was taken in ethanol and showed absorptions at \(\lambda_{\text{max}} 222\) (log \(\varepsilon = 3.56\)) and 218 (log \(\varepsilon = 3.60\)) nm. All three compounds exhibited moderate HIV-inhibitory activity in a standard anti-HIV assay.
1. What kind of isomers are Compounds 1 and 2?
   (a) Constitutional
   (b) Enantiomers
   (c) Diastereomers
   (d) Anomers

2. Excluding carbon-carbon double bonds, what functional groups are present in Compound 2?
   (a) Acid and lactone
   (b) Acid, ketone, and ether
   (c) Peroxide and lactone
   (d) Acid and hemiacetal

3. If Compound 1 were to react with dimethylamine to form Compound 3, the reaction would be described as what type of addition?
   (a) 1,2
   (b) 1,4
   (c) 2,3
   (d) 3,4

4. Which carbon atoms in Compound 3 are stereogenic? (The numbering system used for carbon atoms in Compound 3 is analogous to that used in Compound 1.)
   (a) 1, 2, and 15
   (b) 1, 2, and 17
   (c) 3, 7, and 11
   (d) 1, 2, 3, 7, 11, and 15
5. How many degrees of unsaturation are present in Compound 3?
   (a) 2
   (b) 3
   (c) 6
   (d) 7

For further information, see Chapters 5, 11, and 20.

Passage Number XVII

Albuterol (α’-[tert-butylamino)methyl]-4-hydroxy-m-xylene-α,α’-diol), a drug used for the treatment of asthma, is synthesized according to the following pathway.

Sodium borohydride (NaBH₄) is utilized in Step 2 because it is much less reactive than LiAlH₄ and is consequently more selective. Typically, only aldehydes and ketones react with NaBH₄. Albuterol is water-soluble and is a long-acting bronchodilator.

1. Which of the following shows the correct structure of the C₄H₉ group that is bonded to the nitrogen of albuterol (α’-[tert-butylamino)methyl]-4-hydroxy-m-xylene-α,α’-diol)?
   (a) \( \begin{array}{c} \text{CH₃} \\
                      \text{CH} \end{array} \)
   (b) \( \begin{array}{c} \text{CH₃CH₂CH—} \\
                     \text{CH₃} \end{array} \)
2. When albuterol is dissolved in water, which of the following hydrogen-bonded structures does NOT contribute to its water solubility?

(a) \[ \text{HOCH}_2 - \text{CHCH}_{2} - \text{N-CH}_2\text{C}_4\text{H}_9 - \text{OH} \]

(b) \[ \text{HOCH}_2 - \text{CHCH}_{2} - \text{N-CH}_2\text{C}_4\text{H}_9 - \text{OH} \]

(c) \[ \text{HOCH}_2 - \text{CHCH}_{2} - \text{N-CH}_2\text{C}_4\text{H}_9 - \text{OH} \]

(d) \[ \text{HOCH}_2 - \text{CHCH}_{2} - \text{N-CH}_2\text{C}_4\text{H}_9 - \text{OH} \]

3. In the synthesis of albuterol, Step 2 is which of the following types of reactions?

(a) An oxidation reaction

(b) A reduction reaction

(c) A hydrolysis reaction

(d) A substitution reaction

4. Which of the following structures is formed first when albuterol is dissolved in a dilute aqueous solution of NaOH?

(a) \[ \text{HOCH}_2 - \text{CHCH}_{2} - \text{N-CH}_2\text{C}_4\text{H}_9 - \text{OH} \]

(b) \[ \text{HOCH}_2 - \text{CHCH}_{2} - \text{N-CH}_2\text{C}_4\text{H}_9 - \text{OH} \]
5. What type of reaction is illustrated by Step 3?
(a) Heterogeneous catalysis
(b) Homogeneous catalysis
(c) Halophilic substitution
(d) Bimolecular elimination

6. What is the product of the following reaction?
7. Step 3 represents the conversion of a tertiary amine to:
   (a) a primary amine.
   (b) a secondary amine.
   (c) an amide.
   (d) an imine.

8. How many chiral carbons exist in synthetic albuterol?
   (a) 0
   (b) 1
   (c) 2
   (d) 3

9. Which of the following by-products is formed in Step 1?
   (a) \[ \text{CH}_3\text{C} \rightleftharpoons \text{CH}_3 \]
   (b) \[ \text{CH}_3\text{OH} \]
   (c) \[ \text{CH}_3\text{C} \rightleftharpoons \text{OH} \]
   (d) \[ \text{CH}_3\text{C} \rightleftharpoons \text{CH}_3 \]

For further information, see Chapters 8, 21, and 22.

---

**Passage Number XVIII**

An organic chemistry class was assigned to prepare a variety of alkyl halides from the corresponding alcohols. The students carried out several experiments, 3 of which are summarized below.

**EXPERIMENT 1** Sodium bromide was refluxed with ethanol for 8 hours. No reaction occurred.

\[ \text{C}_2\text{H}_5\text{OH} + \text{NaBr} \rightarrow \text{no reaction} \]

**EXPERIMENT 2** Hydrogen bromide was refluxed with ethanol for 8 hours to produce ethyl bromide and water.

\[ \text{C}_2\text{H}_5\text{OH} + \text{HBr} \rightarrow \text{C}_2\text{H}_5\text{Br} + \text{H}_2\text{O} \]

**EXPERIMENT 3** 3-Methyl-2-butanol was treated with hydrogen bromide to produce only 2-bromo-2-methylbutane.

\[ \text{OH} \quad \text{Br} \]

\[ \text{(CH}_3\text{)}_2\text{CHCHCH}_3 + \text{HBr} \rightarrow \text{(CH}_3\text{)}_2\text{CCH}_2\text{CH}_3 \]
CONCLUSIONS The students ultimately deduced that Experiment 2 proceeded via protonation of the hydroxy group followed by displacement of water by bromide. In contrast, the class concluded that Experiment 3 involved the rearrangement of an intermediate carbocation followed by reaction with bromide.

1. What type of reaction mechanism is exemplified by Experiment 2?
   (a) E₁
   (b) E₂
   (c) S₅₁
   (d) S₅₂

2. Why is Experiment 2 much more efficient than Experiment 1?
   (a) OH⁻ is a better leaving group than water is.
   (b) Water is a better leaving group than OH⁻ is.
   (c) NaBr is more soluble in ethanol than HBr is.
   (d) NaBr is more volatile than HBr is.

3. According to the results in the passage, which of the following reactions should produce the highest yield of CH₃CH₂Br?
   (a) CH₃CH₂OH + Br₂
   (b) CH₃CH₂OH + NaBr + Br₂
   (c) CH₃CH₂OH + NaBr + H₂SO₄
   (d) CH₃CH₂OH + KBr

4. Which of the following carbocations is the most stable?
   (a) CH₃CH₂CH₂CH₂⁺
   (b) CH₃CH₂CH₂CHCH₃
   (c) (CH₃)₃C⁺
   (d) CH₃

5. If the proposed mechanism for the reaction in Experiment 3 is correct, which of the following assumptions can be made?
   (a) The rate of rearrangement is less than the rate of reaction of the carbocation with bromide.
   (b) The rate of rearrangement is greater than the rate of reaction of the carbocation with bromide.
   (c) The rate of rearrangement is equal to the rate of reaction of the carbocation with bromide.
   (d) The rate of rearrangement is directly proportional to the rate of reaction of the carbocation with bromide.

6. To synthesize a pure secondary alkyl halide, which of the following alcohols should the students treat with HBr?
   (a) CH₃CH₂OH
   (b) (CH₃)₂CHCH(OH)CH(CH₃)₂
   (c) (CH₃)₃COH
   (d) (CH₃)₂CHOH

7. In a further experiment, some students heated 2-methyl-2-butanol with concentrated sulfuric acid instead of hydrogen bromide. Which of the following products was most likely formed in the greatest amount?
   (a) CH₃—C≡CH—CH₃
       CH₃
   (b) CH₂=C—CH₂—CH₃
       CH₃
8. During the course of the experiments, the students were surprised to discover that 2-methyl-2-propanol had a significantly lower boiling point than 1-butanol. What is the reason for this difference?
(a) 2-Methyl-2-propanol has a lower molecular weight than 1-butanol.
(b) 2-Methyl-2-propanol has a higher density than 1-butanol.
(c) The branched carbon chain in 2-methyl-2-propanol interferes with hydrogen bonding.
(d) The branched carbon chain in 2-methyl-2-propanol destabilizes the carbocation intermediate.

9. The students tried to synthesize an alkyl chloride by substituting HCl for HBr in the procedure described in Experiment 2, but the reaction was sluggish. What is the reason for this decreased reactivity?
(a) Chloride is a weaker nucleophile than bromide is.
(b) Chloride is a weaker electrophile than bromide is.
(c) Chloride stabilizes the intermediate carbocation that is produced.
(d) Chloride destabilizes the intermediate carbocation that is produced.

For further information, see Chapters 9 and 11.

Passage Number XIX

A new carbon-carbon bond can be created by alkylating a carbanion with an alkyl bromide (RBr). Typically the carbanion is formed by the abstraction of an acidic proton by butyllithium (BuLi). One of the groups that has been utilized to activate the proton toward abstraction is the sulfone substituent that is illustrated in methyl phenyl sulfone, Compound I, in the following reaction.

\[
\begin{align*}
\text{BuLi, THF} & \quad 0^\circ C \\
\text{C}_6\text{H}_5\text{SCH}_3 & \quad \overset{\text{BuLi, THF} \quad 0^\circ C}{\longrightarrow} \quad \text{C}_6\text{H}_5\text{SCH}_2\text{Li} \\
\text{C}_6\text{H}_5\text{SO}_2\text{CR}_3 & \quad \overset{\text{RBr}}{\longrightarrow} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHR}_2 + \text{C}_6\text{H}_5\text{SO}_2\text{CR}_3
\end{align*}
\]

Monoalkylations, dialkylations, and trialkylations are possible, as indicated by Products A–C. The products were distinguished by gas chromatography because the retention times increased in the following order: Compound I < Product A < Product B < Product C. Table 1 shows the distribution of Products A, B, and C and Compound I obtained when methyl phenyl sulfone was alkylated with a variety of alkyl halides.
In another experiment, the reactions were repeated using potassium hydride (KH) instead of butyllithium to determine the effect on monoalkylation versus dialkylation. The results of the comparison between BuLi and KH are compiled in Table 2.

1. The sulfone group activates the hydrogen toward abstraction by BuLi or KH because the resulting:
   (a) carbocation is stabilized by resonance.
   (b) carbocation is destabilized by resonance.
   (c) carbanion is stabilized by resonance.
   (d) carbanion is destabilized by resonance.

2. Which of the following gas chromatograms most accurately represents the mixture of products and Compound I obtained from Trial 4 in Table 1?

3. According to Table 1, which of the following compounds represents the monoalkylated Product A that was formed with the LEAST amount of contamination by the dialkylated Product B?
   (a) C₆H₅SO₂CH₂C₆H₄Br
   (b) C₆H₅SO₂CH₂CH₂C₆H₅
   (c) C₆H₅SO₂CH₂CH₂CH₂CH₂Br
   (d) C₆H₅SO₂CH₂CH₂CH₂CH₃
4. Product B is most likely formed by which of the following reaction mechanisms?

(a) \[ \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{Li} \quad \text{BuLi} \rightarrow \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHLi}_2 \]

\[ \text{BuLi} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHLi}_2 \quad \text{RBr} \]

\[ \text{C}_6\text{H}_5\text{SO}_2\text{CHR}_2 \]

(b) \[ \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{Li} \quad \text{RBr} \rightarrow \quad \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{R} \]

\[ \text{RBr} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{R} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHR}_2 \]

(c) \[ \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{Li} \quad \text{RBr} \rightarrow \quad \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{R} \]

\[ \text{Br} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{Br} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHRBr} \]

(d) \[ \text{C}_6\text{H}_5\text{SO}_2\text{CH}_2\text{Li} \quad \text{Br} \rightarrow \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHBrLi} \]

\[ \text{Br} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHBrLi} \quad \text{C}_6\text{H}_5\text{SO}_2\text{CHR}_2 \]

5. According to Table 2, if chemists want to obtain the highest ratio of a dialkylated product, they should use:

(a) an unsaturated alkyl halide and BuLi.
(b) an unsaturated alkyl halide and KH.
(c) a saturated alkyl halide and BuLi.
(d) a saturated alkyl halide and KH.

6. Which of the following structures corresponds to the major product of Trial 4 in Table 1?

(a) \[ \text{O} \]

\[ \text{C}_6\text{H}_5\text{S} \quad \text{CH}_2 \quad \text{C}_6\text{H}_5 \]

\[ \text{CH}_2 \quad \text{C}_6\text{H}_5 \]

(b) \[ \text{O} \quad \text{H} \]

\[ \text{C}_6\text{H}_5\text{CH}_2\text{S} \quad \text{CCH}_2\text{C}_6\text{H}_5 \]

\[ \text{CH}_2 \quad \text{C}_6\text{H}_5 \]

(c) \[ \text{O} \quad \text{H} \]

\[ \text{C}_6\text{H}_5\text{S} \quad \text{C} \quad \text{C}_6\text{H}_5 \]

\[ \text{CH}_2 \quad \text{C}_6\text{H}_5 \]

(d) \[ \text{O} \quad \text{H} \]

\[ \text{C}_6\text{H}_5\text{S} \quad \text{CCH}_2\text{C}_6\text{H}_5 \]

\[ \text{CH}_2 \quad \text{C}_6\text{H}_5 \]

7. If methyl ethyl sulfone were utilized in the alkylation reaction instead of Compound I, which of the following problems would occur with the alkylation reaction?

(a) A greater number of products could be formed.
(b) The methyl hydrogen would no longer be acidic.
(c) The products would not be volatile enough to analyze by gas chromatography.
(d) The carbanion would be too sterically hindered to undergo alkylation.

For further information, see Chapter 18.

Passage Number XX

The most common glyceryl trialkanoates (commonly known as fats or glycerides) are triesters of glycerol and long-chain carboxylic acids. Compound 1 and Compound 2 are two naturally occurring glyceryl trialkanoates. *(Note: In Compound 1, R = oleic acid; in Compound 2, R = stearic acid.)*

\[
\begin{align*}
\text{Glycerol} & : & \text{Glyceryl trialkanoate} \\
\text{CH}_2\text{OH} & & \text{CH}_2\text{OCOR} \\
\text{CHOH} & & \text{CHOCOR} \\
\text{CH}_2\text{OH} & & \text{CH}_2\text{OCOR}
\end{align*}
\]

The long-chain carboxylic acids, called fatty acids, may be saturated or unsaturated. Oils are fats that are made up of predominantly cis unsaturated fatty acids; they are liquid at room temperature. Fats with little unsaturation are solid at room temperature.

Fats undergo the typical reactions of esters. An important commercial reaction of fats is alkaline hydrolysis, or saponification. The products of saponification are glycerol and the salts of the corresponding fatty acids, which are often used as soaps.

Phosphoglycerides are fats in which glycerol is esterified with 2 different fatty acids and phosphoric acid. These monophosphate esters are called phosphatidic acids. Naturally occurring free phosphatidic acids are rare. Usually the phosphoric acid substituent is esterified to a second alcohol such as choline, as exemplified by phosphatidylcholine.

1. The reduction of Compound 1 to Compound 2 represents the conversion of:
   (a) a solid to an oil.
   (b) an oil to a solid.
   (c) a fatty acid to a triglyceride.
   (d) a triglyceride to a fatty acid.

2. What is the product when Compound 2 undergoes saponification with NaOH?
   (a) CH$_3$(CH$_2$)$_{16}$CH$_2$OH
   (b) CH$_3$(CH$_2$)$_{16}$CH$_2$O$^-$Na$^+$
   (c) CH$_3$(CH$_2$)$_{16}$COOH
   (d) CH$_3$(CH$_2$)$_{16}$COO$^-$Na$^+$
3. Based on the structure of phosphatidylcholine, which of the following structures accurately represents choline?
(a) \((\text{CH}_3)_3\text{N}^+\text{CH}_2\text{CH}_2\text{OH}\)
(b) \((\text{CH}_3)_3\text{N}^+\text{CH}_2\text{CH}_2\text{OPO}_3^-\)
(c) \((\text{CH}_3)_3\text{N}^+\text{CH}_2\text{CH}_2\text{COO}^-\)
(d) \((\text{CH}_3)_3\text{N}^+\text{CH}_2\text{CH}_2\text{OPO}_4\text{CH}_2\text{OH}\)

4. The salts of fatty acids are used as soaps because the salts:
(a) have a polar region and a nonpolar region and are thus insoluble in water.
(b) have a polar region and a nonpolar region and thus help organic materials become water-soluble.
(c) are exclusively polar and thus dissolve in aqueous solutions.
(d) are exclusively nonpolar and thus dissolve organic materials.

5. Which of the following properties is characteristic of the phosphorus-containing substituent on Carbon 3 of phosphatidylcholine?
(a) It is a primary amine.
(b) It is hydrophobic.
(c) It is polar.
(d) It is nonpolar.

6. What is the most likely explanation for the observation that unsaturated glyceryl alkanoates are liquids?
(a) The cis double bonds do not allow the carbon chain to fit into an orderly crystal structure.
(b) The unsaturated glyceryl alkanoates are more susceptible to the effects of hydrogen bonding than the corresponding saturated compounds are.
(c) The molecular weights of unsaturated glyceryl alkanoates are much higher than those of the corresponding saturated compounds.
(d) Unsaturated glyceryl alkanoates have higher densities than the corresponding saturated compounds.

7. Which of the following methods can be used to increase the melting point of a natural fat?
(a) Heating the fat
(b) Cooling the fat
(c) Esterifying the fat
(d) Hydrogenating the fat

8. How many chiral carbons does phosphatidylcholine have?
(a) 0
(b) 1
(c) 2
(d) 3

9. A chemist wants to monitor the conversion of glycerol to a glyceryl trialkanoate by infrared spectroscopy. Which one of the following glycerol stretches will NOT be present in the infrared spectrum of a glyceryl trialkanoate?
(a) The C—C stretch
(b) The C—H stretch
(c) The O—H stretch
(d) The C—O stretch

10. What functional group is formed when a saponification product (fatty acid salt) is treated with HCl?
(a) An alcohol group
(b) An aldehyde group
(c) An ester group
(d) A carboxylic acid group

PREPARING FOR THE MCAT

The Official Guide to the MCAT Exam

- Everything you need in one place
- Current data on how MCAT scores and GPA factor in admissions
- Info to help you make decisions about retesting
- Actual exam questions with explanations of correct and incorrect answers
- Tips to help you come up with the right solutions
- Difficulty rating and percentage of correct answers on actual tests

Online Practice Tests

- Real MCAT questions from previously administered exams
- Simulate actual online testing environment
- Detailed scoring and diagnostic reports
- Solutions explained by the test developers
- Customizable content to target specific material
- Group purchase discounts

Web Resources

- Detailed registration information and test day tips
- Access to MCAT Essentials—required reading
- Content outline for material covered in the MCAT exam
- Tips for creating your own study plan
- Guidance on understanding your scores

This page intentionally left blank
1 Structure and Bonding

Ionic bonds: Formed by transfer of electrons from one atom to another (1-3)

Covalent bonds: Formed by electron sharing between two atoms; polar covalent bonds: Between atoms of differing electronegativity (1-3)

Lewis structures: Electron dot descriptions of molecules; resonance forms: Multiple Lewis structures for a molecule; octet rule: Preferred valence electron total for atoms (2) for H (1-4, 5)

VSEPR: Governs molecular shape and geometry around atoms (1-8)

Hybrid orbitals: Explain geometry; sp²: Tetrahedral (109°), CH₄; sp³: Trigonal planar (120°), BH₃, and H₂C==CH₂; sp: Linear (180°), BeH₂ and HC≡CH (1-8)

σ bonds: From end-to-end orbital overlap; π bonds: From side-by-side orbital overlap (1-8)

Constitutional isomers: Different connectivity (1-9)

2 Structure and Reactivity; Acids and Bases

Thermodynamics: Govern equilibria; ΔG° = –RT ln K at 25°C (2-1)

Gibbs free energy: ΔG° = ΔH° – TΔS°; enthalpy: ΔH°; exothermic if ΔH° < 0; endothermic if ΔH° > 0; entropy: ΔS°; measures energy dispersal (disorder) (2-1)

Kinetics: Govern rates; first order: Rate = k[A]; second order: Rate = k[A][B] (2-1)

Reaction coordinate: Graph of energy vs. structural change; transition state: Maximum-energy point on reaction coordinate; activation energy: Eᵣ = E (transition state) – E (starting point) (2-1, 7, 8)

Brønsted acids: Proton donors; Brønsted bases: Proton acceptors (2-2)

Strong acids HA: Have weak conjugate bases A⁻; acid dissociation constant Kᵣ: pKᵣ = – log Kᵣ; HA acid strength: ↑ for A larger, more electronegative, resonance-delocalized negative charge; ↓ pKᵣ = stronger acid (2-2)

Lewis acids/electrophiles: Electron pair acceptors; Lewis bases/nucleophiles: Electron pair donors (2-2)

2-3-4 Alkanes and Cycloalkanes

IUPAC Nomenclature: Longest continuous chain; numbering: Lowest for first substituent (2-5)

Alkanes: CₙH₂ₙ₊₂; hydrocarbons; straight-chain or branched; acyclic: nearly non-polar; weak intermolecular London forces (2-6)

Conformations: “Free” rotation about single bonds; staggered 2.9 kcal mol⁻¹ more stable (lower energy) than eclipsed (2-7, 8)

Cycloalkanes: CₙH₂ₙ hydrocarbons; n = 3, 4: Cyclopropane, cyclobutane (strained bond angles); n = 6: Cyclohexane (most stable, chair conformation); axial (less stable) & equatorial (more stable) substituent positions (4-2, 3)

Stereoisomers: Same atom connectivity, different three-dimensional arrangement; cis: Two substituents on same ring face; trans: Opposite faces (4-1)

Reactions: Few (nonpolar, lack functional groups); combustion, halogenation (3-3 to 10)

Halogenation: Radical chain mechanism with initiation, propagation, termination steps (3-4)

Reactivity: F₂ > Cl₂ > Br₂ (I, none); selectivity: Br₂ > Cl₂ > F₂ (3-7)

Reactivity: Tet > sec > prim > methane C=H; follows radical stability due to hyperconjugation (3-6)

Bond-dissociation energy: DH°; bond dissociation gives radicals or free atoms (3-1)

5 Stereoisomers

Chiral: Handed; not superimposable on mirror image; enantiomers: Mirror-image stereoisomers; stereocenter: Center of chirality in a molecule, such as a carbon with 4 different groups attached (5-1); nomenclature: R/S system (5-3)

Optical activity: Rotation of the plane of polarized light by an enantiomer; racemate (racemic mixture): Optically inactive 1:1 mixture of two enantiomers (5-2)

Diastereomers: Non-mirror image stereoisomers (5-5)

Meso compound: Achiral molecule with multiple stereocenters (5-6)

Resolution: Separation of enantiomers (5-8)

6-7 Haloalkanes

Functional group: F⁻⁺C—X⁻⁻; electrophilic C, leaving group X⁻ (6-1, 2)

Reactions: Nucleophilic substitution (6-2 to 9, 7-1 to 5), elimination (7-6, 7)

8-9 Alcohols and Ethers

Nomenclature: Alkanol—longest chain containing OH; numbering: Lowest for OH (8-1)

Functional group: C=O—H⁺; Lewis basic O; acidic H (pKᵣ = 16–18, like H₂O), hydrogen bonding (8-2, 3)

Preparation: Hydrate/Grimwald add to C=O; prim: RCHO + LiAlH₄ or H₂C==O + RMgX; sec: RR'C==O + LiAlH₄ or RCHO + R'MgX; tert: RR'C==O + R'MgX (8-6, 8)

Substitution: Prim, sec + SOCl₂, PBr₃, P/I₂ → RX; tert + HX → RX (9-2 to 4)

Dehydration: Conc H₂SO₄ + prim (180°C), sec (100°C), tert (50°C) → alkene; carbocations rearrange (9-2, 3, 7)

Ether synthesis: Williamson, RO⁻ + R'X (R' = Me, prim) → ROR' (9-6)

Ether cleavage: ROR' + HX (X = Br, I) → RX + R'X (9-8)

10-11 Spectroscopy

High-resolution mass spectrometry: Gives molecular formula (11-9, 10)

Degree of unsaturation: Gives number of rings + number of π bonds; degree of unsaturation = (H₂₁₆ – H₂₁₅)/2, where H₂₁₆ = 2n₁₆ + 2 – n₉ + n₈ (11-11)

Infrared spectroscopy: Gives bonds and functional groups (11-8)

Nuclear magnetic resonance: Gives hydrogen and carbon signals; chemical shift: Structural environment;
11-12 Alkenes

Nomenclature: Longest chain containing C=C (OH takes precedence); stereochemistry: cis/trans or E/Z systems (11-1)

Functional group: C=C, π bond electron pair nucleophilic, electrophiles add (11-2, 12-3 to 13)

Stability: ↑ with increased substitution (R,C=C=CR; most stable; H,C=H2 least stable); trans substituted > cis disubstituted

Preparation: Haloalkane + strong base (bulky for prim RX), E2, anti stereospecific, most stable alkene favored (Saytzev rule) except with bulky base (Hofmann rule) (7-7, 11-6)

Hydrogenation: H2 with catalytic Pd or Pt, syn addition → alkane (12-2)

Electrophilic addition mechanism: Electrophile adds to less substituted alkene carbon, nucleophile to more substituted alkene carbon (12-3)

Diels-Alder reaction: Concerted, stereospecific cycloaddition (14-8)

15-16-22 Benzene and Aromaticity

Nomenclature: Special common names, ortho/1,2, meta/1,3, para/1,4 for disubstituted (15-1)

Aromaticity: Special stability, properties, and reactions, based on Hückel’s rule, 4n + 2π electrons in a circle of p orbitals (15-2 to 7)

Electrophilic aromatic substitution mechanism: Electrophile adds to position favored by groups previously present (directing effects, below), followed by loss of H+ (15-8)

Hydrohalogenation: Saytzev regioselectivity, except HBr + peroxides (ROOR) (12-3, 13)

Hydration: Markovnikov regioselectivity; anti-Markovnikov with borane (12-4, 7, 8)

Di 1,2- and 1,4-addition to 1,3-dienes: Via delocalized allylic intermediate; kinetic product forms fastest; thermodynamic is more stable (14-6)

14 Dienes

1,2- and 1,4-addition to 1,3-dienes: Via delocalized allylic intermediate; kinetic product forms fastest; thermodynamic is more stable (14-6)

Directing effects: Ortho/para-directing Gα include alkyl, aryl, halogen, —OR, —NR2; meta-directing Gα include —SO2H, —NO2, >C=O, —CF3, —NR3+ (16-2, 3)
Activation/deactivation: All $G_m$ except halogen are activating; halogen and all $G_m$ are deactivating (16-1 to 3)

**Addition:**

- Michael addition: $\text{RC} + \text{C} = \text{O} \rightarrow \text{RCO}^-$
- Wittig: $\text{C} = \text{O} + \text{CH}_2\text{=PPh}_3 \rightarrow \text{C} = \text{C}$ (17-12)
- Aldol: 2 Aldehydes, aldehyde + ketone, intramolecular $\rightarrow \alpha,\beta$-unsaturated aldehyde/ketone (18-5 to 7)

**Deoxygenation:** $\text{C} = \text{O} \rightarrow \text{CH}_2$, Clemmensen (16-5); dithioacetal $+ \text{Raney Ni}$ (17-8); hydrazone $+ \text{base}$, $\Delta$ (17-10)

Alkylbenzenes: F-C alkylation (may rearrange); F-C acylation, then reduction (16-5)

**Benzylic reactivity:** Halogenation (22-1); oxidation to benzoic acid (22-2)

**Deoxygenation:** $\text{C} = \text{O} \rightarrow \text{CH}_2$, Clemmensen (16-5); dithioacetal $+ \text{Raney Ni}$ (17-8); hydrazone $+ \text{base}$, $\Delta$ (17-10)

**Wittig:** $\text{C} = \text{O} + \text{CH}_2\text{=PPh}_3 \rightarrow \text{C} = \text{C}$ (17-12)

**Aldol:** 2 Aldehydes, aldehyde $+$ ketone, intramolecular $\rightarrow \alpha,\beta$-unsaturated aldehyde/ketone (18-5 to 7)

**1,2- vs 1,4-addition:** $\text{RLi} \rightarrow \text{alcohol}$ (1,2); $\text{H}_2\text{O}$, ROH, RNH$_2$, R$_2$CuLi (cuprate) $\rightarrow$ 3-substituted carbonyl product (1,4); Michael addition: Enolate $\rightarrow$ 1,5-dicarbonyl (1,4); Robinson annulation: Intramolecular aldol $\rightarrow$ 6-membered ring (18-8 to 11)

**Phenols:** Acidic ($pK_a = 10$; more acidic with deactivating substituents); phenoxide $+$ $\text{RO}^-$ $+$ $\text{R}^+$ (Me, prim) $\rightarrow$ ether (22-4, 5)

17-18 Aldehydes and Ketones

**Nomenclature:** Alkanal and alkanone—longest chain containing $\text{C} = \text{O}$; common: Formaldehyde (methanal), acetaldehyde (ethanal), acetone (propanone) (17-1)

**Preparation:** ROH oxidation (8-6); C$=\text{C} + \text{O}_2$ (12-12); C$=\text{C}$ hydration (13-7, 8); F-C acylation (15-13)

**Functional group:** $^+\text{C}=\text{O}^-$; electrophilic C, Nu$^-$ adds (17-2)

**Addition:** $\text{H}_2\text{O}$ $\rightarrow$ hydrate, ROH $\rightarrow$ hemiacetal (both unstable); ROH, H$_2$ $\rightarrow$ acetal (17-6 to 8)

**Addition:** $\text{RNH}_2$ $\rightarrow$ C$=\text{NR}$; R$_2$NH $\rightarrow$ enamine (17-9)

**Hydrolysis:** All $+ \text{excess } \text{H}_2\text{O} \rightarrow \text{RCO}_2\text{H}$ (acid) (20-2 to 6)

**19-20-23 Carboxylic Acids and their Derivatives**

**Nomenclature:** Alkanic acid—longest chain ending with CO$_2$H; common: Formic (methanoic), acetic (ethanoic), benzoic (benzenecarboxylic) (19-1)

**Preparation:** ROH oxidation; RMgX + CO$_2$; RCN hydrolysis (8-6, 19-6)

**Functional group:** Highly polar, H-bonding (19-2); Lewis basic $\rightarrow$ $^+\text{O} = \text{C} \rightarrow \text{O}^-\text{H}^+$ $\leftrightarrow$ acidic ($pK_a = 4$) (19-4); Nu adds to C$=\text{O}$, OH may leave (addition-elimination) (19-7)

**Reduction:** LiAlH$_4$ $\rightarrow$ RCH$_2$OH (19-11)

**Derivatives:** RCO$_2$H (acid) $+$ SOCl$_2$ $\rightarrow$ RCOCl (halide); RCO$_2$H $+$ ROH, H$_2$ $\rightarrow$ RCO$_2$R$^-$ (ester); RCO$_2$H $+$ R$^+$, H$_2$ $\rightarrow$ RCONH$^-$ (amide) (19-8 to 10)

**Reactivity order:** Toward Nu$^-$ addition/elimination of leaving group (bold); halides (and anhydrides)—no catalyst needed; esters, amides—H$^+$ or $\text{OH}$ catalyst required (20-1)

**Esterification:** Halide, ester (transesterification) $+ \text{excess } \text{R}^+\text{OH} \rightarrow \text{RCO}_2\text{R}$ (20-2 to 4)

**Amide formation:** Halide, ester $+ \text{excess } \text{R}^+$ amine $\rightarrow$ RCONHR$^-$ (20-2 to 4)

**Hydride reduction to aldehyde:** Halide + LiAl(OtBu)$_3$, ester, amide $+ \text{DIBAL}$ (20-2 to 6)

**Hydride reduction to prim alcohol:** Halide, ester + LiAIH$_4$ (20-2 to 4)

**Hydride reduction to amine:** RCONHR$^-$ $+ \text{LiAIH}_4$ $\rightarrow$ RCH$_2$NHR (20-6)

**Cuprate addition:** Ketones from halides (20-2)

**Grignard addition:** Tert alcohols from esters (20-4)

**Claisen condensation:** 2 Esters $\rightarrow$ $\beta$-ketoester; 1,7-diester $\rightarrow$ cyclic $\beta$-ketoester (intramolecular: Dieckmann condensation) (23-1)

**Acetoacetic Ester Synthesis of Methyl Ketones:** Alkylate, hydrolyze, decarboxylate (23-2)

**Malonic Ester Synthesis of Carboxylic Acids:** Same (23-2)
21 Amines

**Nomenclature:** Alkanamine, follow rules for alcohols, use \( N \)- for additional groups on nitrogen; common, alkyl amine (21-1)  

- Methanamine (Methyl amine) \( \text{CH}_3\text{NH}_2 \)
- 2-Butanamine (sec-Butyl amine) \( \text{CH}_3\text{CH}_2\text{CHCH}_3\text{NH}_2 \)
- Dimethyl-1-propanamine (Dimethyl propyl amine) \( \text{CH}_3\text{CH}_2\text{CH}_2\text{N(CH}_3)_2 \)

**Functional group:** Nonplanar (pyramidal), \( \text{sp}^3 \) \( \text{N} \), inverts easily; Lewis basic, nucleophilic \( \text{N} \); \( \text{N} \text{O} \) weakly (21-2, 4)

**Basicity:** Amine \( 1 \) \( \text{H} \) \( 2 \) \( \text{N} \) amonium ion (pK\(_a\) 5 10) (21-4)

**Preparation:** \( \text{RX} \) \( 1 \) \( \text{N}_3 \) \( 2 \) \( \text{n} \) \( \text{RN}_3 \) (azide), then \( \text{LiAlH}_4 \) \( \text{n} \) \( \text{RNH}_2 \) (primary amine) (21-5)

- One less carbon: \( \text{RCONH}_2 \) (amide) \( 1 \) \( \text{Cl}_2 \), \( \text{NaOH} \) \( \text{n} \) \( \text{RNH}_2 \) (Hofmann) (20-7, 21-7)

- One more carbon: \( \text{RX} \) \( 2 \) \( \text{CN} \) \( \text{n} \) \( \text{RCN} \) (nitrile), then \( \text{LiAlH}_4 \) \( \text{n} \) \( \text{RCH}_2\text{NH}_2 \) (20-8)

- Reductive amination: \( \text{P} \) \( \text{CO} \) \( / \) \( \text{H} \) \( \text{11001} \) \( \text{NH}_3 \), \( \text{NaBH}_3\text{CN} \) \( \text{D} \) \( \text{G} \) \( \text{D} \) \( \text{G} \) \( \text{CHNH}_2 \) (prim amine); \( \text{P} \) \( \text{CO} \) \( / \) \( \text{H} \) \( \text{11001} \) \( \text{RNH}_2 \), \( \text{NaBH}_3\text{CN} \) \( \text{D} \) \( \text{G} \) \( \text{D} \) \( \text{G} \) \( \text{CHNHR} \) (sec amine); \( \text{P} \) \( \text{CO} \) \( / \) \( \text{H} \) \( \text{11003} \) \( \text{NH} \), \( \text{NaBH}_3\text{CN} \) \( \text{D} \) \( \text{G} \) \( \text{D} \) \( \text{G} \) \( \text{CHNRR} \) (tert amine) (21-6)

24 Carbohydrates

**Conventional representations:** For D-\((+)-\)glucose (24-1, 2)

- Fischer (open-chain) \( \text{CHO} \) \( \text{CH}_2\text{OH} \)
- Haworth (cyclic) \( \text{HO} \) \( \text{HO} \) \( \text{HO} \) \( \text{HO} \) \( \text{HO} \)

25 Heterocycles

**Nomenclature:** Heterocycloalkane; common names for many (25-1)

- Oxazolopyrimidine (Bisoxazole, oxazole)
- Oxazolidine (Oxazine, oxazine)
- 4-Azacyclopyridine (Pyridine, pyridine)

26 Amino Acids, Peptides, Proteins, and Nucleic Acids

**\( \alpha \)-Amino acids:** Most have l. (S) stereocenter, exist as zwitterions, common names (26-1)

**Acid/base properties:** At low pH, H\(^+\) converts COO\(^-\) to CO\(_2\)H; at high pH, \( \text{OH} \) converts NH\(_3\)\(^+\) to NH\(_2\)\(^-\) (26-1)

**Heteroaromatics:** Common names (25-1)

**Polypeptides:** Contain amino acids linked by amide bonds; amide \( \text{N} \) trigonal planar, \( \text{sp}^3 \) (26-4)

**Proteins:** Polypeptides with polar amino acid side chains in an active site that catalyze biochemical reactions (26-8)

**Nucleic acids:** Polymers made of phosphate-linked sugars bearing the heterocyclic bases adenine (A), guanine (G), cytosine (C), and thymine (T) in DNA or uracil (U) in RNA; contain the genetic code for protein biosynthesis (26-9)

Index

Alcohols (cont.)
chromium reagents and, 301–303
complex alcohols, 309–319
conversion, acyl chlorides and,
931–932
dehydration and, 337,
466–468, 517
electrophilic hydration and,
516–518
ester reduction to, 941
esterification and, 344
esters from, 344 –347
ether synthesis and, 355–356
formaldehyde and, 308
fragmentation and, 480
general hydride reductions to,
299–300
“green” oxidation of, 785
Grignard reagents and, 308, 940
haloalkanes from, 336
hydride reduction of carbonyl
group and, 297–301
hydrogen bonding and, 290–291
inductive effects and, 293–294
industrial sources of, 295
ketones and, 308
naming of, 288–289
organometallic reagents and,
304 –309
overoxidation of, 786
oxidation and reduction and, 297
oxidation to ketone and, 302
oxygen electron pairs and, 294
PCC oxidation to aldehyde
and, 303
physical properties of, 290t, 977t
physiological properties and
uses of, 367–371
pKa values in water, 292, 292t
primary alcohols, 308
rapid proton exchange and, 421
reactions with base, 334 –335
reactions with strong acids,
335–338
redox reactions and, 297
retrosynthetic analysis and,
315–317
secondary alcohols, 308,
336–337
steric disruption and, 293–294
strong bases and, 334 –335
structural and physical
properties of, 289–292
structural similarity to water,
289–290, 291
substitution and elimination
reactions and, 335–338
sulfur analogs of, 365–367
synthesis by nucleophilic
substitution, 295–296
synthesis of, 297–304
tertiary alcohols, 309, 336–337
tertiary butyl ethers and, 358–360
typical reaction modes of,
333, 334
utility of oxidations in
synthesis, 316

Alcoholysis, 357
Acylation, 714 –717
Aldaric acids, 1129, 1130, 1140
Aldehydes, 69, 775. See also
Carbonyl groups; Ketones
acidity of, 828–829
acyl chloride reduction and,
933–934
acyl halide reduction to, 934
alcohol synthesis from, 308
alkylation of, 834 –836
amine reduction to, 949
amino acid preparation
and, 1220
base-catalyzed condensation
and, 837–839
boiling points of, 779t
carbon-13 nuclear magnetic
resonance and, 780, 780–781
chemical shifts of, 781
conjugate additions to, 847
coupling, 1102
deshielding in, 779
enamines and alkylation of,
835–836
ester reductions into, 941
formation from chromic
ester, 304
halogenation of, 832–834
hemiacetal formation by,
791–792
hydration reversibility and,
790–791
hydride and organometallic
reagent additions to, 788t
hydride reductions to alcohols,
299–300
hydroboration-oxidation of
alkynes and, 586
imine derivatives of, 800t
imine formation from, 797
laboratory syntheses of,
785–787
mass spectral fragmentation of,
782–784
moderately basic nucleophile
addition to, 788t
naming of, 776–778
nitrile reduction and, 956–957
with other functional
groups, 777
overoxidation of, 786
oxidation of and carboxylic
acids, 883
oxidative chemical tests for, 809
PCC oxidation of alcohol
to, 303
polarization and, 779
preparation of, 785–787
protected and synthesis, 794
protein cross-linking and, 1055
regions of reactivity, 787
resonance in, 876
special imines and, 799–800
spectroscopic properties of,
779–784
syntheses of, 785t

thiazolium salts and,
1099–1103
unsaturated, 846–850
unsaturated in nature, 844 –845
writing structures and, 778

Organic Chemistry at the Click of a Button!

*Organic Chemistry: Structure and Function* 6th edition comes with a suite of media resources to bring your learning online!

**Premium Multimedia Resources**

The Organic Chemistry Book Companion Website, at [www.whfreeman.com/organic6e](http://www.whfreeman.com/organic6e), contains a wealth of study tools. You can unlock these resources with the click of a button, putting extensive concept and problem-solving support right at your fingertips. Some of the resources available are:

**ChemCasts** replicate the face-to-face experience of watching an instructor work a problem. Using a virtual whiteboard, the Organic ChemCast tutors show you the steps involved in solving key worked examples, while explaining the concepts along the way.

**Organic Flashcards** contain over 200 terms and images designed to test your organic chemistry knowledge and reinforce key concepts as you go along. Pulling from the key terms and concepts from the text, the Organic Flashcards also include nomenclature exercise information and reaction summary roadmap content. These dynamic web-based cards also allow you to create your own cards, start review quizzes, and print for on-the-go studying.

**ChemNews from Scientific American** provides an up-to-the-minute streaming feed of new organic chemistry-related stories direct from Scientific American magazine. Stay on top of the latest happenings in chemistry all in one, easy place.

**Organic Chemistry eBook**

Available for purchase through the text web site at [www.whfreeman.com/organic6e](http://www.whfreeman.com/organic6e), this multimedia-enhanced eBook contains the complete text with integrated ChemCasts, molecular models, Organic Flashcards, and ChemNews from *Scientific American*. Customization functions include instructor and student notes, document linking, and editing capabilities.
Spartan Molecular Modeling Software
Unlock the power of computer-based molecular modeling! With purchase of this text, you can buy Spartan Student Edition™ software from Wavefunction, Inc. at a significant discount from [www.wavefun.com/cart/spartaned.html](http://www.wavefun.com/cart/spartaned.html) using the code WHFOCHEM and then use this software to complete molecular modeling problems found on the text’s website.

CourseSmart eBook
*Organic Chemistry* 6th Edition is also available as a CourseSmart eBook, a digital version of the textbook only, without the added features of W. H. Freeman eBook. With thousands of titles across hundreds of courses, CourseSmart helps instructors choose the best textbook for their class and gives their students a digital text at a lower cost. See [www.coursesmart.com](http://www.coursesmart.com) for more details. And get the iPhone application CourseSmart so you can read your CourseSmart ebook on your iphone!
K. PETER C. VOLLHARDT was born in Madrid, raised in Buenos Aires and Munich, studied at the University of Munich, got his Ph.D. with Professor Peter Garratt at the University College, London, and was a postdoctoral fellow with Professor Bob Bergman (then) at the California Institute of Technology. He moved to Berkeley in 1974 when he began his efforts toward the development of organocobalt reagents in organic synthesis, the preparation of theoretically interesting hydrocarbons, the assembly of novel transition metal arrays with potential in catalysis, and the discovery of a parking space. Among other pleasant experiences, he was a Studienstiftler, Adolf Windaus medalist, Humboldt Senior Scientist, ACS Organometallic Awardee, Otto Bayer Prize Awardee, A. C. Cope Scholar, Japan Society for the Promotion of Science Prize Holder, and recipient of the Medal of the University Aix-Marseille and an Honorary Doctorate from The University of Rome Tor Vergata. He is the current Chief Editor of *Synlett*. Among his more than 320 publications, he treasures especially this textbook in organic chemistry, translated into 13 languages. Peter is married to Marie-José Sat, a French artist, and they have two children, Paloma (b. 1994) and Julien (b. 1997), whose picture you can admire on p. 170.

NEIL E. SCHORE was born in Newark, New Jersey, in 1948. His education took him through the public schools of the Bronx, New York, and Ridgefield, New Jersey, after which he completed a B.A. with honors in chemistry at the University of Pennsylvania in 1969. Moving back to New York, he worked with Professor Nicholas Turro at Columbia University, studying photochemical and photophysical processes of organic compounds for his Ph.D. thesis. He first met Peter Vollhardt when he and Peter were doing postdoctoral work in Professor Robert Bergman’s laboratory at Cal Tech in the 1970s. Since joining the U. C. Davis faculty in 1976, he has taught organic chemistry to more than 12,000 nonchemistry majors, winning five teaching awards, publishing over 100 papers in various areas related to organic chemistry, and refereeing several hundred local youth soccer games. Neil is married to Carrie Erickson, a microbiologist at the U.C. Davis School of Veterinary Medicine. They have two children, Michael (b. 1981) and Stefanie (b. 1983), both of whom carried out experiments for this book.
